cardiac injuries involve multiple cardiac structures.[17] Significant intracardiac injuries involved the coronary arteries (39), valvular apparatus (mitral) (2), intracardiac fistulas (i.e., ventricular septal defects [VSD]) (14), and unusual injuries (10). Only 2 percent of patients surviving their initial injury and undergoing an operation required reoperation for a residual defect.[17]

BLUNT CARDIAC TRAUMA.

Nonpenetrating or blunt cardiac trauma has replaced the term "cardiac contusion" and ranges from minor bruises of the myocardium to cardiac rupture.[18] [18A] It can be caused by direct energy to the heart or compression of the heart between the sternum and the vertebral column, even including "cardiac contusion" and cardiac rupture during external cardiac massage during cardiopulmonary resuscitation (CPR). Within this spectrum, blunt cardiac injuries may present as free septal rupture, free wall rupture, coronary artery thrombosis, cardiac failure, complex arrhythmia, simple arrhythmia, and/or rupture of chordae tendineae or papillary muscles.[19] [20] The incidence may be as high as three fourths of the patients with severe bodily trauma. Etiologies include motor vehicle accidents, vehicular-pedestrian accidents, falls, crush injuries, blasts, assaults, CPR, and recreational events. Such injury is often associated with sternal or rib fractures. In one report a fatal cardiac dysrhythmia occurred when the sternum was struck by a baseball,[21] which may be a form of commotio cordis.[22]

Cardiac rupture carries a significant mortality. The biomechanics of cardiac rupture include[23] :

Direct transmission of increased intrathoracic pressure to the chambers of the heart

Hydraulic effect from a large force applied to the abdominal or extremity veins causing force to be transmitted to the right atrium, resulting in rupture

Decelerating force, explaining atriocaval tears, between fixed and mobile areas

Myocardial contusion, necrosis, and delayed rupture

Penetration from broken rib or fractured sternum

Blunt rupture of the cardiac septum occurs most frequently in late diastole or early systole near the apex of the heart.[19] Multiple ruptures and disruption of the conduction system have been reported.[24] In an autopsy series of 546 patients reported by Parmley and colleagues, blunt cardiac trauma with ventricular rupture most often involved the left ventricle, followed by the right ventricle, and, least often, the left atrium. Thirty cases of VSD were reported, with the most common tear involving both the membranous and muscular portions of the septum. Injury to only the membranous portion of the septum was the least common blunt VSD. Parmley and colleagues also reported that traumatic rupture of the thoracic aorta was associated with lethal cardiac rupture in 22 percent of the cases.[12]

Blunt pericardial rupture results from pericardial tears secondary to increased intraabdominal pressure or lateral decelerative forces. The location of the tears occurs on the left side parallel to the phrenic nerve (64 percent), the diaphragmatic surface of the pericardium (18 percent), the right of the pleuropericardium (9 percent), and the mediastinum (9 percent).[19] Cardiac herniation with cardiac dysfunction can occur with these tears. The heart can be displaced into either pleural cavity or even the peritoneum. In the instance of right pericardial rupture the heart can become torsed and the pericardial cavity is surprisingly found to be "empty" of a heart at a resuscitative left anterolateral thoracotomy. With a left-sided cardiac herniation through a pericardial tear, a distending heart prevents the heart from returning into the pericardium, and the term "incarcerated heart" has been applied. Venous filling is impaired and unless the cardiac herniation is reduced, hypotension and cardiac arrest can occur.

IATROGENIC CARDIAC INJURY.

Iatrogenic cardiac injury can occur with central venous line insertion, cardiac catheterization procedures, and pericardiocentesis.

Cardiac injuries caused by central venous lines usually occur with placement from either the left subclavian or the left internal jugular vein.[25] Perforation causing tamponade has also been reported with a right internal jugular introducer sheath for transjugular intrahepatic portocaval shunts.[26] Vigorous insertion of left-sided central lines, especially during dilatation of the line tract, can lead to cardiac perforations. Even appropriate technique carries a discrete rate of iatrogenic injury secondary to central venous catheterization. Common sites of cardiac injury include the superior caval-atrial junction and the superior vena cava-inominate junction. These small perforations often lead to a compensated cardiac tamponade. Drainage by pericardiocentesis is often unsuccessful, and evacuation by the subxiphoid pericardial window or full median sternotomy is required. Once access to the pericardial space is gained, the site of injury has often sealed and may be difficult to find.

Complications from coronary catheterization, including perforation of the coronary arteries, cardiac perforation, and aortic dissection can be catastrophic and require emergency surgical intervention. The incidence of coronary perforation with balloon angioplasty is estimated to be 0.1 to 0.2 percent, but with advanced interventional techniques (e.g., rotablation, directional atherectomy, coronary artery stenting, and laser ablation) the incidence may be as high as 3 percent.[27]

Other potential iatrogenic causes of cardiac injury include external and internal cardiac massage, right ventricular injury during pericardiocentesis, and intracardiac injections.[28]

METABOLIC CARDIAC INJURY.

Metabolic cardiac injury (MCI) refers to cardiac dysfunction in response to traumatic injury and may be associated with injuries caused by burns, electrical injury, sepsis, the systemic inflammatory response syndrome, and multisystem trauma.[29] [30] [31] [32] The exact mechanism responsible for this dysfunction is unclear, but responses to trauma induce a "mediator storm," and it is this release of cytokines that may have a direct effect on the myocardium. Endotoxin, tumor necrosis factor-alpha, tumor necrosis factor-beta, interleukin-1, interleukin-6, interleukin-10, catecholamines (epinephrine, norepinephrine), cell-adhesion molecules, and nitric oxide are all possible responsible mediators.[33] [34] [35]

Metabolic cardiac injury may clinically present as conduction disturbances or decreased contractility leading to decreased output. Myocardial depression can occur in response to the "mediator storm" and alter calcium utilization and depression of the myocyte responsiveness to beta-adrenergic stimulation.[36] [37] [38] [39] Horton and coworkers[36] have shown that myocytes have altered calcium utilization in patients with injuries from burns. Ungureanu-Longrois and coworkers[34] reported that the activation of constitutive nitric oxide synthase appears to modulate cardiac responsiveness to cholinergic and adrenergic stimulation and that production of inducible nitric oxide synthase causes depression of myocyte contractile responsiveness to beta-adrenergic agonists. The myocardial depressive effects appear to be reversible.[32]

Treatment of MCI has been supportive with correction of the initiating insults, but some have attempted to address the involved mediators using intravenous milrinone, corticosteroids, arginine, granulocyte-macrophage colony-stimulating factor, and glutamate.[40] [41] [42] [43] Use of an intraaortic counterpulsation balloon pump can be considered to treat such myocardial depression, but controlled series do not exist to test this hypothesis.

BURNS.

Cardiac complications in the early post-burn period are a major cause of death. The initial cardiovascular

effect of burn injury is attributable to the profound reduction in cardiac output that may occur within minutes of the injury. The overall cardiac response has been described as an *ebb* and *flow* pattern, with the initial *ebb* phase lasting between 1 and 3 days and marked by hypovolemia and myocardial depression and the *flow* phase characterized by a prolonged period of increased metabolic demand with increased cardiac output and peripheral blood flow. The reduction in cardiac output observed in the initial period of burn injury is the result of a dramatic and rapid decrease in intravascular volume due to a "capillary leak" and of a direct myocardial depression. Hypovolemia results from the capillary leak caused by endothelial injury and may be mediated by platelet-activating factor, complement, cytokines, arachidonic acid, or oxygen free radicals. Myocardial depression manifested by a decrease in myocardial contractility and abnormalities in ventricular compliance becomes apparent with total body surface area burn of 20 to 25 percent. Myocardial-depressant factor, tumor necrosis factor, vasopressin, oxygen free radicals, and interleukins may be responsible for the depression.[44]

ELECTRICAL INJURY.

Cardiac complications are the most common cause of death after electrical injury. An estimated 1100 to 1300 deaths occur annually in the United States from electrical injury (including lightning strikes). The cardiac complications after electrical injury include immediate cardiac arrest, acute myocardial necrosis with or without ventricular failure, pseudoinfarction, myocardial ischemia, dysrhythmias, conduction abnormalities, acute hypertension with peripheral vasospasm, and asymptomatic, nonspecific abnormalities evident on an electrocardiogram (ECG). Damage from electrical injury is due to the direct effects on the excitable tissues, heat generated from the current, and the accompanying associated injuries (e.g., falls, explosions, or fires).[45]

OTHERS.

Intrapericardial and intracardiac foreign bodies can cause complications of acute suppurative pericarditis, chronic constrictive pericarditis, foreign body reaction, and hemopericardium.[46] Intrapericardial foreign bodies that have been reported in the literature to result in complications include bullets, hand grenades, shrapnel, knitting needles, and hypodermic needles. Some of these are factitiously inserted by a patient, usually with a psychiatric diagnosis. A report by LeMaire and colleagues[46] advocated removal of intrapericardial foreign bodies that are greater than 1 cm in size, those that are contaminated, and/or those that produce symptoms.

INTRACARDIAC MISSILES.

Intracardiac missiles are foreign bodies that are either embedded in the myocardium, retained in the trabeculations of the endocardial surface, free in a cardiac chamber, or in the pericardium. These are the result of direct penetrating thoracic injury or injury to a peripheral vascular structure with embolization to the heart. Location and other conditions determine the type of complications that can occur and the treatment required. Observation might be considered when the missile is (1) right sided, (2) embedded completely in the wall, (3) contained within a fibrous covering, (4) not contaminated, and (5) producing no symptoms. Right-sided missiles can embolize to the lung, at which point they can be removed, or in rare cases they embolize "paradoxically" through a patent foramen ovale or atrial septal defect.[47] Left-sided missiles can present as systemic embolization shortly after the initial injury. Diagnosis is determined with radiographs in two projections, fluoroscopy, echocardiography, or angiography. Treatment of retained missiles is individualized. Removal is recommended for missiles that are left sided, larger than 1 to 2 cm, rough in shape, or produce symptoms.[47] Although direct approach, either with or without cardiopulmonary bypass, has been advocated in the past, a large percentage of right-sided foreign bodies can now be removed by interventional radiologists.

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY

PENETRATING CARDIAC TRAUMA.

Wounds involving the precordial "box," which is the anatomical area that includes the epigastrium and precordium within 3 cm of the sternum, carry a high incidence of cardiac injury. Stab wounds present a more predictable path of injury than gunshot wounds. Cardiac injury may present with a clinical spectrum from full arrest with no vital signs to a patient who is asymptomatic with normal vital signs. Up to 80 percent of stab wounds eventually present with tamponade. The weapon injures the pericardium and heart, but as the weapon is removed the pericardium seals and may not allow blood to escape. Rapid bleeding into the pericardium favors clotting rather than defibrination.[48] As pericardial fluid accumulates, a decrease in ventricular filling occurs, leading to a decrease in stroke volume. A compensatory rise in catecholamines leads to tachycardia and increased right-sided heart filling pressures. The limits of distensibility are reached, and the septum shifts toward the left side, further compromising left ventricular function. If this cycle persists, this may lead to worsening of the ventricular function and irreversible shock. As little as 60 to 100 ml of blood in the pericardial sac can produce the clinical picture of tamponade.[48]

The rate of accumulation is dependent on the location of the wound. Owing to a thicker wall, right ventricular wounds seal themselves more readily than right atrial wounds. Injuries to the coronary arteries present with rapid onset of tamponade combined with cardiac ischemia. With injuries to the left ventricle, the decompensated state can worsen, leading to cardiac arrest. Injuries to the right side of the heart can compensate, and rapid deterioration may not occur; this subset of patients may benefit from early diagnosis and immediate intervention.

The classic finding of Beck triad (muffled heart sounds, hypotension, and distended neck veins) may be seen in only 10 percent of patients. Pulsus paradoxus (a substantial fall in systolic blood pressure during inspiration) and Kussmaul sign (increase in jugular venous distention on inspiration) may be present but are not reliable[49] (see Chap. 50). A very valuable and reproducible sign of pericardial tamponade is a narrowing of the pulse pressure. An elevation of the central venous pressure often accompanies rapid and cyclic hyperresuscitation with crystalloid solutions, but in such instances there is a widening of the pulse pressure. Elevation of the central venous pressure and narrowing of the pulse pressure represents a pericardial tamponade syndrome until proven otherwise.

In contrast to stab wounds, gunshot wounds to the heart are more frequently associated with hemorrhage than with tamponade. Twenty percent of gunshot wounds to the heart present as tamponade. With firearms, the kinetic energy is greater and the wounds to the heart and pericardium are frequently larger. Thus, these patients present in arrest more often due to hemorrhage.[49]

NONPENETRATING CARDIAC TRAUMA.

As in penetrating cardiac trauma, clinically severe blunt cardiac trauma (e.g., cardiac rupture) presents as either tamponade or as hemorrhage, depending on the status of the pericardium. If the pericardium is intact, tamponade develops; if it is not intact, extrapericardial bleeding occurs and hypovolemic shock ensues. Tamponade may be combined with hypovolemia, thus complicating the clinical presentation.

Blunt cardiac injury can be divided into clinically significant and clinically insignificant injuries. Clinically significant injuries include cardiac rupture (ventricular or atrial), septal rupture, valvular dysfunction, and coronary thrombosis. These injuries present as tamponade, hemorrhage, or severe cardiac dysfunction. Septal rupture and valvular

dysfunction (leaflet tear, papillary muscle, or chordal rupture) may initially present without symptoms but later present as the delayed sequelae of heart failure.[48]

Blunt cardiac injury may also present as dysrhythmias, most commonly premature ventricular contractions, the precise mechanism of which is unknown. Ventricular tachycardia can occur and degenerate into ventricular fibrillation. Supraventricular tachyarrhythmias can also occur. These commonly occur within the first 24 to 48 hours.

Small isolated tears in the pericardium may lead to cardiac herniation. This is a rare complication of pericardial rupture and depends on the size of the pericardial tear. If large enough, cardiac herniation can occur, leading to acute cardiac dysfunction. [48]

EVALUATION

Evaluation of the patient with suspected traumatic heart injury is divided among those patients who are clinically stable and those who are in extremis.

INITIAL ASSESSMENT.

The diagnosis of traumatic heart injury requires a high index of suspicion (Fig. 51-1) . On initial presentation to the emergency center, airway, breathing, and circulation (ABCs) under Advanced Trauma Life Support (ATLS) protocol are evaluated and established.[50] Two large-bore intravenous catheters are inserted, and blood is typed

and cross matched. The patient undergoes a Focused Assessment for the Sonographic examination of the Trauma victim (FAST) and is examined for Beck triad of muffled heart sounds, hypotension, and distended neck veins, as well as for pulsus paradoxus and Kussmaul sign. These findings suggest cardiac injury but may be present in only 10 percent of patients with cardiac tamponade. If the FAST demonstrates pericardial fluid in the patient who is unstable (systemic blood pressure <90 mm Hg), immediate transfer to the operating room for definitive repair or damage control is required.

Patients in extremis require immediate surgical intervention and often require emergent thoracotomy for resuscitation. The clear indications for emergency department thoracotomy include the following[51] :

1. Salvageable postinjury cardiac arrest (e.g., patients who have witnessed cardiac arrest with high likelihood of intrathoracic injury, especially penetrating cardiac wounds)
2. Severe postinjury hypotension (i.e., systolic blood pressure <60 mm Hg) due to cardiac tamponade, air embolism, or thoracic hemorrhage

If after resuscitative thoracotomy vital signs are regained, the patient proceeds to the operating room for definitive repair. The patient with confirmed pericardial fluid by FAST with normal vital signs (systemic blood pressure >90 mm Hg) may undergo a thorough evaluation to identify associated injuries. If other injuries are excluded, then open exploration may be required to exclude cardiac injury. In the absence of known causes of pericardial fluid (e.g., malignant pericardial effusion), a missed cardiac injury may lead to delayed bleeding, deterioration, or death.

Chest radiograph is nonspecific, but it can identify hemothorax or pneumothorax and demonstrate an enlarged

Figure 51-1 Algorithm for the initial assessment of traumatic cardiac injury.

cardiac silhouette suggesting pericardial fluid. Other possibly indicated examinations include ultrasonography, central venous pressure measurements, subxiphoid pericardial window, thoracoscopy, laparoscopy, and pericardiocentesis.

ULTRASONOGRAPHY.

Surgeons are increasingly performing ultrasonography for thoracic trauma. This increase has paralleled the use of ultrasonography for blunt abdominal trauma. The FAST evaluates four anatomical windows for presence of intraabdominal or pericardial fluid[52] (Fig. 51-2) . Ultrasonography in this setting is not intended to reach the precision of studies performed in the radiology suite but is merely intended to determine the presence of abnormal fluid collections, which aid in surgical decision making.[53] Ultrasonography is safe, portable, and expeditious and can be repeated as indicated.[53] If performed by a trained surgeon, the FAST examination has a sensitivity of nearly 100 percent and specificity of 97.3 percent.[54]

To evaluate more subtle findings of blunt cardiac injury in the stable patient, transthoracic (TTE) or transesophageal echocardiography (TEE) may be used. TEE is useful in identifying and characterizing valvular abnormalities and septal defects.

SUBXIPHOID PERICARDIAL WINDOW.

Subxiphoid pericardial window has been performed both in the emergency department and in the operating room with the patient under either general or local anesthesia. A subxiphoid vertical incision is made and a small hole made in the pericardium, looking for blood. In a prospective study, Meyer and coworkers[55] compared the subxiphoid pericardial window with echocardiography in penetrating heart injury and reported that the sensitivity and specificity of subxiphoid pericardial window was 100 percent and 92 percent, respectively, compared with 56 percent and 93 percent with echocardiography. They suggested that the difference in the sensitivity may have been due to the presence of hemothorax, which may confuse the pericardial and pleural space, or due to the fact that the blood had drained into the pleura.[55]

The disadvantage of subxiphoid pericardial window is that it is an invasive procedure; and if a major injury is found, a second thoracic incision is required for definitive repair. Although there has been significant controversy in

Figure 51-2 Focused Assessment for the Sonographic examination of the Trauma victim (FAST). *(From Rozycki GS, Feliciano DV, Schmidt JA, et al: The role of surgeon performed ultrasound in patients with possible cardiac wounds. Ann Surg 223:737-746, 1996.)*

the indication for subxiphoid pericardial window, recent enthusiasm for ultrasound evaluation has almost eliminated the role of subxiphoid pericardial window in the evaluation of cardiac trauma.

PERICARDIOCENTESIS (See Chap. 50).

Pericardiocentesis has had significant historic support, especially at a time when the majority of penetrating cardiac wounds were produced by ice picks and the (surviving) patients arrived several hours and/or days after injury. In such instances there was a natural triage of the more severe cardiac injuries and the intrapericardial blood had become defibrinated and was easy to remove. Currently, many trauma surgeons discourage pericardiocentesis for acute trauma. In general, pericardiocentesis has historically been used as a diagnostic or therapeutic maneuver to drain nonclotted pericardial fluid. In the setting of trauma, cardiac tamponade is acute and due to hemorrhage. Clot forms quickly and is not amenable to needle drainage. Recurrence of tamponade and subsequent increase in mortality, as well as a significant incidence of false-negative results and potential for iatrogenic injury, makes pericardiocentesis a far less than optimal diagnostic tool.[28]

Indications for its use may apply in the iatrogenic injury caused by cardiac catheterization, at which time immediate decompression of the tamponade may be life saving, or in the trauma setting when a surgeon may not be available.

EVALUATION OF BLUNT CARDIAC INJURY

ECG.

In blunt cardiac injury, conduction disturbances are common, and, thus, a screening 12-lead ECG may be helpful for evaluation. The most common rhythm disturbance is sinus tachycardia. Other possible disturbances include the following: T wave and ST segment changes (as seen with myocardial bruising), sinus bradycardia, first-degree atrioventricular block, right bundle branch block, right bundle branch block with hemiblock, third-degree block, atrial fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation.[56]

Cardiac Enzymes.

Much has previously been written about the use of cardiac enzyme determinations in evaluating blunt cardiac injury. However, no correlation between serum assays (e.g., creatine phosphokinase myocardial band, cardiac troponin T, or cardiac troponin I) and identification and prognosis of injury has been demonstrated with blunt cardiac injury.[57] [58] Therefore, cardiac enzyme assays should not be obtained unless evaluating concomitant coronary artery disease.[56]

TREATMENT

PREHOSPITAL AND EMERGENCY DEPARTMENT.

Only a small subset of patients with significant cardiac injury ever reaches the emergency department, and expeditious transport to a designated trauma facility is

essential to survival. Transport times of less than 5 minutes and successful endotracheal intubation are positive factors for survival.

DEFINITIVE TREATMENT.

Definitive treatment involves surgical exposure through a thoracotomy (Fig. 51-3 *A*) or median sternotomy (see Fig. 51-3 *B*). The mainstay of treatment is relief of tamponade and correction of aberrant physiology. This involves correction of the acidosis and hypothermia and reestablishment of effective coronary perfusion (i.e., resuscitation of the heart).

Cardiorrhaphy should be performed by experienced surgeons (Fig. 51-4) . Poor technique may result in enlargement of the lacerations or injury to the coronary arteries. If one is uncomfortable with the suturing technique, digital pressure may be applied until a more experienced surgeon arrives. Other techniques that have been described include the use of a Foley balloon catheter and a skin stapler[17] (Fig. 51-5) .

Figure 51-3 Incisions for cardiac injury. *A,* Left anterior thoracotomy (extension across the sternum if required). *B,* Median sternotomy (extension to the neck can be performed for exposure of the great vessels).

Exposure to the heart is gained by a left anterolateral thoracotomy, which allows access to the pericardium and heart and exposure for aortic cross-clamping if necessary. This incision may be extended across the sternum to gain access to the right side of the chest and for better exposure of the right atrium or right ventricle. This usually requires ligation of both internal thoracic arteries. Manual access to the right hemithorax from the left side of the chest is achieved through the anterior mediastinum by blunt dissection. This maneuver allows rapid evaluation of the right side of the chest for major injuries without transecting the sternum. Once the left pleural space is entered, the lung is retracted to expose the descending thoracic aorta for cross-clamping of the pericardium for exposure. It is helpful to note how much blood is present in the left side of the chest, which indicates hemorrhage versus tamponade. The pericardial sac anterior to the phrenopericardial vessels and phrenic nerve is opened, injuries are rapidly identified, and repair is performed.

In selected cases, particularly stab wounds to the precordium, the median sternotomy may be used. This incision allows excellent exposure to the anterior structures of the heart, but difficulty with access to the posterior mediastinal structures and descending thoracic aorta for cross-clamping may be encountered.

Mechanical support is not often used in the acute setting.[17]

BLUNT CARDIAC INJURY.

Much debate and discussion has occurred over the clinical relevance of "cardiac contusion." Most trauma surgeons conclude this diagnosis should be eliminated because it does not affect how one treats these injuries.[18] Thus, a normotensive patient with a normal initial ECG and suspected blunt cardiac injury is managed with emergency department or "chest pain" observation units with no expected clinical significance. Patients with an abnormal ECG are admitted for monitoring and treated accordingly. Patients who present in cardiogenic shock are evaluated for a structural injury, which is then repaired.

Results

Factors that determine survival in traumatic cardiac injury are mechanism of injury, location of the injury, associated injuries, coronary artery involvement, presence of tamponade, length of prehospital transport, requirement of resuscitative thoracotomy, and experience of the trauma team. The

Figure 51-4 Technique of suture repair. Cardiorrhaphy *(A)*. Should reinforcement be required, interrupted pledgeted sutures *(B),* pledgeted sutures around previously placed staples *(C),* or felt strips *(D)* can be used. *(From Wall MJ Jr, Mattox KL, Chen CD, Baldwin JC: Acute management of complex cardiac injuries. Figure 51-5 Temporary techniques to control bleeding. *A,* Stab wound to left ventricle. *B,* Initial management with interrupted or continuous 4-0 polypropylene sutures tied beneath the surgeon's finger. Additional techniques for complex injuries for temporary control include use of Foley balloon catheter *(C)* or skin stapler *(D)*. *(From Wall MJ Jr, Mattox KL, Chen CD, Baldwin JC: Acute management of complex cardiac injuries. J Trauma 42:905-912, 1997.)*

overall hospital survival for penetrating heart injuries ranges from 30 to 90 percent.[17] [59]

The survival from a stab wound is 70 to 80 percent, whereas survival from a gunshot wound is between 30 and 40 percent.[49] Cardiac rupture has a worse prognosis than penetrating injuries to the heart. Calhoun and colleagues[14] reported a 70 percent survival in 10 patients, but most series report a survival of approximately 20 percent.[19]

Complications

Primary injury-related cardiac complications include coronary artery injury, valvular apparatus injury (annulus, papillary muscles, and chordae tendineae), intracardiac fistulas, arrhythmias, and delayed tamponade. These delayed sequelae have been reported to have a broad range (4-56 percent), depending on the definition of complication.[60]

Coronary artery injury is a rare complication, occurring in 5 to 9 percent of cardiac injuries, with a 69 percent mortality.[12] [17] This mortality is due to the associated cardiac injury and other associated injuries and the state of physiologic compromise when the patient arrives. A coronary artery injury is most often controlled by simple ligation, but bypass grafting using saphenous vein may be required for proximal left anterior descending injuries (with utilization of total cardiopulmonary bypass).[17] With a resurrection of the old concept of coronary artery bypass grafting without cardiopulmonary bypass ("off-pump" bypass), this technique may theoretically be used for these injuries in the highly unlikely event that the patient is hemodynamically stable.

Valvular apparatus dysfunction is rare (0.2-9 percent) and may occur with both blunt and penetrating trauma.[12] [17] Most frequently, the aortic valve, followed by the mitral and tricuspid valves, is injured.[12] Often these injuries are identified after the initial cardiorrhaphy and resuscitation has been performed. Timing of repair depends on the patient's condition. If severe cardiac dysfunction exists at the time of the initial operation, immediate valve repair or replacement may be required; otherwise, delayed repair is advised.

Intracardiac fistulas include VSDs, atrial septal defects, and atrioventricular fistulas, with an incidence of 1.9 percent among cardiac injuries.[17] Management depends on symptoms and degree of cardiac dysfunction, with only a minority of these patients requiring repair.[28] These injuries are often identified after primary repair is accomplished and can be repaired after recovery from the original and associated injuries. Cardiac catheterization should be accomplished before repair so that specific anatomic sites of injury and incision planning can be accomplished.

Arrhythmias may occur due to blunt injury, ischemia, or electrolyte abnormalities and are addressed according to the injury (Table 51-2) (see Chap. 25).

Delayed pericardial tamponade is very rare. It has been reported to occur as early as 1 hour after initial operation and as long as 76 days from the injury.[28]

Follow-Up

Secondary sequelae in survivors of cardiac trauma include valvular abnormalities and intracardiac fistulas.[61] These abnormalities may be identified intraoperatively by gross palpation of a thrill[17] or with the use of TEE. TEE, however, may not be feasible in the acutely injured patient. Early postoperative clinical examination and ECG findings are unreliable.[17] Thus, echocardiography is recommended during the initial hospitalization to identify occult injury and establish a baseline study. Because the incidence of late sequelae may be as high as 56 percent, follow-up echocardiography 3 to 4 weeks after injury has been recommended.[61]

TABLE 51-2 -- ARRHYTHMIAS ASSOCIATED WITH CARDIAC INJURY

Penetrating Injury
Sinus tachycardia
ST segment changes associated with ischemia
Supraventricular tachycardia
Ventricular tachycardia/fibrillation
Blunt Cardiac Injury
Sinus tachycardia
ST segment, T wave abnormalities
Atrioventricular blocks, bradycardia
Ventricular tachycardia/fibrillation
Electrical Injury
Sinus tachycardia
ST segment, T wave abnormalities
Bundle branch block
Axis deviation
Prolonged QT
Paroxysmal supraventricular tachycardia
Atrial fibrillation
Ventricular tachycardia, fibrillation (alternating current)
Asystole (lightning strike)

Chapter 52 - Pulmonary Embolism

SAMUEL Z. GOLDHABER

Pulmonary embolism (PE) and deep venous thrombosis (DVT) account for hundreds of thousands of hospitalizations annually in the United States and afflict millions of individuals worldwide. The future holds great promise as advances in molecular biology, diagnostic imaging, and therapy with low-molecular-weight heparin (LMWH) revolutionize our approach to venous thromboembolism. Nevertheless, despite progress in early detection and treatment, the rates of mortality (Fig. 52-1) and recurrent PE remain high.[1] As the population ages, venous thromboembolism will become more prevalent because the incidence of PE increases with age.[1]

Cardiovascular specialists must keep PE in mind when they evaluate patients with unexplained chest discomfort, shortness of breath, and lightheadedness because these symptoms constitute the cardinal clinical presentations for PE. They should implement streamlined diagnostic algorithms and use risk stratification to recommend the most appropriate therapeutic approach. Finally, cardiologists must provide expertise in the treatment of hemodynamically compromised patients with PE as well as those with right ventricular failure who maintain a stable blood pressure and heart rate.

Figure 52-1 Overall cumulative mortality due to PE in the International Cooperative Pulmonary Embolism Registry (ICOPER) of 2454 patients was 11.4 percent at 2 weeks and 17.4 percent at 3 months. After exclusion of patients in whom PE was first discovered at autopsy, the mortality rate was 15.3 percent. *(From Goldhaber SZ, Visani L, De Rosa M, for ICOPER: Acute pulmonary embolism: Clinical outcomes in the International Cooperative Pulmonary Embolism Registry (ICOPER). Lancet 353:1386, 1999.*

PATHOPHYSIOLOGY

Hypercoagulable States

In 1856, Rudolf Virchow postulated that a triad of factors leads to intravascular coagulation: (1) local trauma to the vessel wall, (2) hypercoagulability, and (3) stasis. Classically, the pathogenesis of PE was dichotomized as due to either unusual "inherited" (primary) or commonly "acquired" (secondary) risk factors. Now, however, it appears likely that many patients who develop PE are genetically predisposed (Tables 52-1 and 52-2) but often require a precipitating environmental stress (Table 52-3) to elicit overt thrombosis.[2]

TABLE 52-1 -- PRINCIPAL HYPERCOAGULABLE STATES ASSOCIATED WITH VENOUS THROMBOSIS

HYPERCOAGULABLE STATE	CITATION	COMMENTS
Mutation in factor V gene	Bertina et al[3]	Replaces arginine 506 with glutamine, rendering factor V resistant to inactivation by activated protein C
	Ridker et al[5]	
Resistance to activated protein C	Zoller et al[11]	Molecular background for resistance to activated protein C was found to be heterogeneous
Prothrombin gene mutation	Poort et al[9]	G20210A point mutation increases prothrombin levels
Mutation in protein C gene	Allaart et al[12]	Associated with protein C deficiency
Protein S deficiency	Gladson et al[13]	Protein S a cofactor for protein C
Antithrombin III deficiency	Bucciarelli et al[14]	Autosomal dominant inheritance; has a higher risk for venous thrombosis than the other genetic defects
Hyperhomocysteinemia	den Heijer et al[15]	Doubles or triples risk[15] [15A] ; potentiates risk from underlying factor V Leiden[16]
	Langman et al[15A]	
	Ridker et al[16]	
Antiphospholipid antibodies	Greaves [17]	Encompasses anticardiolipin antibodies and lupus anticoagulant; associated with venous and arterial thrombosis

PRIMARY HYPERCOAGULABLE STATES (see also Chap. 62).

The identification of a poor anticoagulant response to activated protein C (aPC) is the most exciting and far-reaching development ever to occur in the field of

prothrombotic markers. Normally, a specified amount of aPC can be added to plasma and prolongation of the activated partial thromboplastin time (PTT) can be observed. However, patients with "aPC resistance" have inadequate PTT prolongation. In contrast to classical coagulation protein deficiencies, which are rare (Table 52-2) .*A*, aPC resistance occurs frequently among patients with venous thrombosis (Table 52-2) *B*.

The phenotype of aPC resistance is associated with a single point mutation, designated factor V Leiden, in the factor V gene.[3] This mutation results from a single nucleotide substitution of adenine for guanine 1691 that replaces the amino acid arginine with glutamine at position 506. This change eliminates the protein C cleavage site in factor V.[4]

The allelic frequency of this mutation is about 3 percent in healthy male physicians in the United States. In the Physicians' Health Study, no statistically significant differences were found between the incidence of the mutation among previously healthy men who subsequently developed myocardial infarction or stroke compared with men who remained free of cardiovascular disease. However, the incidence of the factor V mutation was three times higher among men who developed DVT.[5]

In a case-control study of premenopausal women who developed DVT, the risk of thrombosis among users of oral

TABLE 52-3 -- ACQUIRED CONDITIONS THAT MAY PRECIPITATE VENOUS THROMBOSIS

Surgery/immobilization/trauma
Obesity
Increasing age
Cigarette smoking
Systemic arterial hypertension
Oral contraceptives/pregnancy/postpartum
Cancer (sometimes occult adenocarcinoma) and cancer chemotherapy
Stroke/spinal cord injury
Indwelling central venous catheter

contraceptives was increased fourfold. However, the risk of thrombosis among carriers of the factor V Leiden mutation was eightfold that of noncarriers. Among patients with both oral contraceptive use and the mutation, the risk of thrombosis was increased more than 30-fold.[6] The factor V Leiden mutation is also a risk factor for recurrent pregnancy loss[7] and in the Physicians' Health Study is associated with a fourfold increased risk of *recurrent* PE or DVT after completion of a course of anticoagulation.[8]

However, in a cohort of patients with venous thromboembolism in Rome and Milan, the risk of recurrent thrombosis after discontinuing anticoagulation was similar among carriers of factor V Leiden and patients without this mutation.[8A] Furthermore, the prevalence of the factor V Leiden mutation appears to be twice as high in patients with DVT compared with patients with PE. Some investigators speculate that the mutation confers an increased stability and adherence of thrombus to the vein wall, thereby decreasing the frequency of embolization to the lungs.[8B]

A single-point mutation in the 3
untranslated region of the prothrombin gene (G-to-A transition at nucleotide position 20210) is associated with increased levels of prothrombin.[9] In the Physicians' Health Study, the prevalence of the prothrombin gene mutation among control subjects was 3.9 percent, and this G20210A mutation doubled the risk of venous thrombosis.[10] Women with both factor V Leiden and the G20210A prothrombin-gene mutation have a disproportionately high risk of DVT or PE.[10A] Recently, high levels of coagulation factor XI have been described as doubling the risk of venous thrombosis.[10B]

Although molecular medicine can help elucidate pathogenesis, a careful family history is still the most rapid and cost-effective method of identifying a predisposition to venous thrombosis. Investigation with blood tests (see Table 52-1) to detect a hypercoagulable state can be misleading. For example, consumption coagulopathy due to venous thrombosis may be misdiagnosed as deficiency of antithrombin III, protein C, or protein S. Heparin administration can depress antithrombin III levels, and use of warfarin ordinarily causes a mild deficiency of protein C or S. Both oral contraceptives and pregnancy depress protein S levels.

ACQUIRED CONDITIONS THAT MAY PRECIPITATE VENOUS THROMBOSIS.

Conditions that increase venous stasis or cause endothelial damage (see Table 52-3) are likely to predispose toward venous thrombosis, especially among patients who already have subclinical hypercoagulable states. Even minor events such as travel and minor surgery increase the venous thromboembolism risk.[21A]

The stasis and immobilization associated with postoperative venous thrombosis may increase after hospital discharge, because many patients who are forced to ambulate during hospitalization may become confined to bed on returning home. PE is increasingly likely to occur *after* hospital discharge because of the contemporary emphasis on minimizing the length of stay after surgery. Among 45,000 total hip and total knee replacement operations in a State of California data base, the diagnosis of venous thromboembolism was made after hospital discharge in 76 percent and 47 percent of the total hip and total knee replacement operations, respectively. The median interval until diagnosis was 17 days for total hip and 7 days for total knee replacements.[22]

Coronary artery bypass grafting has been associated with a 4 percent risk of PE [23] and a 20 percent risk of venous thrombosis of the deep leg veins.[24] After *major trauma,* the DVT rate was 58 percent in a prospective study in which contrast venograms were obtained.[25] Among immobilized *patients in a medical intensive care unit,* the rate of venous thrombosis detected with ultrasonography was 33 percent.[26]

OTHER RISK FACTORS FOR PULMONARY EMBOLISM

Marked obesity in women was a strong risk factor for PE in both the Framingham Heart Study[27] and the Nurses' Health Study. [28] Other environmental risk factors for PE in the Nurses' Health Study were *cigarette smoking* and systemic arterial *hypertension.*[28]

With respect to *oral contraceptives,* decreasing the estrogen content has diminished the risk of venous thromboembolism. However, third-generation oral contraceptives with the new progestogens, desogestrel and gestodene, are problematic, with an approximate doubling in thrombotic risk even though they are less androgenic, have less effect on carbohydrate and lipid metabolism, and may have stronger suppression of ovarian activity than second-generation oral contraceptives.[29] They appear to cause an acquired resistance to aPC.[30]

Even the low dose of estrogen prescribed for *postmenopausal hormone replacement* doubles the risk of PE.[31] The risk is increased for *raloxifene,* a selective estrogen receptor modulator, [32] as well as for the more commonly used conjugated equine estrogens.

PE is the leading cause of maternal mortality during *pregnancy.* Antenatal DVT is usually left sided, involves the iliofemoral system, and occurs about twice as frequently as postpartum DVT. Increasing age and cesarean section are major risk factors for venous thromboembolism.[33] Conversely, women with serious obstetrical complications have an increased incidence of genetic mutations predisposing them to venous thrombosis.[34]

Cancer promotes the synthesis and secretion of procoagulants and is a risk factor for PE; conversely, venous thromboembolism may be the initial manifestation of an otherwise occult cancer. In a Danish registry, there was a threefold increase in cancer diagnoses during the initial 6 months after DVT or PE became evident. The cancers were often widely metastatic at the time of discovery, and the most frequent cancers were pancreatic, ovarian, primary hepatic, and brain.[35]

Patients receiving chemotherapy for metastatic breast cancer are at risk of developing venous thromboembolic disease. In a randomized controlled trial of very low-dose warfarin versus placebo, 4 percent of the placebo group developed venous thrombosis during the average 6-month follow-up period.[36]

Leg DVT is a common complication of *acute ischemic stroke,* particularly in the paralyzed limb. Even when patients receive 5000 units twice daily of unfractionated heparin for prophylaxis, the venous thrombosis rate is as high as 31 percent.[37] With *spinal cord injury,* there is also a high rate of venous thrombosis.[38]

Thrombotic complications due to indwelling central venous catheters are common and are often associated with catheter sepsis.[39] Indwelling vascular catheters can become engulfed In a thrombin or fibrin sheath that serves as a nidus for subsequent infection.

RELATIONSHIP BETWEEN DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM.

Most PE result from thrombi that originate in the pelvic or deep veins of the leg; occasionally, thrombi in the axillary or subclavian veins embolize to the pulmonary arteries. In a treatment trial of proximal leg DVT, Moser and colleagues found that nearly 40 percent of patients had asymptomatic PE, based on concomitantly obtained ventilation-perfusion scans.[40] There is also an appreciable risk of asymptomatic PE due to upper-extremity thrombosis.[41] However, many patients with PE do not have detectable DVT.[42]

When venous thrombi detach from their sites of formation, they flow through the venous system toward the pulmonary arterial circulation. If an embolus is extremely large, it may lodge at the bifurcation of the pulmonary artery, forming a saddle embolus (Fig. 52-2 *top*). More commonly, a major pulmonary vessel is occluded (Fig. 52-2 *bottom*).

RIGHT VENTRICULAR DYSFUNCTION.

The extent of pulmonary vascular obstruction is probably the most important factor determining whether right ventricular dysfunction ensues. As obstruction increases, pulmonary artery pressures rise. Moreover, the release of vasoconstricting compounds (e.g., serotonin), reflex pulmonary artery vasoconstriction, and hypoxemia may further increase pulmonary vascular resistance and result in pulmonary hypertension.[43]

VENTRICULAR INTERDEPENDENCY.

The sudden rise in pulmonary artery pressure reflects an abrupt increase in right ventricular afterload, with consequent elevation of right ventricular wall tension followed by right ventricular dilatation and dysfunction (Fig. 52-3) . [44] As the right ventricle dilates, the interventricular septum shifts toward the left ventricle, with resultant underfilling of this chamber due to

Figure 52-2 *Top,* Saddle embolus (arrow) at the bifurcation of the pulmonary artery. *Bottom,* Pulmonary embolus in left lower lobe pulmonary artery, with minimal attachment to the wall of the vessel. The embolus was dark red, typical of venous thrombi, and had indentations believed to represent impressions of the venous valves (arrows). *(From Godleski JJ: Pathology of deep venous thrombosis and pulmonary embolism. In Goldhaber SZ [ed]: Pulmonary Embolism and Deep Venous Thrombosis. Philadelphia, WB Saunders, 1985, p 17.)*

pericardial constraint.[45] In addition, right ventricular contractile dysfunction may decrease right ventricular cardiac output and further reduce left ventricular preload. As the right ventricle distends, coronary venous pressure increases and left ventricular diastolic distensibility decreases.[46]

The reduction in left ventricular preload may also lead to interventricular septal shift toward the left ventricle. With underfilling of the left ventricle, both systemic cardiac output and pressure decrease, potentially compromising coronary perfusion and producing myocardial ischemia, with release of troponin.[47] Elevated right ventricular wall tension following massive PE reduces right coronary flow and increases right ventricular myocardial oxygen demand, which may result in ischemia and possibly cardiogenic shock. Perpetuation of this cycle can lead to right ventricular infarction, circulatory collapse, and death.

Figure 52-3 Pathophysiology of right ventricular dysfunction. PA = pulmonary artery; RV = right ventricle; LV = left ventricle.

SUMMARY OF PATHOPHYSIOLOGY.

PE can have the following pathophysiological effects: (1) increased pulmonary vascular resistance due to vascular obstruction, neurohumoral agents, or pulmonary artery baroreceptors; (2) impaired gas exchange due to increased alveolar dead space from vascular obstruction and hypoxemia from alveolar hypoventilation, low ventilation-perfusion units, and right-to-left shunting, as well as impaired carbon monoxide transfer due to loss of gas-exchange surface; (3) alveolar hyperventilation due to reflex stimulation of irritant receptors; (4) increased airway resistance due to bronchoconstriction; and (5) decreased pulmonary compliance due to lung edema, lung hemorrhage, and loss of surfactant.[43]

DIAGNOSIS

Diagnosis of PE is more difficult than treatment or prevention. For patients with PE, the most dangerous period is that preceding the establishment of the correct diagnosis. Fortunately, reliable noninvasive diagnostic approaches have become increasingly available--particularly venous ultrasound, plasma D-dimer enzyme-linked immunosorbent assay (ELISA) chest computed tomography (CT) scanning, and echocardiography. The contemporary diagnostic strategy integrates clinical findings with various diagnostic techniques.[47A]

Clinical Presentation

Clinical suspicion of PE is of paramount importance in guiding diagnostic testing. Dyspnea is the most frequent symptom, and tachypnea is the most frequent sign of PE (Table 52-4) . In general, severe dyspnea, syncope, or cyanosis portends a major life-threatening PE. However, pleuritic pain often signifies that the embolism is small and located in the distal pulmonary arterial system, near the pleural lining.

PE should be suspected in hypotensive patients when (1) there is evidence of venous thrombosis or predisposing factors for it and (2) there is clinical evidence of acute cor pulmonale (acute right ventricular failure) such as distended neck veins, an S_3 gallop, a right ventricular heave, tachycardia, or tachypnea, especially if (3) there are echocardiographic findings of right ventricular dilatation and hypokinesis or electrocardiographic (ECG) evidence of acute cor pulmonale manifested by a new S_1 -Q_3 -T_3 pattern, new incomplete right bundle branch block, or right ventricular ischemia.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of PE is broad and covers a spectrum from life-threatening disease such as acute myocardial infarction to innocuous anxiety states (Table 52-5) . Some patients have concomitant PE and other illnesses. Therefore, for example, if pneumonia or heart failure does not respond to appropriate therapy, the possibility of coexisting PE should be considered.

Distinguishing between PE and primary pulmonary hypertension (see Chap. 53) deserves special vigilance (Table 52-6) . Surprisingly, some patients have a hybrid condition that is similar to primary pulmonary hypertension but that includes thrombi. Among these patients, large central pulmonary artery thrombi can develop.[47B] It is often impossible

TABLE 52-4 -- MOST COMMON SYMPTOMS AND SIGNS AMONG THE 2454 PATIENTS IN THE INTERNATIONAL COOPERATIVE PULMONARY EMBOLISM REGISTRY (ICOPER)

SYMPTOM OR SIGN	PERCENT

to determine whether these thrombi formed in situ or whether they embolized to the pulmonary arteries from a separate site.

Clinical Syndromes of Pulmonary Embolism

Classification of PE into various syndromes (Table 52-7) is useful for prognostication and for deciding on subsequent clinical management.[48]

MASSIVE PULMONARY EMBOLISM.

Patients with massive PE are at risk for cardiogenic shock. They have thrombosis often affecting at least half of the pulmonary arterial system. Clot is almost always present bilaterally. Dyspnea is usually the cardinal symptom, and systemic arterial hypotension requiring pressor support is the predominant sign.

MODERATE TO LARGE PULMONARY EMBOLISM.

These patients have right ventricular hypokinesis on echocardiography but normal systemic arterial pressure. Usually, lung scanning indicates that more than 30 percent of the lung is not perfused. These patients have various degrees of right ventricular hemodynamic instability that is masked by normal systemic arterial pressure. They may be at risk for recurrent (and possibly fatal) PE, even with adequate anticoagulation.[49] Therefore, especially if right ventricular dysfunction persists, one should consider using thrombolytics or embolectomy.

TABLE 52-6 -- PRIMARY PULMONARY HYPERTENSION (PPH) VS. RECURRENT PULMONARY EMBOLISM (PE)

SIMILARITIES	
Symptoms	Fatigue, dyspnea on exertion--most common; chest pain, syncope, hemoptysis, cyanosis--also common
Clinical course	Progressive dyspnea, right-heart failure
Hemodynamics	Elevated right-heart pressures, normal pulmonary capillary wedge pressure
Histology	Thrombotic lesions usually present
Treatment	Includes anticoagulation

DIFFERENCES		
Variable	**PPH**	**Recurrent PE**
Age (years)	20-40	>50
Female/male ratio	4:1	1:1
Clinical course	Continued deterioration	Deterioration, with intermittent stabilization
Perfusion lung scan	No segmental perfusion defects	Segmental or larger perfusion defects
Pulmonary artery systolic pressure	>60 mm Hg	<60 mm Hg
Pulmonary angiogram	"Pruning"	Intraluminal filling defects
Confounding problems with angiogram	Thrombi may occur on or distal to PPH lesions	"Pruning" can also suggest PE
Diagnostic alternatives	Lung biopsy	Pulmonary angioscopy
Therapy	Anticoagulation; high-dose nifedipine or diltiazem; long-term continuous intravenous prostacyclin	Anticoagulation; inferior vena caval interruption; thromboendarterectomy

Adapted from Goldhaber SZ: Strategies for diagnosis. In Goldhaber SZ (ed): Pulmonary Embolism and Deep Vein Thrombosis. Philadelphia, WB Saunders, 1985, p 89.

SMALL TO MODERATE PULMONARY EMBOLISM.

This syndrome is characterized by both normal systemic arterial pressure and normal right ventricular function. Patients usually have a good prognosis if anticoagulation or an inferior

TABLE 52-7 -- SIX SYNDROMES OF ACUTE PULMONARY EMBOLISM

SYNDROME	PRESENTATION	RIGHT VENTRICULAR DYSFUNCTION	THERAPY
Massive	Breathelessness, syncope, and cyanosis with persistent systemic arterial hypotension; typically >50 percent obstruction of pulmonary vasculature	Present	Heparin plus thrombolytic therapy or mechanical intervention

Moderate to large	Normal systemic arterial blood pressure; typically >30 percent perfusion defect on lung scan	Present	Heparin plus or minus thrombolytic therapy or mechanical intervention*
Small to moderate	Normal arterial blood pressure	Absent	Heparin
Pulmonary infarction	Pleuritic chest pain, hemoptysis, pleural rub, or evidence of lung consolidation; typically small peripheral emboli	Rare	Heparin and nonsteroidal antiinflammatory drugs
Paradoxical embolism	Sudden systemic embolic event such as stroke	Rare	Anticoagulation ± closure of right-to-left cardiac shunt
Nonthrombotic embolism	Most commonly air, fat, tumor fragments, or amniotic fluid	Rare	Supportive

Adapted from Goldhaber SZ: Treatment of acute pulmonary embolism. In Goldhaber SZ (ed): Cardiopulmonary Diseases and Cardiac Tumors. In Braunwald E (series ed): Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 7.1-7.12.T wave inversion in leads III and aV_F or in leads V_1 -V_4

*Therapy depends on degree of impairment of right ventricular function and presence or absence of contraindications to thrombolysis or heparin.

vena caval (IVC) filter is used to prevent recurrent PE.

PULMONARY INFARCTION.

This syndrome is characterized by unremitting chest pain, occasionally accompanied by hemoptysis. The embolus usually lodges in the peripheral pulmonary arterial tree, near the pleura and close to the diaphragm.[50] Tissue infarction usually occurs 3 to 7 days after embolism. The syndrome at that time often includes fever, leukocytosis, and chest radiological evidence of infarction.

PARADOXICAL EMBOLISM.

This syndrome often presents with a sudden, devastating stroke and concomitant PE. Patients often have abnormally elevated pulmonary arterial pressure with a patent foramen ovale evident on echocardiography.[51] Among patients suspected of having paradoxical embolism, occult leg vein thrombosis is frequently present and often is confined to the calves.[52]

NONTHROMBOTIC PULMONARY EMBOLISM.

Sources of embolism other than thrombus are less commonly detected than thrombotic PE. Fat embolism syndrome is most often observed after blunt trauma complicated by long-bone fractures.[53] Among patients with cancer, tumor embolism is more difficult to diagnose clinically than thrombotic PE because presenting symptoms and signs are similar in both conditions.[54] Gas embolism,[54A] particularly air embolus, can occur during placement or removal of a central venous catheter.[55] It has also been described as resulting from presumed inadvertent pressure placed on a partially empty plastic intravenous infusion bag.[56]

Intravenous drug abusers tend inadvertently to inject various substances that contaminate their drug supply. Materials commonly found at autopsy include hair, talc, and cotton. These patients are also susceptible to septic PE, which may be accompanied by endocarditis of the tricuspid or pulmonic valves.

Nonimaging Diagnostic Methods

PLASMA D-DIMER ELISA.

This is the most promising blood test for pulmonary embolism screening. An abnormally elevated level of *ELISA-determined plasma D-dimer* has more than 90 percent sensitivity for identifying patients with PE proven by lung scan[57] or by angiogram.[58] This test relies on the principle that most patients with PE have ongoing endogenous fibrinolysis that is not effective enough to prevent PE but that does break down some of the fibrin clot to D-dimers. These D-dimers can be assayed by monoclonal antibodies in commercially available kits.

Although elevated plasma concentrations of D-dimers are sensitive for the presence of PE, they are not specific. Levels are elevated in patients for at least 1 week postoperatively and are also increased in patients with myocardial infarction, sepsis, cancer, or almost any other systemic illness.[58A] Therefore the plasma D-dimer ELISA is best used in patients who have suspected PE but no coexisting acute systemic illness.

In the past, plasma D-dimer ELISA was a cumbersome test, especially for emergency use. It was designed, like many ELISAs, to be run in batches; furthermore, skilled technologists were needed to run daily controls and to process the samples. A rapid, individual, and quantitative automated D-dimer ELISA has been validated[59] and approved for use in clinical laboratories. The analytical procedure is straightforward, and turnaround time should be less than 1 hour. This advance in technology promises to expedite the screening of patients with suspected PE.

ARTERIAL BLOOD GASES.

Among patients who were suspected of having PE and who underwent angiography in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) (see p. 1893), determination of the Pa_{O_2} did not discriminate between those with and without PE. There

Modified from Sreeram N, Cheriex EC, Smeets JLRM, et al: Value of the 12-lead electrocardiogram at hospital admission in the diagnosis of pulmonary embolism. Am J Cardiol 73:298, 1994.

was no difference between the average Pa_{O_2} (70 mm Hg) among patients with PE compared with those without PE (72 mm Hg) at angiography. Importantly, among patients with angiographically proven PE who had no prior cardiopulmonary disease, the Pa_{O_2} was more than or equal to 80 mm Hg in 26 percent.[60] Furthermore, normal values of the alveolar-arterial oxygen gradient did not preclude the diagnosis of acute PE.[61] Therefore, arterial blood gas determinations should not be part of the diagnostic strategy when investigating suspected PE.

ELECTROCARDIOGRAM.

An ECG is useful not only to help preclude acute myocardial infarction but also for rapidly identifying some patients with large PE, who may have ECG manifestations of right-heart strain. In a series of 49 consecutive patients with subsequently proven PE, at least three of seven ECG features suggestive of right ventricular overload

(Table 52-8) were identified on 76 percent of ECGs obtained at hospital admission.[62]

IMPEDANCE PLETHYSMOGRAPHY.

This is a very indirect approach to DVT diagnosis; it measures changes in electrical resistance caused by obstruction to venous outflow. Impedance plethysmography (IPG) should not be used routinely to detect DVT. In a study of consecutive patients with suspected DVT who underwent both IPG and contrast venography, IPG failed to identify 35 percent of patients with proximal leg DVT.[63]

Imaging Methods

CHEST ROENTGENOGRAPHY.

The chest radiograph is usually the first imaging study obtained in patients with suspected PE. Although more than half of patients with PE have an abnormal chest film examination, a near-normal radiograph in the setting of severe respiratory compromise is highly suggestive of massive PE. Classical chest film abnormalities are uncommon but include focal oligemia (Westermark's sign) (Fig. 52-4) , indicating massive central embolic occlusion.[64] A peripheral wedge-shaped density above the diaphragm (Hampton's hump) (Fig. 52-5) usually indicates pulmonary infarction.[65] In PIOPED, patients with PE and either a prominent central pulmonary artery or cardiomegaly had higher pulmonary arterial mean pressures than did patients with atelectasis, a pulmonary parenchymal abnormality, or pleural effusion.[66]

One should always search for subtle abnormalities such as distention of the descending right pulmonary artery. The vessel often tapers rapidly after the enlarged portion. The chest radiograph can also help to identify patients with diseases that can mimic PE, such as lobar pneumonia or pneumothorax. Patients with these latter illnesses can also have concomitant PE.[67]

VENOUS ULTRASONOGRAPHY.

The primary diagnostic criterion to establish the presence of DVT by ultrasonography is the loss of vein compressibility (Fig. 52-6) . Normally, the vein collapses completely when gentle pressure is applied to the skin overlying it. Upper extremity DVT may be more difficult to diagnose because the clavicle can

Figure 52-4 *A,* Chest film of a patient with clinical signs of pulmonary embolism; marked oligemia (Westermark's sign) is seen in the entire right lobe. *B,* Arteriogram from the same patient shows massive saddle embolus in the right main pulmonary artery (arrow). *(Courtesy of Dr. Jack L. Westcott, The New York Hospital and Cornell University Medical College.)*

hinder attempts to compress the subclavian vein. With acute DVT of either the upper extremity or leg, there is associated passive dilation of the vein.[68]

As many as half of patients with PE have no imaging evidence of DVT.[42] Therefore, if clinical suspicion of PE is high, patients without evidence of DVT should still be investigated for PE. For detection of DVT, ultrasound examination is more accurate than IPG.[69]

Ultrasonography is usually reliable in diagnosing proximal leg DVT in *symptomatic outpatients.*[70] The presence of newly detected DVT may sometimes be a useful surrogate for PE. At selected centers with special expertise, ultrasonography may also be dependable for evaluating suspected symptomatic infrapopliteal DVT.[71] Serial ultrasound measurement of thrombus mass after an episode of acute DVT may allow subsequent correct identification of recurrent DVT.[72] Unfortunately, ultrasonography may yield disappointing results when screening *asymptomatic patients* with possible DVT after orthopedic surgery[73] or after craniotomy.[74]

NUCLEAR VENOGRAPHY.

In 1998, the Food and Drug Administration (FDA) approved technetium-99m-apcitide (AcuTect; Diatide, Inc; Londonderry, NH) for the diagnosis of acute leg DVT. A complex of the synthetic peptide apcitide and the radionuclide technetium binds preferentially to the glycoprotein IIb/IIIa receptors found on activated platelets. This diagnostic modality may be complementary to ultrasonography and provide information on pelvic vein thrombosis (not ordinarily imaged by ultrasound), acute DVT superimposed on chronic DVT (not well differentiated by ultrasound), and acute DVT when the ultrasound examination is technically limited owing to body habitus or ambiguous

Figure 52-5 Posteroanterior chest film of a patient with pulmonary embolism shows a "Hampton's hump" in the right lower lung field, a homogeneous, wedge-shaped density in the peripheral field, convex to the hilum. *(Courtesy of Dr. Jack L. Westcott, The New York Hospital and Cornell University Medical College.)*

findings. However, broad clinical experience with this technique has not yet been realized.

CONTRAST PHLEBOGRAPHY.

Although contrast phlebography has traditionally been considered the gold standard for DVT diagnosis,[75] venograms are now being obtained with less frequency because of the widespread availability, convenience, and generally excellent results with ultrasonography. Venography is costly and invasive and occasionally results in contrast allergy or contrast-induced phlebitis. Furthermore, there is considerable disagreement in the interpretation of contrast venograms among experienced readers.[76] Patients with massive leg DVT often have nondiagnostic venograms because the contrast agent simply cannot reach the totally obstructed deep leg veins. Consequently, we reserve contrast phlebography for situations in which the ultrasound findings are equivocal or, alternatively, when the ultrasound examination result is normal despite a high clinical suspicion for DVT.

LUNG SCANNING.

Although lung scanning remains the principal diagnostic imaging test when PE is suspected, there is increasing dissatisfaction with this approach because the majority of scans do not provide definitive results. Perfusion scintigraphy uses radiolabeled aggregates of albumin or microspheres that are trapped in the pulmonary capillary bed. Six standard views are obtained with a gamma camera. Patients with large PE may have many defects on the perfusion scan. If ventilation scanning is performed on a patient who has PE but no intrinsic lung disease, a normal ventilation study result is expected, yielding a ventilation-perfusion mismatch (Fig. 52-7) and a lung scan interpreted as "high probability for PE."

The utility of the ventilation scan has undergone intense

Figure 52-6 Right common femoral vein (RT CFV) thrombosis (transverse view) diagnosed by compression ultrasonography. The left half of the image is the baseline ultrasound examination demonstrating the artery (A) superior to the vein (V). During the examination, the artery can be seen to pulsate and appears to wink at the examiner. The vein is typically larger than the artery but normally is not severalfold larger. With compression (COMP) in the right half of the image, the artery is deformed (curved upper arrows), but the vein fails to compress (straight lower arrows).

Figure 52-7 A 41-year-old woman presented with sudden onset of shortness of breath and retrosternal chest discomfort. Her heart rate was 168 beats/min, respiratory rate 32/min, oxygen saturation 86 percent, and blood pressure 112/70 mm Hg. She underwent a ventilation (*right panel*)-perfusion (*left panel*) lung scan with xenon-133 gas (26 mCi) and technetium-99m macroaggregated albumin (3.2 mCi) in the left posterior oblique position. Numerous scattered segmental (arrows) and subsegmental perfusion defects with near normal ventilation were found. This ventilation-perfusion mismatch

was interpreted as high probability for pulmonary embolism.

scrutiny. [76A] In the PIOPED, the ventilation scan was of questionable incremental benefit in establishing or precluding the diagnosis of PE.[77] The European Cardiology Society's Working Group on Thrombosis and Platelets plans to declare that a ventilation scan is no more useful than a chest radiograph for interpretation of perfusion lung scans.

PE is very unlikely in patients with normal and near-normal scans.[78] High-probability scans usually indicate acute PE, but fewer than half of patients with PE have a high-probability scan (Table 52-9) . Scans that fall between these extremes of the spectrum should be called intermediate probability.[79] Many patients with low-probability scans but high clinical suspicion for PE do, in fact, have PE at angiography (Table 52-10) . Therefore the term *low-probability* scan is a potentially lethal misnomer.[80]

CHEST COMPUTED TOMOGRAPHY.

Chest CT is being used with increasing frequency as the initial imaging test in patients with suspected PE (Fig. 52-8) . Chest CT is beginning to supplant lung scans because the chest CT result usually is not equivocal. Thrombus is either present or absent, without any "intermediate" or "indeterminate" probability of PE. For patients with intrinsic lung disease and abnormal chest radiograph results, CT scan has the added benefit of potentially suggesting an alternative or concomitant pulmonary disease to explain the clinical presentation.

Figure 52-8 A 62-year-old physician suffered a massive pulmonary embolism 2 weeks after prostatectomy. Spiral chest CT with contrast provided a definitive diagnosis, with a large thrombus burden apparent in the right and left main pulmonary arteries (arrows).

The test requires injection of intravenous contrast but is accomplished quickly, while holding a single breath. Although excellent for central large PE, the examination is not reliable for precluding clinically important smaller PE in peripheral pulmonary arteries.[81] [81A]

MAGNETIC RESONANCE IMAGING.

Gadolinium-enhanced magnetic resonance (MR) angiography appears comparable to conventional contrast pulmonary angiography in preliminary studies.[82] Unlike standard angiography, MR does not require ionizing radiation or injection of iodinated contrast agent. MR can be performed safely in patients with poor renal function. The test itself imposes virtually no risk to the patient. Finally, MR pulmonary angiography can include assessment of ventricular function; therefore, MR testing can diagnose PE and image right and left ventricular size and pattern of contraction.

ECHOCARDIOGRAPHY (see Chap. 7).

Echocardiography is insensitive for the diagnosis of PE but is a rapid, practical, and sensitive technique for detection of right ventricular overload among patients with established and large PE (Fig. 52-9) . The frequency of echocardiographic signs of PE (Table 52-11) depends on the population being studied. For those patients in whom transthoracic imaging is unsatisfactory, transesophageal echocardiography can be carried out.[83]

Echocardiographic detection of right ventricular dysfunction at the time of presentation with PE is useful for risk stratification and prognostication. Among patients with major PE, echocardiographic evidence of a patent foramen

TABLE 52-11 -- ECHOCARDIOGRAPHIC SIGNS OF PULMONARY EMBOLISM

ovale signifies a high risk of death and paradoxical arterial thromboembolism.[84]

Right ventricular dilatation and hypokinesis may occur in chronic pulmonary hypertension due to any cause. Long-term elevation of right ventricular afterload is usually accompanied by right ventricular hypertrophy. In patients with chronic pulmonary hypertension, the velocity of the tricuspid regurgitant jet may be elevated to a greater level than in patients with acute PE and no underlying cardiopulmonary disease. Right ventricular infarction, cardiomyopathy, and right ventricular dysplasia may also result in right ventricular hypokinesis and dilatation on the echocardiogram. In these conditions, however, the velocity of tricuspid regurgitation is usually less than in acute PE.

It appears that right ventricular contractile dysfunction following PE has a distinct regional pattern in which wall excursion is hypokinetic from the base through the free

Figure 52-9 *A,* Parasternal short-axis views of the right ventricle (RV) and left ventricle (LV) in diastole (*left*) and systole (*right*). Diastolic and systolic bowing of the interventricular septum (arrows) into the LV is compatible with RV volume and pressure overload, respectively. The RV is appreciably dilated and markedly hypokinetic, with little change in apparent RV area from diastole to systole. PE = small pericardial effusion. *(From Come PC: Echocardiographic evaluation of pulmonary embolism and its response to therapeutic interventions. Chest 101:151S, 1992.) B,* Segmental RV free wall excursion (mean ± SEM) by centerline analysis in patients with acute pulmonary embolism (PE) or primary pulmonary hypertension (PPH) and in normal persons. The acute increase in afterload in PE results in regional RV dysfunction predominantly affecting the mid free wall as it assumes a more spherical shape to equalize wall stress. The RV apex is spared (McConnell's sign). In contrast, the chronic pressure overload of PPH results in more diffuse RV dysfunction, with limited shape change of the hypertrophied RV. *(From McConnell MV, Rayan ME, Solomon SD, et al: Echocardiographic diagnosis of acute pulmonary embolism: A distinct pattern of abnormal right ventricular wall motion. Am J Cardiol 78:469, 1996).*

wall but remains almost normal at the right ventricular apex (McConnell's sign) (Fig. 52-9 *B*) This pattern of right ventricular contractile dysfunction differs from the global dysfunction observed in primary pulmonary hypertension.[85] A possible explanation is that in PE, the left ventricle may tether the right ventricular apex, thereby preserving near-normal wall motion in this region.

PULMONARY ANGIOGRAPHY.

Standard contrast pulmonary angiography has been considered the gold standard for accurate in vivo diagnosis or exclusion of PE. With appropriate techniques and experience, it can be performed expeditiously and safely in most patients. Angiography is most useful when a diagnostic dilemma persists despite the use of noninvasive tests. This situation is most common when the diagnostic test results are negative or ambiguous in the presence of high clinical suspicion for PE. Pulmonary angiography is obviously also required when interventions are planned such as suction catheter embolectomy, mechanical clot fragmentation, or catheter-directed thrombolysis (discussed later).

PREPARATION OF THE PATIENT.

A history of allergy to contrast medium should be sought. If present, high-dose corticosteroids should be administered. Heparin can be discontinued immediately before the procedure, unless the clinical suspicion for PE is very high. Patients should avoid heavy meals for at least 4 hours before angiography.

THE ANGIOGRAPHIC PROCEDURE.

The perfusion lung scan serves as a road map to the angiographer, who performs selective angiography rather than injecting into the main pulmonary artery. Obtaining accurate and high-quality recordings of right-heart pressures and waveforms is of paramount importance. If the pressure tracing "dampens" or "wedges" in the proximal pulmonary artery, anatomically massive PE should be suspected before injection of contrast agent. If the pulmonary artery systolic pressure exceeds approximately 50 mm Hg, the differential diagnosis should include chronic PE or acute superimposed on chronic PE.

Our preferred approach is via the femoral vein, although brachial or internal jugular approaches are alternatives. The best means of identifying the correct level for puncture in the groin is with fluoroscopy; the skin incision site should be at the level of the upper region of the femoral neck. We prefer a single wall puncture to avoid the possibility of passing first through the femoral artery before entering the femoral vein. Once access has been obtained, a guidewire is inserted through the needle, and the needle is exchanged for either a pigtail catheter or a sheath with a side arm. To advance through the cardiac chambers and measure right heart pressures, we use either (1) a pigtail catheter with a tip deflector wire or (2) a Swan-Ganz catheter followed by exchange over a guidewire for a pigtail catheter. The pigtail catheter permits a high contrast injection rate with considerable safety.

To carry out a complete diagnostic procedure, at least two views of each lung should be obtained. One view on each side should be the *ipsilateral posterior oblique* (approximately 45 degrees), and the other view can be either an *anteroposterior* view or the *ipsilateral anterior oblique* (approximately 45 degrees). Low-osmolar contrast medium is used because it does not cause the severe coughing that occurs with high-osmolar contrast medium and it gives a greater margin of safety among patients with elevated right-sided heart pressures. The contrast medium is injected usually at a rate of 20 to 25 ml/sec for 2 seconds. If the right-sided heart pressures are elevated, the rate of injection can be decreased, depending on the severity of the elevation. If the right ventricular end-diastolic pressure exceeds 20 mm Hg, consider superselective arteriography with a decreased rate and volume of contrast into the lobe that is most likely to yield a positive result.

We now perform all of our filming for pulmonary arteriography using digital acquisition. The filming rate is 7.5 frames/sec for 1 second before injection (to obtain mask images for digital subtraction), followed by 7.5 frames/sec for the first 3 seconds after the beginning of the injection. However, with digital subtraction, one should view the images in the unsubtracted mode, because subtraction may lead to artifacts that can simulate pulmonary emboli. After the initial rapid filming rate, the filming rate can be decreased to 1 to 2 frames/sec for approximately 5 seconds. If the foregoing views are nondiagnostic, selective magnification angiography (also acquired digitally) of any areas in question can be obtained. If these views do not lead to a diagnostic resolution, balloon occlusion arteriography may be performed.

INTERPRETING THE ANGIOGRAM.

A definitive diagnosis of PE depends on visualization in two projections of an intraluminal filling defect in a pulmonary arterial branch or cutoff of a branch with the visualized "tail" of the embolus. Secondary signs of PE reflect decreased perfusion and consist of abrupt occlusion (cutoff) of vessels, oligemia or avascularity of a segment, a prolonged arterial phase with slow filling and emptying of veins, and tortuous, tapering peripheral vessels.[86]

Not all pulmonary artery filling defects or occlusions are due to acute PE. In chronic PE, arteries may appear pouched, and thrombus appears organized with a concave edge. Bandlike defects called *webs* may be present, in addition to intimal irregularities and abrupt narrowing or occlusion of lobar vessels.[87] Other causes of intraluminal filling defects include pulmonary Takayasu's arteritis (see Chap. 40), angiosarcoma, and sarcoidosis.[67]

Overall Strategy: An Integrated Diagnostic Approach

A wide array of diagnostic tests is available for the investigation of suspected PE. Familiarity with each test's strengths and weaknesses (Table 52-12) as well as knowledge of the availability and reliability of specific tests at one's hospital will facilitate a concise and streamlined work-up.

At Brigham and Women's Hospital, we are initiating an interdisciplinary protocol for patients who present to the emergency department with suspected PE (Fig. 52-10) . The initial assessment includes the history, physical examination, and ECG, with special attention to the patient's clinical milieu and risk factors for venous thromboembolism. Next we obtain a chest radiograph and a rapid plasma D-dimer ELISA. If both are nondiagnostic, then PE is exceedingly unlikely, and we consider the diagnosis excluded at that point. If either result is abnormal, the diagnostic work-up continues. Most patients then undergo lung scanning, despite its limitations. If the chest radiograph appears abnormal, however, the likelihood of a diagnostic lung scan is low, and we usually perform chest CT with contrast in our emergency department scanner in lieu of lung scanning. For those patients in whom the diagnosis is not clarified with lung scanning or chest CT, the next step is venous ultrasonography. If the result is normal and our clinical suspicion remains high, we usually proceed with contrast pulmonary angiography. We do not consider a low-probability lung scan and a nondiagnostic venous ultrasonogram of the leg to be sufficient to preclude PE in the presence of high clinical suspicion.[88]

Using a similar protocol, investigators collaborating in Geneva and Montreal evaluated 918 consecutive patients suspected of having PE or DVT. After 3 months of follow-up, only 2 percent developed clinical evidence of PE. Pulmonary angiography or contrast venography of the legs was required in only 6 percent of the entire cohort.[89]

MANAGEMENT

Rapid and accurate risk stratification is of paramount importance. Patients with PE present with a wide spectrum of illness, and appropriate care can range from prevention of recurrent PE (with anticoagulation alone or insertion of an IVC filter) to clot dissolution or removal with thrombolysis or embolectomy. Anticoagulation with LMWH is being used with increasing frequency as a bridge to full and therapeutic levels of warfarin.

Adjunctive measures include provision of supplemental oxygen and adequate pain relief, usually most effective with nonsteroidal antiinflammatory medications. Patients who appear toxic and hypoxic should be considered for prompt temporary mechanical ventilation. Those with impending hypotension or poor organ perfusion require rapid institution of an inotrope.

Dobutamine--a beta-adrenergic agonist with positive inotropic and pulmonary vasodilating effects (see Chapter 18) should be considered a first-line agent to treat right-sided heart failure and cardiogenic shock.[89A] In general, volume loading these patients is ill advised because ventricular interdependence can lead to even further reductions in

TABLE 52-12 -- ADVANTAGES AND DISADVANTAGES OF DIAGNOSTIC TESTS FOR SUSPECTED PULMONARY EMBOLISM

DIAGNOSTIC TEST	ADVANTAGES	DISADVANTAGES
Plasma D-dimer ELISA	A normal result makes PE exceedingly unlikely	Level is elevated in many systemic illnesses that mimic PE; unless a rapid assay is available, the turnaround time will be long
(ECG)	Universally available; may indicate acute cor pulmonale	Acute cor pulmonale on ECG is not specific for PE; not a sensitive test
Impedance plethysmography	Portable, inexpensive, easy to use	Inaccurate, with failure to detect major nonobstructive proximal DVT
Chest radiograph	Usually has minor abnormalities but occasionally pathognomonic; may suggest alternative diagnoses; may guide work-up toward chest CT rather than lung scan	Not specific
Venous ultrasonography	Excellent for detecting symptomatic proximal DVT; surrogate for PE	Cannot image iliac vein thrombosis; imaging of calf is operator dependent; DVT may have embolized completely, resulting in a normal result
Nuclear venography	Image pelvic and calf veins; differentiate acute versus chronic DVT	Limited experience with this test
Contrast venography	Used to be gold standard; excellent for calf veins	Can cause chemical phlebitis; uncomfortable; costly; may fail to diagnose massive DVT because veins are filled with thrombus and cannot be opacified
Lung scanning	Standard initial imaging test for PE; high-probability scans are reliable for detecting PE; normal/near-normal scans are reliable for precluding PE	Most scans are neither high probability nor normal/near-normal; ventilation scans are falling out of favor; most test results are equivocal
Chest CT	Excellent for PE in the proximal pulmonary arterial tree	Insensitive for important but distal PE
MRI	Excellent for anatomy and cardiac function	In preliminary use; not widely available; experience very limited
Echocardiography	Excellent for identifying right ventricular dilatation and dysfunction that is not obvious clinically, thus providing an early warning of potentially adverse outcome	Not specific; many patients with PE have normal echocardiograms; the test cannot reliably differentiate causes of right ventricular dysfunction
Pulmonary angiography	Considered the gold standard for diagnosis	Invasive, costly, uncomfortable

ELISA=enzyme-linked immunosorbent assay; PE=pulmonary embolism; ECG=electrocardiogram; DVT=deep vein thrombosis; CT=computed tomography; MRI=magnetic resonance imaging.

left ventricular output. For patients with pulmonary hypertension and a patent foramen ovale, inhaled nitric oxide may reverse right-to-left shunting and improve oxygenation.[90]

Prevention of Pulmonary Embolism and Deep Venous Thromboembolism

Heparin

UNFRACTIONATED HEPARIN (see also Chap. 62).

Standard, unfractionated heparin is a highly sulfated glycosaminoglycan that is partially purified from either porcine intestinal mucosa or bovine lung. Its molecular weight ranges from 3000 to 30,000 and averages 15,000. Heparin acts primarily by binding to antithrombin III (AT III), an enzyme that inhibits the coagulation factors thrombin (factor IIa), Xa, IXa, XIa, and XIIa. Heparin subsequently promotes a conformational change in AT III that accelerates its activity approximately 100- to 1000-fold.[91] This prevents additional thrombus formation and permits endogenous fibrinolytic mechanisms to lyse clot that has already formed. However, heparin does *not* directly dissolve thrombus that already exists. The efficacy of heparin is limited because clot-bound thrombin is protected from heparin-antithrombin III inhibition.[92] Furthermore, heparin resistance can occur because unfractionated heparin binds to plasma proteins.[93]

LOW-MOLECULAR-WEIGHT HEPARINS (LMWHs).

LMWHs are fragments of unfractionated heparin that exhibit less binding to plasma proteins and endothelial cells than unfractionated heparin. Therefore, LMWHs have greater bioavailability, more predictable dose response, and longer half-life than unfractionated heparin.[94]

The introduction of LMWHs for treatment of venous thromboembolism is revolutionizing the management of DVT and PE, especially for the majority of patients who are hemodynamically stable. Many large randomized trials of patients with acute DVT have compared subcutaneously administered

LMWH with continuous intravenous unfractionated heparin as a bridge to full and therapeutic anticoagulation.[95] [96] [97] LMWH was at least as effective and safe as continuous intravenous unfractionated heparin.

A metaanalysis of randomized trials comparing 3674 patients with acute DVT receiving LMWH versus unfractionated heparin[98] demonstrated that LMWH reduced the mortality rate over 3 to 6 months of follow-up by 29 percent. The major bleeding complication rate was reduced by 43 percent. These data were used in a

cost-effectiveness analysis that showed that LMWH is highly cost effective compared with unfractionated heparin for DVT management.[99]

The excellent bioavailability and subcutaneous administration of LMWH permit a strategy of weight-based LMWH dosing (without laboratory tests for dose adjustment in most instances) coupled with the possibility of outpatient therapy or an abbreviated hospitalization. With a concerted effort, it appears that the majority of ambulatory patients who present with DVT can be treated as outpatients,[100] as long as an infrastructure has been established to ensure close and meticulous follow-up.[101]

On December 31, 1998, the FDA approved outpatient treatment of DVT *without PE* using enoxaparin 1 mg/kg every 12 hours for a minimum of 5 days. Warfarin is usually begun on the first evening of therapy, and enoxaparin is continued until a stable and therapeutic INR of 2.0 to 3.0 is achieved. The dose of enoxaparin must be decreased in patients with renal insufficiency because LMWH is primarily renally excreted.

The FDA approved the same enoxaparin dosing regimen for inpatient treatment of DVT *with or without PE.* An alternative dosing regimen was also approved for the same indication: 1.5 mg/kg/24 hr of enoxaparin. However, there is less clinical experience with this dosing regimen.[102] Importantly, no trial of patients with symptomatic PE has attempted outpatient or abbreviated hospitalization with LMWH.[103]

MONITORING HEPARIN.

An activated PTT that is at least 1½times greater than the control value should provide a minimum therapeutic level of unfractionated heparin. However, there are many different PTT reagent kits and virtually no standardization of PTT levels.[104] Therefore, an individual hospital's target PTT range for anticoagulation with unfractionated heparin should correspond to a plasma anti-Xa level of approximately 0.4 to 1.0 units/ml. At Brigham and Women's Hospital, we assay the anti-Xa level with a HEPRN pack (Du Pont) in the automated clinical analyzer used for other chemistry tests. This is a chromogenic assay based on the inhibition of factor X_a by heparin-activated antithrombin III.

The plasma anti-Xa level is particularly useful in three situations: (1) monitoring heparin anticoagulation among patients with baseline elevated PTTs due to a lupus anticoagulant or anticardiolipin antibodies, (2) monitoring heparin among DVT and PE patients who require large daily doses of heparin,[105] and (3) monitoring LMWH, which blunts the elevation in the PTT and in the activated clotting time that occurs with unfractionated heparin.

When LMWH is given for prophylaxis, it is administered in a fixed dose, with no or at most slight adjustments based on weight. However, when LMWH is given to achieve full and therapeutic levels of anticoagulation, the dose is based on weight. Ordinarily, no blood tests are needed to monitor LMWH. However, titration of LMWH is warranted for patients with massive obesity or for patients with renal insufficiency. In both circumstances, the dose of LMWH that is administered needs to be adjusted downward from the calculated weight-based dose.

In general, anticoagulation for prophylaxis can be achieved with an anti-factor Xa level of 0.2 to 0.4 units/ml. Full anticoagulation for therapy can be attained with an anti-factor Xa level of 0.4 to 1.0 units/ml. The level peaks approximately 3 hours after subcutaneous injection,[105] and an anti-factor Xa level is optimally obtained during the plateau phase, 4 to 6 hours after injection.[106]

For patients in whom warfarin therapy has failed or who cannot take warfarin (e.g., pregnant women), we treat with LMWH injected subcutaneously and usually teach self-administration.

INITIATING HEPARIN THERAPY.

Heparin is the cornerstone of treatment for acute PE. Before heparin therapy is begun, risk factors for bleeding should be considered, such as a prior history of bleeding with anticoagulation, thrombocytopenia, vitamin K deficiency, increasing age, underlying diseases, and concomitant drug therapy. The most frequently overlooked portion of the physical examination is a rectal examination for occult blood.

There is a transition toward the use of LMWH for patients who present with acute symptomatic PE, even though this approach is not FDA approved. The conventional treatment strategy uses unfractionated heparin, with an initial bolus of 5000 to 10,000 units, followed by a continuous intravenous infusion based on weight. Most patients require at least 30,000 units/24 hr. There are many nomograms, such as Raschke's,[107] to assist in adjusting the dose of continuous intravenous unfractionated heparin, with guidelines provided by the patient's weight and PTT. An automated heparin-delivery system has been described; it controls the PTT based on a computer-generated algorithm and relies on automated venous blood sampling.[108]

Unless a severe bleeding problem such as active gastrointestinal bleeding is detected, heparin can be started before lung scanning or pulmonary angiography. In cases of severe bleeding, heparin therapy should be withheld, and nonpharmacological treatment (secondary prevention) with insertion of an IVC filter should be considered if the diagnosis of PE is confirmed.

COMPLICATIONS.

The most important adverse effect of heparin is hemorrhage. Major bleeding during anticoagulation may unmask a previously silent lesion, such as bladder or colon cancer. For most cases of moderate bleeding, cessation of heparin will suffice, and the PTT usually returns to normal within 6 hours because the half-life of unfractionated heparin is only 60 to 90 minutes.

Resumption of heparin at a lower dose or implementing alternative therapy depends on the severity of the bleeding, the risk of recurrent thromboembolism, and the extent to which bleeding may have resulted from excessive anticoagulation. Risk factors for major in-hospital bleeding among anticoagulated patients include the presence of comorbid conditions, age greater than 60 years, the intensity of anticoagulation, concurrent medications, or liver dysfunction that worsens during treatment.[109]

In the event of life-threatening or intracranial hemorrhage, protamine sulfate can be administered at the time heparin is discontinued. Protamine, a strongly basic protein, immediately reverses anticoagulant activity by forming a stable complex with the acidic heparin. For life-threatening hemorrhage, the usual dose is approximately 1 mg/100 units of heparin, administered slowly (e.g., 50 mg over 10 to 30 minutes). Protamine sulfate may cause allergic reactions, particularly in diabetic patients who have had prior exposure to protamine after using neutral protamine Hagedorn (NPH) insulin.[91]

HEPARIN-INDUCED THROMBOCYTOPENIA.

This complication is caused by IgG antibodies that recognize complexes of heparin and platelet factor 4, leading to platelet activation via platelet Fc gamma IIa receptors. Formation of procoagulant, platelet-derived microparticles generates thrombin and makes patients especially vulnerable to venous thromboembolism.[110] These clots are often large and bilateral, and they get worse if heparin is continued.

The diagnosis should be suspected if patients develop DVT or PE while receiving heparin, especially if the platelet count decreases to less than 100,000/mm^3 or if it decreases by more than 50 percent of baseline. The peak incidence is 4 to 14 days after initiating heparin. Heparin-induced thrombocytopenia occurs much more commonly with unfractionated heparin than with LMWH.[111] However, LMWH usually cross-reacts with unfractionated heparin after heparin-induced thrombocytopenia occurs and therefore should not be used for treatment.

Patients with heparin-induced thrombocytopenia are especially susceptible to venous limb gangrene if warfarin is given before several days of effective antithrombotic therapy[112] such as danaparoid,[113] which reduces thrombin generation, or lepirudin,[114] which inhibits thrombin. Lepirudin currently is the only FDA-approved therapy for heparin-induced thrombocytopenia. The weight-adjusted dose must be reduced in the presence of renal insufficiency, and there is no specific antidote if bleeding occurs. Another direct thrombin inhibitor, argatroban, effectively treats heparin-induced thrombocytopenia.[115] Argatroban does not require dose adjustments with renal dysfunction, and FDA approval is imminent.[115A]

HEPARIN-INDUCED OSTEOPENIA.

Patients receiving prolonged heparin therapy may develop osteopenia, osteoporosis, or pathological bone fractures. In most cases, asymptomatic osteopenia is the most severe adverse effect on bone metabolism. This finding is most readily assessed with bone densitometry.[116] Among women who have discontinued heparin after pregnancy, the osteopenia usually resolves within a year.[117] For reasons not well understood, LMWH may cause less osteopenia than does unfractionated heparin.[118]

SPINAL AND EPIDURAL HEMATOMA.

Over a 5-year period, the FDA received reports of 43 patients in the United States who suffered spinal or epidural hematoma after receiving LMWH. Emergency decompressive laminectomy was performed in 28, and permanent paraplegia occurred in 16.[119] Consequently, most patients receiving LMWH during pregnancy are switched to unfractionated heparin for several weeks before their due date. Alternatively, LMWH is withheld for at least 24 hours before a scheduled induction of delivery.

HEPARIN-ASSOCIATED TRANSAMINITIS AND HYPERKALEMIA.

Heparin-associated elevations in transaminase levels occur commonly, have no relation to whether the heparin is of bovine or porcine origin, and are rarely associated with clinical toxicity.[120] [121] Heparin causes aldosterone depression by an unknown mechanism within 4 to 8 days after initiation of therapy. In patients with a normally functioning renin-angiotensin-aldosterone axis, this is probably of no clinical significance, although serum sodium levels may drop slightly. However, it may cause clinically important hyperkalemia in certain patients, such as those with diabetes or renal failure.[122]

Warfarin Sodium (See also Chap. 62)

Warfarin is a vitamin K antagonist that prevents gamma carboxylation activation of coagulation factors II, VII, IX, and X. The full anticoagulant effect of warfarin may not be apparent for 5 days, even if the prothrombin time, used to monitor warfarin's effect, becomes elevated more rapidly. Elevation in the prothrombin time may initially reflect depletion of coagulation factor VII, which has a half-life of about 6 hours, whereas factor II has a half-life of about 5 days.

OVERLAP WITH HEPARIN.

When warfarin therapy is initiated during an active thrombotic state, the levels of protein C and S decline, thus creating a thrombogenic potential. By overlapping heparin and warfarin for 5 days, the procoagulant effect of unopposed warfarin can be counteracted. In a Dutch study, patients with DVT were randomized to oral anticoagulation alone versus heparin plus oral anticoagulation. The recurrent DVT rate was three times higher in the group that received oral anticoagulation alone.[123] This study demonstrates that warfarin should be given with heparin coverage and overlap to patients with an active thrombotic state.

MONITORING WARFARIN.

The prothrombin time, used to adjust the dose of warfarin, should be reported according to the International Normalized Ratio (INR), not the prothrombin time ratio or the prothrombin time expressed in seconds. Fewer bleeding complications occur when the INR is used to monitor warfarin dosing rather than the prothrombin time ratio.[124]

INTENSITY AND DURATION OF THERAPY.

It is our practice to treat with 5 to 7 days of heparin and to initiate warfarin administration on the first hospital day after documenting a PTT within the therapeutic range[125] or several hours after subcutaneous injection of a therapeutic dose of LMWH. The recurrence rate after completion of anticoagulation is halved by using 6 months of oral anticoagulation rather than 6 weeks.[126] One small study suggests using an indefinite duration of anticoagulation after a first episode of idiopathic venous thromboembolism.[127] However, this approach is not generally accepted. Ongoing trials are investigating the optimal duration and intensity of antiocoagulation among patients at highest risk, those who suffer DVT or PE without recent surgery or antecedent trauma.[128]

There is disagreement about whether patients with venous thromboembolism and factor V Leiden are at increased risk of recurrence after anticoagulation has been discontinued.[8] [8A] The ongoing NIH-sponsored clinical trial, PREVENT, is addressing this issue.[128]

In otherwise healthy patients, I usually initiate warfarin therapy with 5 mg and achieve the target INR in about 5 days.[129] Among systemically ill patients, however, vitamin K deficiency[130] may lead to marked overanticoagulation just after a single modest dose of warfarin. I tend to treat first-time DVT of the calf[131] or upper extremities[132] for 3 months, and proximal DVT or PE for 6 months. The target INR for first-time DVT is 2.0 to 3.0, but I tend to treat PE more intensively, with a target INR of at least 3.0. Whenever possible, patients who have DVT or PE and who also have the antiphospholipid-antibody syndrome should be maintained with a target INR of at least 3.0.[133]

COMPLICATIONS.

The major toxic effect of warfarin is bleeding. The risk of bleeding increases as the INR increases. Risk factors for hemorrhage include severe hepatic or renal disease, alcoholism, drug interactions (including acetaminophen[134]), trauma, malignant disease, and known previous bleeding sites in the gastrointestinal tract. The incidence of rehospitalization for bleeding after hospitalization for DVT is greatest during the first 30 days after discharge. Women and nonwhite patients appear to be at especially increased risk for anticoagulant-related bleeding.[134A]

About 1 to 2 percent of patients will have an extremely low warfarin requirement of 1.5 mg or less in the absence of liver dysfunction, drug interaction, or concomitant disease. A subset is born with CYP2CP variant alleles that are associated with impaired hydroxylation of S-warfarin. If not recognized when warfarin is initiated, these individuals are at a potentially high risk of bleeding complications.[135]

Major life-threatening bleeding requires immediate treatment with enough cryoprecipitate or fresh frozen plasma (FFP) (usually 2 units) to normalize the INR and achieve immediate hemostasis. To treat less serious bleeding, vitamin K has traditionally been administered parenterally; a dose of 10 mg subcutaneously or intramuscularly usually reverses the effects of warfarin in 6 to 12 hours. However, this approach makes patients relatively refractory to warfarin for up to 2 weeks, so that reinstitution of warfarin becomes more difficult. A novel and alternative approach is to administer a single dose of vitamin K. In a cohort of patients who were not bleeding and who had an INR greater than 5.0, a single average dose of 10 mg of vitamin K sufficed to lower the INR to the targeted therapeutic range, without disrupting the subsequent daily dosing of warfarin.[136]

Minor bleeding with a prolonged INR may merely require interruption of warfarin therapy, without administration of FFP, until the INR has returned to the therapeutic range. If bleeding occurs when the INR is within the therapeutic range, occult malignant disease should be suspected and ruled out. Evaluation of cases of minor bleeding and an INR above the therapeutic range is less productive.

Warfarin-induced skin necrosis[137] is a rare but important complication that may be related to warfarin-induced reduction of protein C. The "purple toes syndrome" is another rare complication of warfarin therapy that appears to be caused by cholesterol microembolization.[137] In this syndrome, crystals are released from ulcerated atherosclerotic plaques. It appears that warfarin may worsen cholesterol microembolic disease by interfering with the healing of ulcerated atherosclerotic plaques.

During pregnancy, heparin should generally be used instead of warfarin because warfarin is associated with a markedly higher rate of congenital anomalies. The fetus is particularly susceptible to warfarin embryopathy during the 6th through 12th weeks of gestation. The main features are saddle nose, nasal hypoplasia, frontal bossing, short stature, stippled epiphyses, optic atrophy, cataracts, mental retardation, and flexure contractures. Intracranial bleeding may also lead to secondary central nervous system deformities.[138] Women can take warfarin post partum and breast feed safely, but reliable contraception is essential because warfarin is teratogenic.[139] The level of warfarin in breast milk is so low (25 ng/ml)[140] that it cannot be detected in the baby's plasma.[140]

In the office setting, I routinely assess warfarin dosing with a "point-of-care" device that provides the INR result in 2 minutes by use of a drop of whole blood obtained from a fingertip puncture. Substantial time savings have resulted, and patients leave the office with greater peace of mind and with a more accurate understanding of their warfarin dosing regimen. Appropriately selected patients can self-manage their warfarin dosing at home with a point-of-care device. In a randomized trial comparing self-management with conventional management, the self-managed patients more frequently achieved their target INRs and reported an improved quality of life compared with the conventionally managed group.[141]

ASPIRIN (see also Chap. 62).

Aspirin exerts its antithrombotic effect

TABLE 52-13 -- INDICATIONS FOR INFERIOR VENA CAVAL FILTERS

Anticoagulation Contraindicated and PE Documented
Active bleeding that might cause exsanguination (e.g., gastrointestinal)
Feared bleeding that might be catastrophic (e.g., postoperative craniotomy)
Ongoing complications of anticoagulation (e.g., heparin-associated thrombocytopenia)
Planned intensive cancer chemotherapy (with anticipated pancytopenia or thrombocytopenia)
PE=pulmonary embolism.
Anticoagulation Failure Despite Documentation of Adequate Therapy (e.g., Recurrent PE)
Prophylaxis in High-Risk Patients
Extensive or progressive venous thrombosis
In conjunction with catheter-based or surgical pulmonary embolectomy
Severe pulmonary hypertension or cor pulmonale
PE=pulmonary embolism.

by eliminating platelet prostaglandin synthesis, thereby blocking thromboxane A_2 formation and causing a moderate decrease in platelet function and a mild hemostatic defect.[142] Consequently, aspirin has at least a modest role in prevention of venous thrombosis.[143] I prescribe low-dose aspirin, usually 81 mg daily, for some patients who have finished their full course of warfarin. This strategy averts an abrupt transition from full anticoagulation to no anticoagulation.

Secondary Prevention: Inferior Vena Caval Interruption

The major indications for placement of an IVC filter are listed in Table 52-13 . An IVC filter prevents PE, not DVT.[144] Therefore, when a filter is inserted, anticoagulation should also be used, whenever possible, to prevent further thrombosis.[145]

Most IVC filters are placed below the renal veins. For suprarenal vein placement, the largest experience is with the Greenfield filter. At Brigham and Women's Hospital, we primarily use the bird's nest filter for infrarenal placement (Fig. 52-11) .

Primary Treatment

Thrombolysis

Thrombolytic therapy is a useful adjunct to heparin in patients who have PE and who are hemodynamically unstable.[146]

Figure 52-11 Inferior vena caval filters. Most filters are placed percutaneously via the right femoral vein. Our current preference is percutaneous placement of a Bird's Nest Filter (Cook Incorporated, Bloomington, IN), which has a low rate of failure, thrombogenicity, and occlusion. The smallness of its sheath may help minimize the risk of bleeding during and after the procedure. To insert the Bird's Nest Filter, the right-angled handle of the wire guide pusher is rotated counterclockwise for 10 to 15 turns to disengage it from the filter. Then the wire guide pusher is removed first, followed by the empty filter catheter. The introducing sheath is left in place so that a postprocedure venacavogram can be obtained. *(From Goldhaber SZ: Treatment of venous thrombosis. In Goldhaber SZ [ed]: Cardiopulmonary Diseases and Cardiac Tumors. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 12.1-12.14.)*

The definition of "hemodynamically unstable" is controversial and varies from systemic arterial hypotension to normal systemic arterial pressure with moderate or severe right ventricular dysfunction. Rapid improvement of right ventricular function and pulmonary perfusion, accomplished with thrombolytic therapy followed by heparin, may lead to a lower rate of death and recurrent PE.[49] Thrombolysis may (1) prevent the downhill spiral of right-sided heart failure by physical dissolution of anatomically obstructing pulmonary arterial thrombus (Fig. 52-12) ; (2) prevent the continued release of serotonin and other neurohumoral factors that might otherwise lead to worsening pulmonary hypertension; and (3) dissolve much of the source of the thrombus in the pelvic or deep leg veins, thereby decreasing the likelihood of recurrent large PE.

The potential benefits of immediately reversing right heart failure and preventing recurrent PE must be balanced by the risk of hemorrhage. Contraindications to thrombolysis,

Figure 52-12 *Left,* A large embolus in the right pulmonary artery (arrow). *Right,* After a 2-hour infusion of tissue plasminogen activator through a peripheral vein, resolution is pronounced, with only a small amount of residual thrombus in segmental branches. *(From Goldhaber SZ, Vaughan DE, Markis JE, et al: Acute pulmonary embolism treated with tissue plasminogen activator. Lancet 2:886, 1986.)*

such as intracranial disease, recent surgery, or trauma, preclude its use in some patients who can safely receive heparin alone. There is a 1 to 2 percent risk of intracranial hemorrhage.[147] Carefully screening patients for contraindications to thrombolysis is the best way to minimize bleeding risk (see Chap. 62) .

At Brigham and Women's Hospital, we have coordinated five trials of PE thrombolysis, including the largest trial of tissue plasminogen activator (t-PA, 100 mg/2 hr) plus heparin versus heparin alone.[148] The initial systemic arterial systolic pressure was at least 90 mm Hg in every patient. Most importantly, no clinical episodes of PE recurred among patients receiving t-PA, but there were five (two fatal and three nonfatal) clinically suspected recurrent PEs within 14 days in patients randomized to heparin alone (p=0.06). All five initially showed right ventricular hypokinesis on echocardiogram. This latter observation suggests that echocardiography may help identify a subgroup of patients with PE at high risk of adverse clinical outcomes if treated with heparin alone. Such patients in particular would appear to be excellent candidates for thrombolytic therapy in the absence of contraindications.

Qualitative assessment of right ventricular wall motion demonstrated that 39 percent of the t-PA recipients improved (Figs. 52-13 *A* and *B*) and 2.4 percent worsened, compared with 17 percent improvement and 17 percent worsening among those who received heparin alone ($p < 0.005$). Quantitative assessment showed that t-PA recipients had a significant decrease in right ventricular end-diastolic area during the 24 hours after randomization compared with none among those allocated to heparin alone ($p < 0.01$). Recipients of t-PA also had an absolute improvement in pulmonary perfusion of 14.6 percent at 24 hours (Fig. 52-13 *C* and *D*), compared with 1.5 percent improvement among heparin-alone recipients ($p < 0.0001$).

Unlike patients with myocardial infarction-thrombolysis, patients with PE have a wide "window" for effective use of thrombolysis. Specifically, patients who receive thrombolysis up to 14 days after new symptoms or signs maintain an effective response,[149] probably because of the bronchial collateral circulation. Therefore, patients suspected of having PE should be considered as potentially eligible for thrombolysis if they have had any new symptoms or signs within the 2 weeks before presentation. Although t-PA 100 mg/2 hr is the only contemporary FDA-approved dosing regimen for PE thrombolysis,[150] other regimens also appear promising, including 1,500,000 units of streptokinase/2 hr[151] and double-bolus reteplase (r-PA) (10-unit bolus followed 30 minutes later by a second 10-unit bolus).[152]

DVT THROMBOLYSIS

Most patients with DVT have contraindications to thrombolysis.[153] Totally occlusive venous thrombosis usually does not lyse if the agent is administered through a peripheral vein.[154] For patients with iliofemoral venous thrombosis, catheter-directed thrombolysis[155] or thrombolysis plus venous angioplasty[156] may be successful.

VENOUS INSUFFICIENCY.

Many patients with PE are plagued with chronic lower leg swelling and calf discomfort that can become problematic years after an episode of venous thromboembolism. This is known as *venous insufficiency* or *postthrombotic syndrome.* In most situations, the pathophysiology is damage of venous valves from antecedent DVT. Under extreme circumstances, venous ulceration can occur, particularly in the medial malleolus. The condition is usually manageable with below-knee vascular compression stockings. However, the frequency of venous insufficiency can be halved by preventive use of sized-to-fit compression stockings of 20 to 40 mm Hg.[156A]

Embolectomy

The results of embolectomy can be optimized if patients are referred for this procedure before the onset of cardiogenic shock.[156B] Greenfield's embolectomy device is a classical catheter-based method of extracting pulmonary arterial thrombus (Fig. 52-14) .[157] It consists of a 10F steerable catheter with a suction cup attached at the tip. Because of the cup's large size, a surgical venotomy is used, usually to access the right internal jugular vein. A steerable handle controls progression of the catheter through the right cardiac chambers and the pulmonary arterial branches.

Alternative catheterization methods[158] include mechanical fragmentation of thrombus with a standard pulmonary

Figure 52-13 Echocardiograms (four-chamber view) and perfusion lung scans (anterior view) in a previously healthy 53-year-old man treated with tissue plasminogen activator (t-PA) for pulmonary embolism. *A,* Enlargement of the right ventricle (RV) before treatment. The RV end-diastolic area was 42.9 cm^2 , and the interventricular septum (arrow) was displaced toward the left ventricle (LV). There was moderately severe RV hypokinesis. *B,* Three hours after initiation of t-PA therapy, the size of the RV normalized (with a planimetered area of 25.7 cm^2) and the interventricular septum resumed its normal configuration. RV wall motion normalized. *C,* The pretherapy lung scan (*left*) shows absence of perfusion in the right middle lobe (lower arrowhead) and in most of the right upper lobe, particularly the apical segment of the right upper lobe (upper arrowhead). The left lung shows absence of perfusion in the lingula and anterior segment of the left upper lobe (horizontal arrowhead) and irregular perfusion in the apical-posterior segment of the left upper lobe. *D,* The posttherapy scan (*right*) shows marked improvement in perfusion. *(From Goldhaber SZ: Treatment of acute pulmonary embolism. In Goldhaber SZ [ed]: Cardiopulmonary Diseases and Cardiac Tumors. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 3.1-3.25.)*

Figure 52-14 Philippe Reynaud, M.D., at the Laennec Hospital in Paris, used a Greenfield embolectomy catheter to remove this 17-cm thrombus from a severely compromised patient with PE. Rapid hemodynamic improvement ensued. *(From Meyer G, Tamiser D, Reynaud P, Sors H: Acute pulmonary embolectomy. In Goldhaber SZ [ed]: Cardiopulmonary Diseases and Cardiac Tumors. In Braunwald E [series ed]: Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 7.1-7.12.)*

artery catheter, clot pulverization with a rotating basket catheter, percutaneous rheolytic thrombectomy,[159] and pigtail rotational catheter embolectomy.[160] This 5F Teflon catheter has a distal tip that is divided into four 15-mm bends. The high-speed mechanical rotation of the catheter (about 100,000 rpm) causes centrifugal force to open the distal bends and form a soft flexible helical spiral that can disintegrate thrombus into microscopic particles within seconds.[159] Another approach is simultaneous mechanical clot fragmentation and pharmacological thrombolysis (Fig. 52-15 *A* and *B*). [161] Finally, balloon angioplasty has also been used to improve pulmonary arterial flow among patients with PE.[162]

If catheter-based strategies fail, emergency surgical embolectomy with cardiopulmonary bypass can be undertaken (Fig. 52-16) .[163] A nonrandomized comparison of t-PA

Figure 52-15 A 77-year-old woman had right-sided heart failure despite 3 days of full-dose heparin. Therefore, she underwent right heart catheterization and pulmonary angiography. Her pulmonary arterial pressure was 55/30 mm Hg. Seen on her baseline angiogram (*A*) were large right middle and right upper lobe pulmonary emboli (arrows). Because of relative contraindications to full-dose thrombolysis (systemic arterial hypertension and mild dementia), she underwent combined suction catheter embolectomy and catheter-directed thrombolysis with a bolus pulse spray of 8 mg of tissue plasminogen activator followed by an overnight infusion of 1 mg/hr. Her follow-up angiogram (*B*) shows marked improvement and reperfusion.

Figure 52-16 A 52-year-old woman was on the medical service to treat multiple sclerosis when she became short of breath and collapsed. Her echocardiogram showed a dilated right ventricle and collapsed left ventricle. Shortly thereafter, she suffered cardiac arrest and was immediately taken to the operating room with the presumptive diagnosis of pulmonary embolism. She was placed on cardiopulmonary bypass, and massive amounts of thrombus (*shown above*) were removed from her pulmonary arteries. She subsequently recovered uneventfully.

Figure 52-17 Proposed strategy for treatment of pulmonary embolism in which risk stratification, often with echocardiography, is undertaken to determine clinical and hemodynamic stability. This evaluation helps to determine prognosis as well as appropriateness of aggressive intervention with thrombolysis or mechanical measures to remove thrombus. IVC = inferior vena caval.

thrombolysis versus surgical embolectomy indicated that both approaches can be life saving in the majority of patients with massive PE.[164] For patients with PE causing hemodynamic instability, pulmonary embolectomy in the catheterization laboratory or operating room should be considered when there are contraindications to thrombolysis or when thrombolysis has failed.[165]

Management Approach for Acute Pulmonary Embolism

Therapy for PE should be tailored according to the anatomical extent of the embolus, the presence of underlying cardiopulmonary disease, and the detection of right-sided-heart dysfunction.[166] [167] The echocardiogram is becoming increasingly important for determination of hemodynamic stability, risk stratification, and prognostication (Fig. 52-17) . Primary therapy is being used with increasing frequency for patients with moderate or severe right ventricular dilatation and hypokinesis on echocardiogram, even in the presence of normal systemic arterial pressure. Secondary prevention of recurrent PE is directed toward all patients and appears to suffice in those with small to moderate PE in the absence of major right ventricular dysfunction. Before hospital discharge, obtaining a follow-up perfusion lung scan is useful to establish a new baseline, in case the patient subsequently complains of symptoms suggesting recurrent PE.

EMOTIONAL SUPPORT.

Although PE can be as emotionally devastating as myocardial infarction, the psychological burden for patients with PE may be greater. The lay public is not familiar with PE, particularly in terms of the possibility of genetic predisposition, long-term disability, and recurrence of disease. By discussing the implications of PE with patients and their families, the emotional burden may be assuaged. We initiated a Pulmonary Embolism Support Group, co-led by a nurse-physician team, and have been gratified by the experience. Although these sessions have an educational component,[168] the major emphasis is on discussing the anxieties and living difficulties that occur in the aftermath of PE.

Chronic Pulmonary Embolism

Patients with chronic pulmonary hypertension due to previous PE may be virtually bedridden with breathlessness due to high pulmonary arterial pressures. They should be considered for pulmonary thromboendarterectomy, which, if successful, can reduce and at times even cure pulmonary hypertension. The operation involves a median sternotomy, institution of cardiopulmonary bypass, and deep hypothermia with circulatory arrest periods. Incisions are made in both pulmonary arteries into the lower-lobe branches. Pulmonary thromboendarterectomy is always bilateral, with removal of organized thrombus from all involved vessels.

At the University of California at San Diego, more than 1000 patients debilitated by chronic pulmonary hypertension due to PE have undergone pulmonary thromboendarterectomy with good results and at an acceptable risk (Fig. 52-18) . The two major causes of mortality are (1) inability to remove sufficient thrombotic material at operation, resulting in persistent postoperative pulmonary hypertension and right ventricular dysfunction; and (2) severe reperfusion lung injury.[169]

Prevention

PE is difficult to diagnose, expensive to treat, and occasionally lethal despite therapy. Therefore, preventive measures are paramount.[170] Various mechanical measures and pharmacological agents can be used. The most recent innovation has been FDA approval of two different LMWHs, one (enoxaparin) for use in patients undergoing total hip or knee replacement or general surgery and another (dalteparin) for patients undergoing total hip replacement or general surgery.

American [171] and European[172] consensus conferences have provided detailed guidelines for prevention of venous thromboembolism. The concept of prophylaxis has gained wide acceptance. This is, at least in part, because of the medicolegal liability of physicians who omit prophylaxis among their hospitalized patients with risk factors for venous thrombosis.[173] Furthermore, a policy of prophylaxis is cost-effective. It is estimated that for every 1,000,000 patients undergoing operation who receive prophylaxis against DVT and PE, approximately $60,000,000 can be saved in direct health care costs.[174]

MECHANICAL MEASURES

GRADUATED COMPRESSION STOCKINGS.

These provide continuous stimulation of blood flow and prevent dilation of the venous system

Figure 52-18 A 30-year-old man with chronic pulmonary embolism complained of exercise intolerance. His echocardiogram showed mild to moderate right ventricular dysfunction and enlargement. Lung scan, chest CT scan, and pulmonary angiogram showed numerous thrombi. He underwent pulmonary thromboendarterectomy after insertion of a prophylactic inferior vena caval filter. At surgery, a moderate amount of thromboembolic material (*shown above*) was removed from both lungs. His pulmonary artery pressure decreased from a baseline of 35/10 mm Hg to 18/9 mm Hg before the pulmonary artery catheter was removed. He has enjoyed an excellent and uncomplicated recovery. *(Courtesy of Dr. Kim M. Kerr.)*

in the legs. Graduated compression stockings (GCS) exert more compression at the ankles (usually 18 mm Hg) than at the popliteal fossa or upper thigh (usually 8 mm Hg). In an overview of 12 trials in moderate-risk surgery, GCS reduced the DVT rate by two-thirds.[175] Thus, GCS should be considered first-line prophylaxis for most hospitalized patients and should suffice for prophylaxis among low-risk patients.

INTERMITTENT PNEUMATIC COMPRESSION.

Intermittent pneumatic compression (IPC) devices expel blood from the leg veins and thus prevent venous stasis. The mechanical force of compression appears to enhance systemic fibrinolytic activity.[176] IPC is particularly worthwhile among patients who have an absolute contraindication to anticoagulation. In addition, for patients receiving postoperative warfarin prophylaxis, IPC devices have special utility because they are immediately useful, whereas warfarin requires 4 to 5 days of administration before it is entirely effective as an anticoagulant. IPC devices are, in general, used properly in intensive care units. In one survey, however, they were either not applied or applied improperly in the majority of patients after transfer from an intensive care to a regular general surgery unit.[177]

INFERIOR VENA CAVAL INTERRUPTION.

(see p. 1899). The most invasive mechanical prophylaxis measure that can be implemented is IVC filter placement. Use of an IVC filter might be appropriate for patients with recently diagnosed PE or DVT who must undergo major surgery that places them at high risk for suffering perioperative PE. The filter prevents PE but not DVT.[144]

PHARMACOLOGICAL AGENTS

UNFRACTIONATED HEPARIN.

"Minidose heparin" has traditionally been used to prevent perioperative venous thromboembolism. Unfractionated heparin is administered two or three times daily in a dose of 5000 units subcutaneously. The first injection is usually given 2 hours before the skin incision. An overview of 78 randomized controlled trials with 15,598 patients found a 40 percent reduction in nonfatal PE and a 64 percent reduction in fatal PE.[176] In more recent pharmacological prophylaxis trials, at times, prophylaxis has been deferred until the early postoperative period. Any loss of efficacy resulting from deferring prophylaxis until shortly after surgery is unlikely to be marked.[178]

LOW-MOLECULAR-WEIGHT-HEPARIN.

LMWH has a more predictable dose response, more dose-independent mechanisms of clearance, and a longer plasma half-life than unfractionated heparin. LMWHs can achieve higher plasma heparin levels with less bleeding than equivalent doses of unfractionated heparin. Because of its favorable profile (see p. 1896), an increasing number of orthopedic and general surgical patients are receiving once-daily fixed-dose prophylaxis with LMWH rather than injections of minidose unfractionated heparin two or three times daily.

DANAPAROID.

Danaparoid is a heparinoid glycosaminoglycuronan that inhibits factors Xa and IIa (thrombin) in a ratio greater than 20.[178A] The active components are heparan sulfate (
84 percent), dermatan sulfate (
12 percent), and chondroitin sulfate (
4 percent). The average molecular weight is about 5500. The only FDA-approved indication is prophylaxis in patients undergoing total hip replacement (in a dose of 750 units administered subcutaneously twice daily).[179] However, it is often used for "off-label" treatment of heparin-induced thrombocytopenia,[180] even though there is about a 10 to 15 percent rate of cross reactivity between unfractionated heparin and danaparoid. Danaparoid can be administered subcutaneously, unlike the only FDA-approved treatment for heparin-induced thrombocytopenia, lepirudin, which can be administered only intravenously.

ASPIRIN.

Although aspirin provides modest pharmacological prophylaxis against perioperative venous thromboembolism,[143] it is too weak an agent to be considered the standard of care for prevention of PE or DVT.

PROPHYLAXIS STRATEGIES FOR SPECIFIC CONDITIONS

Fortunately, numerous prophylaxis options are available for preventing PE and DVT in most patients (Table 52-14) . The specific prophylaxis modality that is chosen is not nearly as important as upholding a standard that virtually all hospitalized patients receive some preventive measure appropriate to their level of risk.

ORTHOPEDIC SURGERY.

Both adjusted-dose warfarin (target INR 2.0 to 3.0) and fixed-dose LMWH effectively prevent most episodes of venous thromboembolism that occur after total hip replacement,[181] total knee replacement, or hip fracture surgery. In one trial, desirudin appeared even more effective than LMWH in preventing venous thromboembolism after total hip replacement[182] ; however, it is not commercially available.

To determine whether low-dose aspirin could prevent PE in patients with hip fracture, a megatrial of 13,356 patients was undertaken. They were assigned to 160 mg of enteric-coated aspirin once daily or its placebo in a randomized controlled design. At 5 weeks, 81 patients in the placebo group suffered PE (43 fatal and 38 nonfatal), compared with 46 in the aspirin group (18 fatal and 28 nonfatal), for an overall 43 percent risk reduction (p = 0.002) without any increase in major bleeding.[183]

Foot-compression pumps have become popular as a mechanical prophylaxis method, particularly in patients undergoing orthopedic

TABLE 52-14 -- PREVENTION OF VENOUS THROMBOEMBOLISM

INDICATION	POTENTIAL PROPHYLAXIS REGIMEN
Orthopedic surgery	Enoxaparin 30 mg twice daily
	Enoxaparin 40 mg once daily*
	Dalteparin 5000 units once daily*
	Danaparoid 750 units twice daily*
	Warfarin (target INR=2.0-3.0)
	GCS plus IPC
General surgery	Enoxaparin 40 mg daily
	Dalteparin 2500 or 5000 units once daily
	GCS plus IPC
Pregnancy	Enoxaparin 40 mg daily
	Dalteparin 5000 units daily
Medical patients	Enoxaparin 40 mg daily
	GCS plus IPC

GCS=graduated compression stockings; IPC=intermittent pneumatic compression boots; INR=International Normalized Ratio.

*Approved only for total hip replacement prophylaxis.

surgery. However, the effectiveness of these pumps in preventing PE and DVT has not been extensively studied. In one trial of patients receiving foot-pump prophylaxis for total knee replacement, 54 percent had postoperative DVT.[184] Thus, these devices cannot be recommended at this time.

Two important concepts have recently emerged. First, DVT occurs with surprisingly high frequency after knee arthroscopy, affecting 18 percent of patients in one series.[185] Second, patients remain at high risk of venous thromboembolism after hospital discharge following total hip or knee replacement.[186] The median time for diagnosis of venous thromboembolism was 17 days postoperatively for total hip replacement and 7 days postoperatively for total knee replacement in a series of approximately 45,000 patients undergoing surgery in California. The FDA has approved prophylaxis for 3 weeks after hospital discharge with enoxaparin 40 mg once daily for patients undergoing total hip replacement.

CARDIAC SURGERY.

In a trial of 2786 patients undergoing open-heart surgery, prophylaxis was randomized to pneumatic compression devices plus minidose heparin versus minidose heparin alone. The frequency of PE was 1.5 percent in the combined prophylaxis group versus 4 percent in the group given minidose heparin alone.[187]

MEDICAL PATIENTS.

Medical patients have not been nearly as well studied as surgical patients in terms of prevention of venous thromboembolism. In the MEDENOX Trial of 1102 hospitalized medical patients, prophylaxis with enoxaparin 40 mg once daily reduced by two-thirds the frequency of DVT as assessed by bilateral contrast venography between days 6 and 14.

Chapter 53 - Pulmonary Hypertension

STUART RICH

Normal Pulmonary Circulation

During the passage of red blood cells through the lungs, hemoglobin is normally oxygenated to nearly full capacity and the blood is cleansed of much particulate matter and bacteria. The lungs, in addition to functioning as a blood oxygenator and filter, play a dominant role in achieving acid-base balance by excreting carbon dioxide, thereby helping maintain optimal blood pH.[1]

PULMONARY BLOOD FLOW, PRESSURE, AND RESISTANCE

PULMONARY CIRCULATION IN THE NORMAL ADULT.

The lung has a unique double arterial blood supply from the pulmonary and bronchial arteries, as well as double venous drainage into the pulmonary and azygos veins.[2] The right and left pulmonary arteries carry the entire output of the right ventricle and follow a course adjacent to the airways. Inside the lung each pulmonary artery accompanies the appropriate-generation bronchus and divides with it down to the level of the respiratory bronchiole. Additional supernumerary branches originate without relation to bronchial divisions and directly penetrate into the lung parenchyma. The diameter of the arteries decreases more rapidly than that of the airways they accompany, so in the lung periphery the diameters of the arteries are smaller than those of the adjacent airways. Within the respiratory units the pulmonary arteries and arterioles are centrally located and give rise to precapillary arterioles from which a network of capillaries radiate into the alveolar walls. The alveolar capillaries collect at the periphery of the acini and then drain into venules located within the interlobular and interlobar septa.

The pulmonary arteries are classified as elastic or muscular based on the structure of the tunica media. The elastic arteries are conducting vessels, highly distensible at low transmural pressure. As the arteries decrease in size, the number of elastic laminae decreases and smooth muscle increases. Eventually, in vessels between 1000 and 500 mum, elastic tissue is lost from the media and the arteries become muscular. The intima of the pulmonary arteries consists of a single layer of endothelial cells and their basement membrane. The adventitia is composed of dense connective tissue in direct continuity with the peribronchial connective tissue sheath. The muscular arteries are 500 mum in diameter or less and are characterized by a muscular media bounded by internal and external elastic laminae. In normal adults, the lumen is wide and the media is thin and represents less than 10 percent of the arterial cross-sectional area. Arterioles are precapillary arteries smaller than 100 mum in outer diameter and composed solely of a thin intima and single elastic lamina. The alveolar capillaries are lined with a continuous layer of endothelium resting on a continuous basement membrane and focally connected to scattered pericytes located beneath the basement membrane.

The bronchial arteries ramify into a capillary network drained by bronchial veins, some of which empty into the pulmonary veins, whereas the remainder empty into the systemic venous bed. The bronchial circulation therefore constitutes a physiological "right-to-left" shunt. The function of the bronchial circulation is to provide nutrition to the airways. Normally, blood flow through this system is quite low and amounts to approximately 1 percent of the cardiac output[3] ; the resulting desaturation of left atrial blood is usually trivial. However, in some forms of pulmonary disease, e.g., severe bronchiectasis, and in the presence of many congenital cardiovascular malformations that cause cyanosis, blood flow through the bronchial circulation can increase significantly, account for nearly 30 percent of left ventricular output,[4] and produce a significant right-to-left shunt. In pulmonary disease, significant right-to-left shunting through the bronchial circulation may also result in arterial desaturation. In cyanotic congenital heart disease, bronchial blood is not fully oxygenated; it may participate in gas exchange and improve systemic oxygenation.

Normal pulmonary artery pressure in a person living at sea level has a peak systolic value of 18 to 25 mm Hg, an end-diastolic value of 6 to 10 mm Hg, and a mean value ranging from 12 to 16 mm Hg* (see Chap. 11) . Definite pulmonary hypertension is present when pulmonary artery systolic and mean pressures exceed 30 and 20 mm Hg, respectively. Normal mean pulmonary venous pressure is 6 to 10 mm Hg; therefore, the normal arteriovenous pressure difference, which moves the entire cardiac output across the pulmonary vascular bed, ranges from 2 to 10 mm Hg. This small pressure gradient is all the more remarkable when one considers that to move the same amount of blood per minute through the systemic vascular bed, a pressure

*All pressures discussed here are in reference to atmospheric pressure at the level of the heart. True transmural pressures are more physiologically meaningful, especially when pulmonary parenchymal disease is present, but are rarely measured.

Isolated medial hypertrophy

differential of approximately 90 mm Hg (systemic arterial mean pressure minus right atrial mean pressure) is required.

Pulmonary Vascular Resistance.

Thus, the normal pulmonary vascular bed offers less than one-tenth the *resistance* to flow offered by the systemic bed. *Vascular resistance* is generally quantified, by analogy to Ohm's law, as the ratio of pressure drop (DeltaP in millimeters Hg) to mean flow (Q in liters per minute). The ratio is commonly multiplied by 79.9 (or 80 for simplification) to express the results in dynes-seconds centimeters^{-5} . This conversion to metric units may be avoided, i.e., resistance may be expressed in millimeters Hg per liter per minute, which is sometimes referred to as hybrid units, PRU (peripheral resistance units), or Wood units (after the English cardiologist Paul Wood). The calculated pulmonary vascular resistance in normal adults[5] is 67±23 (SD) dyne sec cm^{-5} , or 1 Wood unit.

Vascular resistance reflects a composite of variables that includes, but is not limited to the cross-sectional area of small muscular arteries and arterioles. Other determinants are blood viscosity, the total mass of lung tissue (i.e., resistance is higher in infants and children than in adults), proximal vascular obstruction (e.g., pulmonary coarctation, pulmonary embolism, peripheral pulmonic stenosis), and extramural compression of vessels (perivascular edema).

The reduction in resistance in a distensible vascular bed that occurs with increased flow has been offered as the explanation for the absence of pulmonary hypertension in many patients with large left-to-right intracardiac shunts, particularly atrial septal defects.

REGIONAL PERFUSION.

A large degree of heterogeneity in regional pulmonary perfusion is characteristic of the pulmonary circulation and can be explained by a fractal branching network.[6] The pulmonary vascular tree can be conceptualized as having a fixed structure that is the primary determinant of overall perfusion and a variable component that can be influenced by passive and active regional factors such as recruitment and/or distention from changing driving or hydrostatic pressures. Active factors such as vasomotion and response to shear stress or hypoxic vasoconstriction influence regional perfusion, which is constantly changing.

PULMONARY CIRCULATION WITH EXERCISE.

With moderate exercise, a large increase in pulmonary blood flow is normally accompanied by only a small increase in pulmonary artery pressure. It is important to note that exercise results in an increase in left atrial pressure that is progressive with exercise intensity and accounts for the majority of the increase in pulmonary arterial pressure that is observed.[7] This marked effect of downstream pressure on upstream pressure is unique to the lung circulation inasmuch as systemic arterial pressure during exercise is largely independent of right atrial pressure. Because of the high vascular compliance in the normal lung microcirculation, an increase in left atrial pressure that results from the increased flow will act to distend the small vessels, thereby accounting for the dramatic fall in pulmonary vascular resistance during exercise. Microcirculatory distention increases the surface area for diffusion and slows passage of red cells through the lung, which facilitates oxygen transfer.

FETAL AND NEONATAL CIRCULATION (see alsoChap. 43) .

In the fetus, oxygenated blood enters the heart from the inferior vena cava and streams across the foramen ovale to the left atrium, left ventricle, ascending aorta, and cranial vessels. Desaturated blood returns from the superior vena cava and passes through the tricuspid valve into the right ventricle and pulmonary artery. Because the resistance of the pulmonary vascular bed in the collapsed fetal lung is extremely high, only 10 to 30 percent of the total right ventricular output passes through the lungs, the remainder being shunted across the ductus arteriosus to the descending aorta and then back to the placenta. An abrupt change in the pulmonary circulation occurs at birth. With the first breath, expansion of the lungs and the abrupt rise in P_{O_2} of blood lead to a release of pulmonary arteriolar vasoconstriction and stretching and dilatation of muscular pulmonary arteries and arterioles, with a marked drop in vascular resistance.[8] This decreased resistance facilitates a large increase in pulmonary blood flow and raises left atrial volume and pressure. The latter closes the flap valve of the foramen ovale, and interatrial right-to-left shunting ordinarily ceases within the first hour of life. Normally, the ductus arteriosus closes over the next 10 hours as a result of contraction of the thick smooth muscle bundles within its wall in response to rising arterial oxygen tension and a change in the prostaglandin milieu. Following the initial dramatic fall in pulmonary vascular resistance at birth, a continuous decline occurs over the first few months of life that is associated with thinning of the media of muscular pulmonary arteries and arterioles until the normal adult pattern is achieved[9] (Fig. 53-1) .

AGING AND THE PULMONARY CIRCULATION.

Pulmonary artery pressure and pulmonary vascular resistance increase with advanced age, similar to increases that occur in systemic vascular resistance.[10] [11] [12] Reduced compliance of the pulmonary vascular bed secondary to intimal fibrosis or increased wall thickness in the muscular pulmonary arteries is a possible cause. It is also possible that some of the changes in the pulmonary arteries relate to reduced compliance of left ventricular filling that is passively reflected back on the pulmonary vascular bed.[11] The prevalence of mild pulmonary hypertension (mean pulmonary artery pressure
20 mm Hg) may be as high as 13 percent in persons up to 45 years old and 28 percent in those up to 75 years old.[13]

RESPONSE TO HYPOXIA, DRUGS, AND NEURAL AND ENVIRONMENTAL FACTORS

HYPOXIA.

Acute *hypoxia* elicits pulmonary vasoconstriction[14] as a self-regulatory mechanism for adjusting capillary perfusion to alveolar ventilation. Hypoxia in humans (P_{O_2} 55 mm Hg) is associated with rapid onset of vasoconstriction.[15] Potassium, calcium, and probably chloride channels play important roles in determining pulmonary vascular tone.[16] Ionic control over membrane potential and cytosolic calcium regulates the degree of vasoconstriction and influences proliferation of smooth muscle cells. It seems likely that hypoxia inhibits outward potassium currents, thereby resulting in depolarization of the pulmonary vascular smooth muscle cell membrane, which allows calcium entry into voltage-dependent calcium channels, followed by contraction. Hypoxic pulmonary vasoconstriction is widely variable among healthy people. It also varies markedly with the age of an individual and among different mammalian species. (For further discussion, see Chapter 54.)

NEURAL REGULATION.

The media and adventitia of the large elastic pulmonary arteries and the large pulmonary veins are supplied by nerve fibers that influence the distensibility of these capacitance vessels.[3] Although *neural regulation* of pulmonary vascular resistance can be demonstrated[17] and may be particularly important in fetal life, its importance in a normal human adult is less certain.

Figure 53-1 Changes in pulmonary arteries after birth. Comparison of relative medial thicknesses at birth (*A*), at 2 months of age (*B*), and at 7 months of age (*C*). Elastic-van Gieson stain; magnification × 360; reduced 17 percent. (From Petersen RC, Edwards WD: Pulmonary vascular disease in 57 necropsy cases of total anomalous pulmonary venous connections. Histopathology 7:47, 1983.)

ADRENERGIC RECEPTORS.

The pulmonary vasculature expresses both alpha and beta adrenoreceptors, both of which help regulate pulmonary vascular tone by producing vasoconstriction or vasodilatation, respectively.[18] $Alpha_1$ adrenoreceptors in the pulmonary arteries have increased affinity and responsiveness to their agonists when compared with other vessels.[19] The downstream signaling events in $alpha_1$ -adrenergic stimulation are an increase in ionic calcium levels and activation of protein kinase, which mediate vascular contractile and proliferative responses. The increased sensitivity of $alpha_1$ adrenoreceptors to norepinephrine in the pulmonary arteries may greatly facilitate local regulation of vascular tone in response to acute changes in oxygen concentrations, thereby adjusting regional perfusion. Stimulation of $alpha_1$ adrenoreceptors increases intracellular free calcium levels by at least two mechanisms: (1) coupling to specific G proteins on the cell membrane and (2) blockade of potassium ion channels.[20] [21] Excessive stimulation of $alpha_1$ -adrenergic receptors produces smooth muscle contraction, proliferation, and growth. Factors that produce an increase in $alpha_1$ adrenoreceptor gene synthesis, density, and activity greatly enhance pulmonary artery smooth muscle contractile and proliferative responses. Such factors include norepinephrine, appetite suppressants, and cocaine.[22] [23] It also is plausible that an estrogen-induced increase in the number and affinity of vascular $alpha_1$ adrenoreceptors in women is the explanation for the female preponderance noted in conditions associated with pulmonary hypertension[24] (Fig. 53-2) .

DRUGS.

The alpha-adrenergic blocking agent phentolamine, as well as tolazoline (Priscoline), which also exhibits alpha-adrenergic blocking action, can lower pulmonary vascular resistance. *Beta-adrenergic stimulation* with isoproterenol has been repeatedly shown to cause pulmonary *vasodilatation.* In contrast, beta-adrenergic blockade does not produce any change in pulmonary vascular resistance, which suggests that tonic activation of beta receptors is not necessary for maintenance of the normal low pulmonary vascular resistance. *Acetylcholine* is also a potent relaxant of pulmonary arteries and arterioles and transiently lowers pulmonary vascular resistance in patients with elevated pulmonary vascular resistance with a major reversible component.

PROSTAGLANDINS.

Lung tissue is particularly active in the synthesis, metabolism, and release of a number of *prostaglandins,* some of which may play a role in the regulation of pulmonary vascular resistance. Prostaglandins I_2 (PGI_2) and E (PGE_2) are active pulmonary vasodilators, whereas PGF_2 alpha and PGA_2 are pulmonary vasoconstrictors.[25] Counterregulatory actions have been ascribed to prostacyclin (PGI_2) and thromboxane within the pulmonary circulation. Pulmonary endothelial cells have an abundance of prostacyclin synthase, whereas platelets are replete with thromboxane synthase.[26] [27] Both convert the cyclic endoperoxide precursors PGG_2 and PGH_2 into specific bioactive eicosanoids. Prostacyclin is a powerful vasodilator that also inhibits platelet aggregation through activation of adenylate cyclase. Its metabolic

half-life in the bloodstream is less than one circulation time, with its metabolite 6-keto-prostaglandin F_1 alpha having little biological activity.[28]

A variety of drugs with diverse mechanisms of action are reported to encourage prostacyclin production and include calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, diuretics, and nitrates.[26] Physiologically, prostacyclin is a local hormone rather than a circulating one. Release of prostacyclin by endothelial cells causes relaxation of the underlying vascular smooth muscle and prevents platelet aggregation within the bloodstream. Thromboxane is synthesized in platelets and macrophages.[27] It also has a short half-life. Thromboxane is a potent agonist for platelet aggregation and vasoconstriction, and it may function as a growth factor for smooth muscles by acting via protein kinase C-linked pathways.[29] Because the biological actions of prostacyclin are the opposite those of thromboxane,

Figure 53-2 Signaling pathways of alpha$_1$ -adrenergic receptors in smooth muscle cells that lead to pulmonary hypertension. Alpha$_1$ -adrenergic receptors activate phospholipase C to produce inositol 1,4,5-triphosphate (IP_3), which mobilizes calcium from intracellular stores. Activation of protein kinase C also activates transcription factors such as mitogen-activated protein kinase (MAP kinase) and nuclear factor kappa-B (NFkappaB), which induce DNA synthesis and cell proliferation. By increasing levels of oncoprotein (Bcl-2) to inhibit apoptosis, the survival of vascular smooth muscle cells is promoted. Alpha$_1$ -adrenergic receptors also couple to K^+ channels, which leads to entry of calcium from extracellular sources through voltage-sensitive channels. An increase in intracellular calcium is the major signal transduction mechanism responsible for producing smooth muscle contraction via the calcium calmodulin pathway, and protein kinase C activation is the major signal transduction pathway involved in the proliferation of pulmonary vascular smooth muscle cells. (From Salvi SS: alpha-1 Adrenergic hypothesis for pulmonary hypertension. Chest 115:1708-1719, 1999.)

Figure 53-3 Generation of prostacyclin (PGI_2), endothelial-derived relaxing factor-nitric oxide (EDRF-NO), and endothelin-1 (ET-1) in endothelial cells. Stimulation of receptors on the cells by serotonin (5HT [5-hydroxytryptomine]) or adenosine diphosphate (ADP) released from platelets or by thrombin, bradykinin, or shear stress leads to the release of vasoactive mediators. PGI_2 relaxes vascular smooth muscle and inhibits aggregation of platelets by increasing levels of cyclic adenosine monophosphate (cAMP). EDRF-NO relaxes vascular smooth muscle and inhibits platelet aggregation and adhesion by increasing levels of cyclic guanosine monophosphate (cGMP). The simultaneous increase in cAMP and cGMP inhibits platelet aggregation. (From Vane JR, Anggard EE, Bolting RM: Regulatory functions of the vascular endothelium. N Engl J Med 323:27, 1990. Copyright © 1990 Massachusetts Medical Society. All rights reserved.)

the balance between these two peptides appears to control the local environment within the vascular bed.

NITRIC OXIDE.

The biological action of nitric oxide (NO) is quite similar to that of prostacyclin in that it relaxes vascular smooth muscle. It differs, however, in that its effects are mediated by changing levels of cyclic guanosine monophosphate (GMP).[30] Endothelial NO synthase is found in the vascular endothelium of the normal pulmonary vasculature, where it is responsible for generating NO to govern vascular tone. Release of NO occurs in response to a multitude of physiological stimuli, which include thrombin, bradykinin, and shear stress.[31] Besides its direct hemodynamic effects, NO inhibits platelet activation and confers an important antithrombotic property on the endothelial surface. NO also inhibits the growth of vascular smooth muscle cells and is probably involved in vascular remodeling in response to injury.[30] NO is also important in the signal transduction of angiogenesis inasmuch as vascular endothelial growth factor receptor activation results in increased NO production[32] (Fig. 53-3) .

OTHER VASOACTIVE SUBSTANCES.

Endothelin is a potent vasoconstrictor peptide that also plays an important role in the regulation of pulmonary vascular tone. Because of its long half-life, subtle disturbances in production or release can lead to sustained vasoconstriction.[33] Several studies have demonstrated an interaction between NO and endothelin-1 (ET-1) in the vascular endothelium.[34] Expression of endothelin is inversely related to that of NO synthase, thus suggesting an opposite regulatory pathway for these two factors. Two types of ET-1 receptor are known: ET_A is expressed mainly on smooth muscle cells and ET_B is expressed on endothelial cells. [34] The former mediates vasoconstriction, while the latter mediates vasorelaxation through release of nitric oxide (Fig. 53-4) .

Serotonin is an important constituent of platelet dense granules and is released upon activation.[35] Normal endothelial cells respond to serotonin by enhancing the release of NO, thereby leading to vascular smooth muscle relaxation and vasodilatation. In the setting of endothelial dysfunction, serotonin is unable to stimulate NO release and increases vascular smooth muscle tone, thereby leading to vasoconstriction.[36] In addition, serotonin can act as a growth factor and contribute to medial hypertrophy and promote vascular remodeling.[37]

Angiotensin II is generated in the lung by means of enzymatic conversion of angiotensin I, a potent pulmonary vasoconstrictor. Angiotensin II stimulates cell proliferation, extracellular matrix proteins synthesis, and smooth muscle cell migration. Elevated plasma renin and angiotensin II levels have been found during acute hypoxia and hypercapnia in CO_2 -retaining patients with chronic obstructive lung disease.[38]

Figure 53-4 Regulation of the effects of endothelin (ET). ET may be active in the final stage of transduction of a number of pulmonary smooth muscle contractile and mitogenic factors. Nitric oxide (NO) and prostacyclin (PGI_2), together with atrial natriuretic peptide (ANP), inhibit expression of ET-1. ET_A receptors are involved in contraction and in mitogenic effects on smooth muscle cells and fibroblasts. The small resistance arteries in humans appear to have contraction-inducing ET_B receptors as well. TGF-beta-transforming growth factor-beta. Primary Pulmonary Hypertension

Primary pulmonary hypertension (PPH) is the diagnosis given to patients with pulmonary hypertension of unexplained etiology. Although the name of the disease stems from its distinction from pulmonary hypertension secondary to known cardiac or pulmonary causes, PPH should not be considered as only pulmonary hypertension for which no cause is found. The clinical features, usual age of onset, progression of the disease, and autopsy findings make PPH a distinct clinical entity and distinguish it from many forms of secondary pulmonary hypertension even though its diagnosis requires careful exclusion of secondary causes.[39] The actual incidence of PPH appears to be approximately two cases per million population, thus qualifying it as an orphan disease.[40] [40A]

ETIOLOGY

The precise cause of PPH is unknown, but it probably represents the clinical expression of pulmonary arterial hypertension as the final common pathway from multiple biological abnormalities within the pulmonary circulation. As understanding of vascular biology is improving, many studies point to abnormalities in pulmonary endothelial cell function as causing or contributing to the development of pulmonary hypertension in humans.[41] It is now understood that the endothelial cell regulates pulmonary smooth muscle cell tone.[26] It should be pointed out that even though endothelial cells may appear normal histologically, they may be quite abnormal with respect to function. Dysfunction of the counterregulatory systems within the pulmonary vascular bed seems to be common in pulmonary hypertension. The normal pulmonary vascular endothelial cell maintains the vascular smooth muscle in a state of relaxation.[26] The finding of increased pulmonary vascular reactivity and vasoconstriction in patients with PPH suggests that a marked vasoconstrictive tendency underlies the development of PPH in predisposed individuals,[42] possibly as a result of loss of endothelial cell integrity.[41] The autonomic nervous system has been considered a contributory factor in the development of PPH through stimulation of the pulmonary vascular bed by either neuronally released or circulating catecholamines. In some patients with PPH, the response to vasodilators such as tolazoline, acetylcholine, or isoproterenol is a reduction in pulmonary artery pressure and pulmonary vascular resistance,[43] which supports the notion that the autonomic nervous system is at least in part maintaining a role in constant elevation of pulmonary vascular resistance.

Reduced expression of NO synthase in the endothelium of patients with pulmonary hypertension has been demonstrated and correlates inversely with the extent and severity of morphological lesions.[45] Although it is unsettled whether reduced NO synthase production is a cause or result of the disease, it is consistent with endothelial dysfunction underlying PPH as part of the disease process. Studies of vasodilators in pulmonary hypertension demonstrate that responsiveness to endothelium-dependent vasodilating agents is impaired before response to endothelium-independent vasodilators.[44] [46] This impaired responsiveness may reflect the underlying severity of vascular damage. Conversely, endothelin, a potent vasoconstrictor peptide, may also play an important role in the regulation of pulmonary vascular tone.[34] Its secretion may be enhanced in the presence of vasoconstriction or in the setting of platelet aggregation. Because it has a long half-life, subtle disturbances in production or release could lead to sustained vasoconstriction. ET_A receptor antagonists have been reported to reduce pulmonary artery pressure in experimental animals.[47] Given that the major resistance vessels in the pulmonary vascular bed are at the arteriolar level, diffuse arteriolar vasoconstriction could easily cause chronically sustained elevations in pulmonary vascular resistance and result in pulmonary hypertension. Elevations in endothelin levels within the pulmonary vasculature of patients with primary and secondary forms of pulmonary hypertension have been documented. [48] This finding would suggest that regardless of whether abnormal endothelial function is the underlying cause of PPH, progression of the disease is invariably accompanied by worsening of endothelial function, which itself can promote disease progression.

A striking feature of the pulmonary vasculature in patients with PPH is intimal proliferation, and in some vessels it causes virtually complete vascular occlusion[49] [50] (Fig. 53-5) . Several growth factors have been implicated in the development of this type of vascular pathology, including basic fibroblast growth factor from the endothelium[51] and platelet-derived growth factor[52] and transforming growth factor-beta [53] from platelets. Enhanced growth factor release, activation, and intracellular signaling may lead to smooth muscle cell proliferation and migration, as well as extracellular matrix synthesis. Even advanced lesions show evidence of in situ activity of ongoing synthesis of connective tissue proteins such as elastin, collagen, and fibronectin.[54] [55]

An equally important etiologic feature of PPH is the widespread development of in situ thrombosis of the small pulmonary arteries with resultant vascular obstruction.[49] [50] [56] [57] [57A] Although it was once believed that recurrent, systemic venous microembolism could be an underlying mechanism in PPH, this theory has been essentially rejected for lack of both animal and human data to support it as a clinical entity. Animal studies suggest that more than 22 million thromboemboli in the pulmonary arterioles would be required to raise the mean pulmonary artery pressure 5 mm Hg, yet no source of these emboli has ever been found in patients dying of PPH.[56] Various defects in coagulation; including abnormal platelet function and defective fibrinolysis, have been demonstrated in patients with PPH.[57] [58] In situ thrombosis of the pulmonary vascular bed has been proposed as a causative or contributing feature of pulmonary hypertension.[56] [59] Abnormalities in platelet activation and function and biochemical features of a procoagulant environment within the pulmonary vasculature support a role of thrombosis in disease initiation in some patients.[57] [58] [60] [61] Interactions between growth factors, platelets, and the vessel wall suggest that thrombosis may play a fundamental role in many of the pathobiological processes described in PPH and in disease progression.[62] A prothrombotic state can arise as a consequence of fibrinolysis, enhanced coagulation, or increased platelet activation. Platelet activation not only promotes thrombosis but also leads to the release of granules that contain mitogenic agents and vasoconstrictive substances.[63]

Several studies suggest that local hemodynamics can influence pulmonary vascular remodeling.[64] A classic example is the pulmonary hypertension that occurs in congenital systemic-to-pulmonary shunts. It is believed that endothelial cells can release mediators that induce vascular smooth muscle cell growth in response to changes in pulmonary blood flow or pressure. Experimental data suggest that medial hypertrophy can be converted to a neointimal pattern when pulmonary vascular injury is coupled with increased pulmonary blood flow.[65] These neointimal lesions are composed of smooth muscle cells that are immunoreactive to anti-alpha smooth muscle actin antibody. It is now accepted that hemodynamic shear stress acts through the endothelium to regulate vessel tone and in the chronic restructuring of blood vessels.[64] Endothelial denudation also results in platelet adherence to exposed tissue collagen, with release of platelet-derived smooth muscle mitogens that also have vasoconstrictor properties. This process in turn leads to an inflammatory response and thrombosis, thereby narrowing the lumen of pulmonary vessels. In a person who is susceptible--whether on a genetic or an acquired basis--intense vasoconstriction may lead to fibrinoid necrosis of the arteriolar wall and the development of plexiform lesions. Ultimately, the vessels are reduced in number, and the residua of these destroyed vessels can be seen histologically as "ghost vessels." Destruction of large numbers of pulmonary arterioles reduces the cross-sectional

Figure 53-5 Photomicrographs of pulmonary arterial histological lesions seen in clinically unexplained pulmonary hypertension. All slides were stained with Verhoeff-van Gieson stain. *A,* Medial hypertrophy (×100). *B,* Concentric laminal intimal fibrosis--seen most often in association with plexiform lesions (×200). *C,* Plexiform lesion demonstrating obstruction in the arterial lumen, aneurysmal dilatation, and proliferation of anastomosing vascular channels (×200). *D,* Eccentric intimal fibrosis--often seen in association with organized microthrombi but also present in many patients with plexiform lesions (×100). (From Palevsky HI, Schloo BL, Pietria CC, et al: Primary pulmonary hypertension. Vascular structure, morphometry and responsiveness to vasodilator agents. Circulation 80:1207, 1989.)

area of the pulmonary vascular bed, thereby producing a permanent increase in pulmonary vascular resistance and fixed pulmonary hypertension. The latter in turn damages other blood vessels and initiates a vicious circle, with progressively rising pulmonary arterial pressure (Fig. 53-6) (Figure Not Available) .

Vascular remodeling is becoming recognized as an important component in the pathogenesis of pulmonary hypertension.[64] An essential role of ACE in the pathogenesis of pulmonary hypertension is strongly suggested by the presence of increased ACE immunoreactivity at sites of increased matrix gene expression in human hypertensive pulmonary arteries.[66] Further supporting a role for ACE in pulmonary vascular remodeling are observations that ACE protein and mRNA expression are focally increased in rat pulmonary arteries with medial hypertrophy from chronic hypoxia.[67]
Processed, ng, 5/2/00

Increased activity of elastolytic enzymes appears to be important in the pathophysiology of pulmonary vascular disease.[68] High elastin turnover and neosynthesis of elastin have been attributed to degradation of elastin from the increased activity of serine elastase. A cause-and-effect relationship between elastase and pulmonary vascular disease was demonstrated when elastase inhibitors were shown to be effective in attenuating the development and retarding the progression of pulmonary hypertension in monocrotaline-injected and hypoxic rats.[69] Progression of pulmonary hypertension may involve a series of switches in smooth muscle cell phenotype and proliferation to account for the medial hypertrophy and smooth muscle cell migration resulting in neointimal formation. Structural and functional alterations in the endothelial cell could result in loss of barrier function and allow leakage into the subendothelium of a serum factor normally excluded from this region. Enzymes released from precursor or mature smooth muscle cells could activate growth factors normally stored in the extracellular matrix, such as basic fibroblast growth factor and transforming growth factor-beta, which are known to induce smooth muscle cell hypertrophy and proliferation and increase connective tissue protein synthesis. In muscular arteries, release of growth factors would result in hypertrophy of the vessel wall[69] (Fig. 53-7) .

Potassium channels are found throughout the pulmonary vascular bed.[35] They consist of voltage-dependent potassium channels and calcium-dependent potassium channels (see also Chap. 22) . The role of these channels has been studied primarily in the presence of acute hypoxia in animals. It is believed that potassium channels modulate adult pulmonary vascular tone. It is probable that calcium channels also serve a regulatory role in modulating vascular tone, particularly the L-type calcium channel. Inhibition of the voltage-regulated potassium channel by hypoxia or drugs can produce vasoconstriction and has been described in pulmonary artery smooth muscle cells harvested from patients with PPH.[70] It has been suggested that defects in the potassium channel of pulmonary resistance smooth muscle cells are involved in the initiation or progression of pulmonary hypertension. A genetic defect related to potassium channels in the lungs of patients with PPH that leads to vasoconstriction may be one mechanism for the development of PPH in some patients[70] (Fig. 53-8) .

The dysfunctional pulmonary hypertensive endothelial cell phenotype is characterized by uncontrolled proliferation, increased production of vasoconstrictor mediators such as endothelin, expression of 5-lipoxygenase, and decreased synthesis of prostacyclin. In normal lungs, larger proximal pulmonary arteries express more prostacyclin synthase than do smaller arteries.[71] In patients with PPH, expression of prostacyclin synthase is reduced in pulmonary arteries ranging from 1 mm to less than 100 mum in diameter, which suggests that the reduction in prostacyclin synthesis in otherwise morphologically normal to minimally remodeled vessels may play a role in the early stages of pathogenesis. Alternatively, endothelial cells of pulmonary small arteries may become dysfunctional as the disease progresses and pulmonary artery pressure progressively rises. The decrease in prostacyclin production by pulmonary endothelial cells could predispose the lung vessels to additional vasoconstriction and/or in situ thrombosis from enhanced platelet adhesion. Loss of expression of prostacyclin synthase is one of the phenotypic alterations present in pulmonary endothelial cells in severe pulmonary hypertension.[71]

Serotonin may play a role in pulmonary hypertension. Elevations in serotonin levels have been correlated with the pulmonary vascular pressure gradient in patients with acute respiratory distress syndrome.[72] Children with congenital heart disease and pulmonary hypertension have increased turnover of serotonin.[73] PPH has been reported in a patient with familial platelet storage pool disease, which represents a defect in serotonin handling and release.[74]

One series reported increased serotonin in patients with pulmonary hypertension associated with the use of fenfluramine and with collagen-vascular disease.[75] Of interest is that after six of these patients underwent heart/lung transplantation, they had persistently elevated concentrations of plasma serotonin and decreased platelet serotonin concentrations, thus suggesting that the abnormality in platelet serotonin handling was a primary process in the evolution of their pulmonary hypertension.

Genetics

An important emerging concept in the development of PPH is that the disease develops in patients with an underlying genetic predisposition following exposure to specific stimuli, which serve as triggers. Predisposition to the development of pulmonary hypertension has been noted by the marked heterogeneity in responses of the pulmonary vasculature

Figure 53-6 (Figure Not Available) Possible pathogenesis of primary pulmonary hypertension (PPH). Endothelial injury or dysfunction sets off a cascade of cellular events that lead to the abnormal pulmonary vascular response seen in PPH and subsequently to a perpetuating vicious circle promoting plexogenic and thrombotic pulmonary arteriopathy. (From Rubin L J: ACCP Consensus Statement: Primary pulmonary hypertension. Chest 104:236, 1993.)

Figure 53-7 Schema of the pathophysiology of pulmonary hypertension related to elastase activity. Alterations in the endothelium that result in loss of its barrier function may allow leakage of a serum factor that stimulates smooth muscle cell (SMC) production and release of endogenous vascular elastase (EVE). EVE will degrade elastin and proteoglycans, which serve as storage sites for growth factors such as transforming growth factor-beta (TGFbeta) and basic fibroblast growth factor (bFGF). Subsequent stimulation of production of the matrix glycoprotein tenascin leads to an increase in SMC hypertrophy and the synthesis of connective tissue (CT) proteins. The elastin peptides also stimulate production of the matrix glycoprotein fibronectin, which changes SMC from a contractile to a migratory phenotype. (From Rabinovitch M: Pulmonary hypertension: Updating a mysterious disease. Caradiovasc Res 34:268-272, 1997. Copyright 1997, with permission from Elsevier Science.)

Figure 53-8 One proposed cellular mechanism responsible for the development of primary pulmonary hypertension initiated by abnormal gene transcription and expression of voltage-regulated potassium (K_v) channels. Increased calcium influx would raise cytosolic calcium ($[Ca^{2+}]_{cyt}$) and serve to trigger pulmonary vasoconstriction and stimulate cell proliferation with subsequent pulmonary vascular remodeling. Endothelium-derived relaxing factors (EDRFs) also participate in regulating potassium and calcium channels in pulmonary artery smooth muscle cells (PASMCs). (From Yuan JX, Aldinger AM, Juhaszova M, et al: Dysfunctional voltage-gated K^+ channels in pulmonary artery smooth muscle cells of patients with primary pulmonary hypertension. Circulation 98:1400-1406, 1998.)

in a variety of disease states. Examples include the considerable variability among individuals to vasoconstrictive stimuli such as hypoxia or acidosis, which can produce marked pulmonary hypertension in one person and be essentially without effect in another. The pulmonary arterial pressure response to hypoxia is particularly great in individuals with blood group A.[14] This variability in responsiveness of the pulmonary vascular bed undoubtedly accounts for the fact that pulmonary edema develops in only a minority of individuals on exposure to high altitude. Also, the severity of pulmonary hypertension and the level of pulmonary vascular resistance vary considerably among individuals with congenital heart disease and comparably sized ventricular septal defects. Presumably, a genetic basis underlies these differences in pulmonary vascular reactivity, just as there appears to be a genetic basis for the increased reactivity of the systemic vascular bed in essential systemic hypertension.

FAMILIAL PPH.

PPH has been diagnosed in families worldwide. The prevalence of familial PPH is uncertain, but it occurs in at least 6 percent of cases and the incidence is probably higher.[76] Many unique features are associated with the transmission and development of PPH in families.[77] The age of onset is variable and penetrance is incomplete. Many individuals in families with PPH inherit the gene and have progeny in whom PPH never develops. The observation that fewer males are born in PPH families than in the population at large suggests that the PPH gene might influence fertilization or cause male fetal wastage.

Patients with familial PPH have a similar female-to-male ratio, age of onset, and natural history of the disease as those with sporadic PPH. Documentation of familial PPH can be difficult since remote common ancestry occurs in patients with apparently sporadic PPH and skip generations caused either by incomplete penetrance or by variable expression can mimic sporadic disease. Because the clinical and pathological features of familial and sporadic PPH are virtually identical, it seems likely that the same genes may be involved in both forms of the disease. It also seems likely that the disease will not be due to an abnormal gene product resulting from a mutation but rather due to abnormal production or regulation of a normal gene product.

Vertical transmission has been demonstrated in as many as five generations in one family and is probably indicative of a single dominant gene that is believed to be autosomal for PPH.[78] Genetic anticipation has been described in familial PPH since the early reports. Trinucleotide repeat expansion, originally described in several

neurological disorders, remains the only known biological explanation for genetic anticipation in PPH and raises the possibility that the pathogenesis of familial PPH might have a neurological basis (Fig. 53-9) .

The locus of a gene linked to familial PPH has been identified on chromosome 2q31,-33,[78A] and analysis of the genome containing the gene has been reduced to less than 7 million base pairs.[79] PPH-1 is the Human Genome Organization-approved designation DGB:1381541. The low penetrance of this gene confers only about a 10 to 20 percent likelihood of development of the disease.

Risk Factors in the Development of PPH

Although pulmonary hypertension can be the clear result of a disease process affecting the pulmonary parenchyma or vessels directly, a number of conditions have been identified that appear to be associated with the development of primary or unexplained pulmonary hypertension. Risk factors for PPH include drugs, chemical products, and other diseases. Expression of PPH may depend on other clinical features, such as the patient's gender or age at the time of disease expression.[80] The clinical features of PPH in patients with known risk factors are generally determined by the severity of the PPH and whatever influence the risk factor has on the overall medical condition. For example, the association of PPH and cirrhosis would have the combined clinical features of PPH and liver disease.

PORTAL HYPERTENSION

Pulmonary abnormalities have been commonly associated with the development of hepatic cirrhosis and portal hypertension[81] and include hypoxemia and intrapulmonary shunting, portal-pulmonary shunting, impaired hypoxic pulmonary vasoconstriction, and pulmonary hypertension.[82] [83] [84] Studies show that the liver plays an important role in regulating pulmonary vascular tone. Although the relative risk associated with the development of pulmonary hypertension in patients with portal hypertension is unknown, a large postmortem study from the Johns Hopkins Hospital showed that the prevalence of unexplained or pulmonary hypertension in patients with cirrhosis was 5.6 times higher than that of PPH alone. A modest increase in pulmonary artery pressure is not unusual in patients with cirrhosis and portal hypertension.[83] The increase in pulmonary artery pressure is usually passive and relates to the increase in cardiac output and/or blood volume and is associated with near-normal pulmonary vascular resistance. Published studies indicate a strong association between portal hypertension and pulmonary hypertension regardless of

Figure 53-9 The pedigrees of two families (*A* and *B*) with familial primary pulmonary hypertension (PPH). Shaded symbols represent affected individuals. Genotyped individuals are indicated by the respective pedigree designations. The PPH-1 region on chromosome 2 (2q31-q32) contains a number of candidate genes. (From Morse JH, Jones AC, Barst RJ, et al: Mapping of familial primary pulmonary hypertension locus (PPH-1) to chromosome 2q31-32. Circulation 95:2603-2606, 1997.)

whether liver disease is present.[84] [85] [86] Although the mechanisms are uncertain, several possibilities are consistent. Portal hypertension itself induces numerous modifications in the vascular medium that may trigger a cascade of intracellular signals and/or cause activation or repression of various genes in endothelial and smooth muscle cells.

Pulmonary hypertension may develop in susceptible patients with portal hypertension in response to an increase in vascular wall shear stress caused simply by the increased pulmonary blood flow through the lungs. The presence of a portosystemic shunt may also allow substances normally cleared by the liver to gain access to the pulmonary circulation. Increased levels of several vasoactive mediators, cytokines, and growth factors have been demonstrated in patients with portal hypertension, including serotonin and interleukin-1.[86] Other angiogenic factors such as hepatocyte growth factor or vascular endothelial growth factor may be involved in pulmonary artery remodeling.[87] [88]

Patients in whom PPH develops in association with cirrhosis appear to be similar to patients without cirrhosis with the sole exception that they tend to have higher cardiac output and consequently lower calculated systemic and pulmonary vascular resistance, which is characteristic of the cirrhotic state.[83] Treatment of portal pulmonary hypertension generally follows the guidelines developed for treating patients with PPH. Although severe pulmonary hypertension is considered a contraindication to liver transplantation because of the risk of irreversible right-sided heart failure, successful liver transplantation has been reported in patients with mild pulmonary hypertension.[89] [90] Whether the pulmonary circulation will eventually return to normal posttransplantation remains uncertain.

ANOREXIGENS

Several anorexigens have been demonstrated to cause pulmonary hypertension in humans. The first observation was made in 1967, when an epidemic of PPH was associated with the use of aminorex in Europe coincident with its introduction in the general population.[91] The mechanism by which aminorex causes pulmonary hypertension remains uncertain, but it has similarities to both adrenaline and ephedrine in its chemical structure. The clinical features of pulmonary hypertension were identical to those attributed to PPH.

In 1981 a cause-and-effect relationship between the ingestion of fenfluramine, another appetite suppressant, and the development of pulmonary hypertension was established in a patient in whom PPH developed but reversed upon drug withdrawal and then redeveloped upon rechallenge.[92] The magnitude of the association between the use of appetite suppressants and the development of PPH was clearly defined in the International Primary Pulmonary Hypertension Study (IPPHS), a case-control study conducted in Europe in 1992-1994.[40] In addition to the association between the use of appetite suppressants and the development of pulmonary hypertension, the IPPHS described a dramatic increase in the risk of development of pulmonary hypertension with increased duration of use. The study resulted in severe restriction of the use of appetite suppressants in Europe, only to see their use popularized in the United States. Ultimately, the marked increase in the number of cases of PPH and cardiac valvulopathy ascribed to the use of fenfluramine drugs in the United States led to their withdrawal in 1997. Unfortunately, in the majority of patients the development of pulmonary hypertension has been progressive despite withdrawal of the appetite suppressants.[93] [94] [94A] Although the drugs mainly identified in the IPPHS were the fenfluramines, amphetamine-like anorexigens were also implicated.

The mechanism by which the fenfluramines and aminorex produce pulmonary hypertension has been investigated. Experimental studies have demonstrated that these drugs can cause pulmonary vasoconstriction by inhibiting voltage-gated potassium channels in the smooth muscle cells of resistance-level pulmonary arteries.[95] Although the degree of pulmonary vasoconstriction noted was small, it increased dramatically when NO synthase was inhibited. One recent study compared NO production in patients with PPH and patients with pulmonary hypertension associated with the use of anorexigens.[96] It appears that the latter group had a deficiency in basal NO production when compared with patients with PPH, which suggests that NO may be a compensatory product of the pulmonary arterial endothelium that increases in pulmonary hypertension to counteract the effects of chronic vasoconstriction.

Because of the consistent association with anorexigens and unexplained pulmonary hypertension, clinicians should be exceedingly careful in the use of these drugs in the future, especially in patients who may have increased susceptibility to the development of pulmonary hypertension (Fig. 53-10) .

HIV INFECTION

Although well documented, it remains unclear how human immunodeficiency virus (HIV) infection results in an increased incidence of PPH in HIV-infected patients.[97] [98] A direct pathogenic role of HIV seems unlikely inasmuch as no viral constituents have been detected in the vascular endothelium of these patients.[99] On the other hand, reports of pulmonary arteriopathy with intimal proliferation in monkeys experimentally infected with the simian immunodeficiency virus and in a murine model of acquired immunodeficiency syndrome suggest a pathogenetic link between infection with an immunodeficiency virus and the development of PPH, possibility mediated by release of inflammatory mediators or by autoimmune mechanisms.[100] A large case-control study of HIV-associated PPH was recently conducted in the Swiss HIV Cohort Study.[101] The cumulative incidence was 0.6 percent within the entire HIV-infected population. PPH was diagnosed in all stages of HIV infection and without an obvious relationship to immune deficiency. The clinical and hemodynamic features of these patients were similar to those of patients with PPH. Of great interest, however, is that antiretroviral treatment seemed to exert a beneficial effect on the course of hemodynamic progression of the disease.

SYSTEMIC HYPERTENSION

Systemic hypertension is two to three times more common in patients with PPH than in an age-matched population.[40] The underlying mechanisms related to the development of essential hypertension are quite diverse, but the possibility exists that in some patients the mechanism that increases systemic vascular resistance

similarly affects the pulmonary vascular bed.[102] It has been suggested that neurohumoral factors may play a role[103] or that the pulmonary vasculature is hypercontractile and overreacts to sympathetic stimulation.[104] Given that essential hypertension is extremely common in the general population, other confounding factors probably contribute to the development of pulmonary hypertension in affected individuals.

INCREASED PULMONARY BLOOD FLOW

For many years it has been observed that PPH can develop in adulthood in patients with atrial septal defect.[105] However, the incidence of this combination is extremely low, thus raising the possibility that they are two completely unrelated events. It is possible that chronically increased pulmonary blood flow may have effects on pulmonary endothelium through some type of mechanical means that would cause perturbations in the integrity of the vascular wall and lead to the development of pulmonary vascular disease. Increased pulmonary blood flow from hyperthyroidism and beriberi have been reported to be associated with the development of unexplained pulmonary hypertension, which suggests that high pulmonary blood flow,[106] rather than mere coincidence, is the basis for the development of pulmonary

Figure 53-10 Relationship between duration of exposure to anorectic drugs and the development of primary pulmonary hypertension (PPH). The odds ratio of PPH developing increases with increased duration of use. The number of controls taking anorectic drugs in whom PPH does not develop diminishes over time, which raises the possibility that a marked increase in duration of exposure could eventually convert all the controls into cases. (From Abenhaim L, Moride Y, Brenot F, et al: Appetite suppressant drugs and the risk of primary pulmonary hypertension. N Engl J Med 335:609-616, 1996. Copyright © 1996 Massachusetts Medical Society. All rights reserved.)

hypertension in patients with pretricuspid shunts such as atrial septal defect or anomalous pulmonary venous drainage.

PATHOLOGICAL FINDINGS

Morphological abnormalities in each cell line have been described in PPH.[3] [49] [50] The endothelium in particular displays marked heterogeneity in the pulmonary vascular bed. Although endothelial dysfunction has been clearly described in PPH, discordance between phenotype and function is commonly noted.[107] It is not known at what stage during the evolution of PPH that endothelial cell proliferation occurs. It has been proposed, however, that a somatic mutation rather than nonselective cell proliferation in response to injury may account for the growth advantage of endothelial cells in PPH.[108] Heterogeneity in the smooth muscle and fibroblast populations also contributes to discordance between phenotype and function. Interconversion between cell types (fibroblast to smooth muscle cell or endothelium to smooth muscle cell) in addition to neovascularization may occur.

In the large muscular and elastic arteries, smooth muscle cell hypertrophy and increased connective tissue and extracellular matrix are found.[68] [69] In the subendothelial layer, increased thickness may be the result of recruitment and/or proliferation of smooth muscle-like cells. It is possible that precursor smooth muscle cells are in a continuous layer in the subendothelial layer along the entire pulmonary artery. These cells are similar to the pericytes that are responsible for the appearance of muscle in normally nonmuscular arteries and that contribute to intimal thickening in larger arteries. Alterations in the extracellular matrix secondary to proteolytic enzymes also play a role in the pathology of

TABLE 53-1 -- HISTOPATHOLOGICAL CLASSIFICATION OF HYPERTENSIVE PULMONARY VASCULAR DISEASE

CLASSIFICATION	CHARACTERISTIC HISTOPATHOLOGICAL FEATURES
Arteriopathy	
Isolated medial hypertrophy*	Medial hypertrophy: increase of medial muscle in muscular arteries, muscularization of nonmuscularized arterioles; no appreciable intimal or luminal obstructive lesions. No plexiform lesions
Plexogenic pulmonary arteriopathy	Plexiform and dilatation lesions. Medial hypertrophy; eccentric or concentric-laminar and nonlaminar intimal thickening; fibrinoid necrosis, arteritis, and thrombotic lesions
Thrombotic pulmonary arteriopathy	Thrombi (fresh, organizing, or organized and colander lesions). Eccentric and concentric nonlaminar intimal thickening, varying degrees of medial hypertrophy. No plexiform lesions
Isolated pulmonary arteritis	Active or healed arteritis. Limited to pulmonary arteries; varying degrees of medial hypertrophy, intimal fibrosis, and thrombotic lesions. No plexiform lesions. No systemic arteritis
Venopathy	
Pulmonary venoocclusive disease	Eccentric intimal fibrosis and recanalized thrombi within pulmonary veins and venules; arterialized veins, capillary congestion, alveolar edema and siderophages, dilated lymphatics, pleural and septal edema, and arterial medial hypertrophy; intimal thickening and thrombotic lesions
Microangiopathy	
Pulmonary capillary hemangiomatosis	Infiltrating thin-walled blood vessels throughout pulmonary parenchyma, pleura, bronchi, and walls of pulmonary veins and arteries. Medial hypertrophy and intimal thickening of muscular pulmonary arteries and arterioles

*Medial hypertrophy includes muscularization of arterioles.

PPH. Matrix-degrading enzymes can release mitogenically active growth factors that stimulate smooth muscle cell proliferation. In addition, elastase and matrix metalloproteinases contribute to upregulation of proliferation. Degradation of elastin has also been shown to stimulate upregulation of the glycoprotein fibronectin, which in turn stimulates smooth muscle cell migration.[68]

The most common vascular changes in PPH can best be characterized as a *hypertensive pulmonary arteriopathy,* which is present in 85 percent of cases (Table 53-1) . These changes involve medial hypertrophy of the arteries and arterioles, often in conjunction with other vascular changes. Isolated medial hypertrophy is uncommon, and when present it has been assumed to represent an early stage of the disease. Plexogenic pulmonary arteriopathy is the most common pattern of hypertensive arteriopathy seen in patients with PPH.[3] [50] It is characterized by medial hypertrophy along with intimal proliferation and other complex lesions. The intimal proliferation may be concentric laminar intimal fibrosis, eccentric intimal fibrosis, or concentric nonlaminar intimal fibrosis. The frequency of these findings differs from case to case and within regions of the same lung in the same patient. In addition, plexiform and dilatation lesions, as well as a necrotizing arteritis, may be seen throughout the lungs. The fundamental nature of the plexiform lesion remains a mystery.[109] It is possible that it represents endothelial cells that are involved prominently in angiogenesis, perhaps akin to a neoplastic process. Morphologically, they represent a mass of disorganized vessels with proliferating endothelial cells, smooth muscle cells, myofibroblasts, and macrophages. Several studies have demonstrated the involvement of growth factors that have been implicated in angiogenesis.[110] Whether the plexiform lesion represents impaired proliferation or angiogenesis remains unclear. These lesions, however, are not pathognomonic for PPH but representative of a chronic, severe pulmonary hypertensive state.

The other major pattern of vascular changes in PPH is that of a *thrombotic pulmonary arteriopathy.*[111] Typical features include medial hypertrophy of the arteries and arterioles with both eccentric and concentric nonlaminar intimal fibrosis. The presence of colander lesions, which represent recanalized thrombi, is also typical. These lesions are believed to arise as a result of primary in situ thrombosis of the small vascular arteries and not from recurrent pulmonary embolism.

On rare occasion, a diffuse pulmonary arteritis with secondary thrombosis has been reported in patients with PPH, predominantly in children.[112] Although the association has not been reported in patients with underlying collagenvascular disease, it may reflect the vascular response to a specific, but not clearly identified risk factor.

PULMONARY VENOOCCLUSIVE DISEASE

Pulmonary venoocclusive disease is a rare form of PPH observed in approximately 5 percent of cases.[49] [50] The histopathological diagnosis is based on the presence

of obstructive eccentric fibrous intimal pads within the pulmonary veins and venules. Arterialization of the pulmonary veins is often present and associated with alveolar capillary congestion. Other changes of chronic pulmonary hypertension such as medial hypertrophy and muscularization of the arterioles with eccentric intimal fibrosis may also be seen. The pulmonary venous obstruction explains the increased pulmonary capillary wedge pressure described in patients in the late stages of the disease and the increase in basilar bronchovascular markings described on the chest radiograph. These clinical findings, along with a perfusion lung scan showing diffuse, patchy nonsegmental abnormalities, is highly suggestive of the diagnosis on a clinical basis.[113] [114] [115]

PULMONARY CAPILLARY HEMANGIOMATOSIS

This extremely rare condition is characterized by proliferation of the thin-walled microvessels that infiltrate the peribronchial and perivascular interstitium and lung parenchyma.[116] On occasion, it may be confused with pulmonary venoocclusive disease. The lesions are often patchy and the proliferating vessels may form small nodules within the alveolar interstitial space. These thin-walled vessels are prone to bleeding and may be manifested clinically as overt hemoptysis in affected patients. The perfusion lung scan in these patients may show "hot spots" reflective of local areas within the lung that have increased vascularity. These areas are typically seen at the lung periphery and can be confirmed by pulmonary angiography.[117] The natural history of this form of PPH is not yet defined.[118] [119]

CLINICAL FEATURES

NATURAL HISTORY AND SYMPTOMATOLOGY.

The most extensive study on the natural history of PPH was reported from the National Institutes of Health (NIH) Registry on Primary Pulmonary Hypertension from 1981 to 1987.[76] The study included the long-term follow-up of 194 patients in whom PPH was diagnosed by established clinical and hemodynamic criteria. Sixty-three percent of the patients were female, and the mean age was 36 ± 15 years (range, 1 to 81 years) at the time of diagnosis. The mean interval from the onset of symptoms to diagnosis was 2 years, and

the most common initial symptoms were dyspnea (80 percent), fatigue (19 percent), syncope or near syncope (13 percent), and Raynaud phenomenon (10 percent). No ethnic differentiation was observed, with 12.3 percent being black and 2.3 percent being Hispanic.

Syncope is a characteristic symptom of PPH and is assumed to be due to a fixed cardiac output. A recent study on the systolic function and interactions of the left and right ventricles in patients with PPH revealed an increased right ventricular end-diastolic volume and reduced right ventricular ejection fraction, with a greater stroke volume than in the left ventricle.[120] The mechanism for maintaining cardiac output with exercise was primarily through an increased heart rate inasmuch as stroke volume actually decreased. The right ventricular ejection fraction decreased with exercise, thus suggesting exercise-induced right ventricular failure. This result is expected because pulmonary artery pressure increases with exercise in PPH. The left ventricular ejection fraction is maintained, however, but left ventricular end-diastolic volume decreases and left ventricular end-systolic volume becomes extremely small, which suggests that the left ventricle is shortening to its maximum extent. The fact that left ventricular end-diastolic and end-systolic volumes decreased whereas right ventricular end-systolic and end-diastolic volumes remained unchanged supports the concept that underfilling and not external compression accounts for the small left ventricular chamber size observed in PPH. Syncope occurs because of exercise-induced right ventricular failure whereby the heart rate becomes the only mechanism available to increase cardiac output, which has limited effectiveness.

On *physical examination,* an increased pulmonic component of the second heart sound was the most common finding (93 percent), with tricuspid regurgitation noted in 40 percent and peripheral edema in 32 percent. In 90 percent of patients the chest radiograph revealed enlargement of the main pulmonary arteries, and the electrocardiogram revealed right ventricular hypertrophy in 87 percent. The clinical profiles of these patients were remarkably similar to those in a previously reported retrospective study of 120 patients from the Mayo Clinic.[57] In the Mayo Clinic series, 75 percent of the patients were women with a mean age of 34 years (range, 3 to 64 years) and a mean interval from onset of symptoms to diagnosis of 1.9 years.

The NIH Registry also revealed that restrictive changes in pulmonary function testing and reduced diffusing capacity for carbon monoxide were very common, with forced vital capacity approximately 80 percent of predicted and diffusing capacity 70 percent of predicted. These changes, however, do not correspond to any measure of severity of the pulmonary hypertension. An additional, virtually universal finding was mild to moderate hypoxemia (mean P_{O_2} of 72 ± 16 mm Hg), which is attributed to the effect of low mixed venous oxygen from low cardiac output amplified by the underlying ventilation-perfusion inequality.

The hemodynamic findings also suggested that the severity of the disease could be related to a rising right atrial pressure and falling cardiac index, both of which reflect underlying right ventricular dysfunction. The fact that the mean pulmonary artery pressure was similar in patients whose duration of symptoms was less than 1 year and those who were symptomatic for more than 3 years suggests that pulmonary artery pressure rises to fairly high levels early in the course of the disease.

Univariate analysis from the NIH Registry pointed to the mean right atrial pressure, mean pulmonary artery pressure, and cardiac index, as well as the diffusing capacity from carbon monoxide, as significantly related to mortality.[121] In addition, the New York Heart Association classification has also been shown to relate very strongly to survival. Based on estimates obtained from the proportional hazards model, a regression equation was developed that describes the relationship between these three hemodynamic variables and subsequent mortality.

where P(t) = percent survival at t years, t = number of years, x = mean pulmonary artery pressure, y = mean right atrial pressure, and z = cardiac index. This equation has since been validated in two subsequent studies,[122] [123] which suggests that baseline hemodynamic characteristics are very predictive of outcome.

The most common cause of death in patients with PPH in the NIH Registry was progressive right-sided heart failure (47 percent). Sudden cardiac death (both witnessed and unwitnessed) occurred in 26 percent. Of interest is that sudden cardiac death was limited to patients who were New York Heart Association Class IV, thus suggesting that it is a manifestation of end-stage disease rather than a phenomenon that occurs early or unpredictably in the clinical course of the disease. The remainder of the patients died of some other medical complication such as pneumonia or bleeding, which suggests that patients with PPH do not tolerate coexistent medical conditions well. In the NIH Registry experience, no deaths or sustained morbidity was associated with the diagnostic evaluation done at baseline assessment. It should be pointed out, however, that these were university centers with established experience in the management of patients with PPH.

MECHANISMS OF RIGHT VENTRICULAR FAILURE.

It is presumed that right ventricular dysfunction in patients with chronic pulmonary hypertension is a result of chronic pressure overload and associated volume overload with the development of tricuspid regurgitation. However, animal studies suggest that right ventricular ischemia may also be a feature and potentially a very common one.[124] The mechanism of right ventricular failure in pulmonary hypertension is complex. The chronic pressure overload that induces right ventricular hypertrophy and reduced contractility has been shown to cause a reduction in coronary blood flow to the right ventricular myocardium, which can produce right ventricular ischemia, both acutely and chronically. Such right ventricular dysfunction appears to be a result of a reduction in right ventricular coronary artery driving pressure. In an interesting animal study by Vlahakes and colleagues[124] acute right ventricular failure secondary to right ventricular hypertension was overcome by increasing central aortic pressure, which resulted in an increase in right ventricular coronary driving pressure. Murray and Vatner[125] reported that a moderate increase in aortic pressure was accompanied by a large increase in right ventricular myocardial perfusion only when the autonomic nervous system was blocked with an alpha blocker. Because the symptom of angina associated with PPH is characteristic of myocardial ischemia, it probably represents ongoing ischemia caused by this phenomenon.

On occasion, patients with pulmonary hypertension may have a reduced left ventricular ejection fraction and even regional wall motion abnormalities of the left ventricle. In the past, these findings had been attributed to mechanisms related to interventricular dependence, which suggests that in some way a dysfunctional right ventricle can lead to a dysfunctional left ventricle.[126] Clearly, the shared interventricular septum can affect the function of both ventricles. More recently, extrinsic compression of the left main coronary artery by the pulmonary artery in patients with chronic pulmonary hypertension has been described and may be associated with classic angina-like symptoms.[127] [128] It is advisable to look for extrinsic compression of the left main coronary artery with coronary angiography in patients with longstanding pulmonary hypertension who have abnormal left ventricular function.

The clinical course of patients with PPH can be highly variable. However, with the onset of overt right ventricular failure manifested by worsening symptoms and systemic venous congestion, patient survival is generally limited to approximately 6 months. Understanding the clinical course of patients with PPH is important, especially when considering major interventional therapy such as organ transplantation.

PHYSICAL EXAMINATION.

Findings are consistent with pulmonary hypertension and right ventricular pressure overload: a large *a* wave in the jugular venous pulse; a low-volume carotid arterial pulse with a normal upstroke; a left

parasternal (right ventricular) heave; a systolic pulsation produced by a dilated, tense pulmonary artery in the second left interspace; an ejection click and flow murmur in the same area; a closely split second heart sound with a loud pulmonic component; and a fourth heart sound of right ventricular origin. Late in the course, signs of right ventricular failure (hepatomegaly, peripheral edema, and ascites) may be present. Patients with severe pulmonary hypertension may also have prominent *v* waves in the jugular venous pulse as a result of tricuspid regurgitation, a third heart sound of right ventricular origin, a high-pitched early diastolic murmur of pulmonic regurgitation, and a holosystolic murmur of tricuspid regurgitation. Cyanosis is a late finding in PPH and may be worsened by a patent foramen ovale with right-to-left shunting. Other causes of cyanosis include a markedly reduced cardiac output with systemic vasoconstriction and ventilation-perfusion mismatches in the lung. Uncommonly, the left laryngeal nerve becomes paralyzed as a consequence of compression by a dilated pulmonary artery (Ortner syndrome).

LABORATORY FINDINGS

HEMATOLOGICAL AND CHEMICAL STUDIES.

Results of these studies are usually normal in patients with PPH. If chronic arterial oxygen desaturation is noted, polycythemia may be present. A number of investigators have reported hypercoagulable states, abnormal platelet function, defects in fibrinolysis, and other abnormalities of coagulation in patients with PPH.[58] [59] Abnormal liver function tests results can indicate right ventricular failure with resultant systemic venous hypertension.

ELECTROCARDIOGRAPHY.

The electrocardiogram in PPH usually exhibits right atrial and right ventricular enlargement. A direct correlation between the amplitude of the R wave in V_1 , the R/S ratio in V_1 , and the level of pulmonary arterial pressure has been reported.

ROENTGENOGRAPHY.

Radiographic examination of the chest in patients with PPH shows enlargement of the main pulmonary artery and its major branches, with marked tapering of peripheral arteries. The right ventricle and atrium may also be enlarged. Fluoroscopic examination may disclose exaggerated pulsations of secondary pulmonary arterial branches reflecting an elevation in pulmonary arterial pulse pressure. However, in contrast to the plethoric peripheral lung fields in patients with left-to-right shunts, oligemia is noted in these lung regions in patients with PPH. It has been suggested that survival in PPH correlates inversely with the size of the main pulmonary artery--a reasonable suggestion because the latter correlates with the height of pulmonary arterial pressure. The diameter of the pulmonary artery may be determined from computed tomographic (CT) scans and used to estimate pulmonary artery pressures.[129]

PULMONARY FUNCTION TESTS.

Pulmonary function tests typically show mild restriction with a reduced diffusion capacity for carbon monoxide (D_{LCO}) and hypoxemia with hypocapnea. Some patients have increased residual volume and reduced maximum voluntary ventilation.

ECHOCARDIOGRAPHY.

Echocardiography usually demonstrates enlargement of the right atrium and ventricle, normal or small left ventricular dimensions, and a thickened interventricular septum. The septal/posterior left ventricular wall ratio may be abnormally increased, as in hypertrophic obstructive cardiomyopathy, but other echocardiographic signs characteristic of that condition are not observed. Systolic prolapse of the mitral valve is frequently present, as well as abnormal septal motion of the ventricular septum, as a result of chronic right ventricular pressure overload and reduced left ventricular filling.[130] Doppler echocardiographic evidence of right ventricular systolic hypertension may be obtained by measuring the velocity of the tricuspid regurgitant jet and using the Bernoulli formula (see Chap. 7) . Doppler techniques have demonstrated left ventricular diastolic dysfunction with marked dependence on atrial contraction for ventricular filling.[130]

LUNG SCINTIGRAPHY.

A perfusion lung scan is an essential component in making the correct diagnosis of PPH. It may reveal a relatively normal perfusion pattern or diffuse, patchy perfusion abnormalities.[131] The severity of the perfusion abnormality in lung scans does not parallel the hemodynamics inasmuch as serial lung scans performed over time in patients with PPH do not show progressive changes consistent with the patients' worsening clinical state. A perfusion lung scan should help distinguish patients with PPH from those who have pulmonary hypertension secondary to chronic pulmonary thromboembolism (Fig. 53-11) . The risk associated with lung scans in PPH has been grossly overstated. The early literature reported three patients with pulmonary hypertension who died following lung scans, but it is not clear that the deaths were caused by the procedure. In the NIH Registry on PPH, not one morbid clinical event was associated with the performance of lung scans in any of the patients with pulmonary hypertension.[76]

PULMONARY ANGIOGRAPHY.

Pulmonary angiography is essential to establish the correct diagnosis in a patient with presumed PPH in whom a perfusion lung scan suggests segmental or lobar defects. Typically, pulmonary angiography demonstrates large central pulmonary arteries with marked peripheral tapering. Postmortem arteriograms demonstrate the absence of "background haze" secondary to the loss of small, nonmuscular pulmonary arterioles. Although pulmonary angiography carries an increased risk in patients with PPH, it can be performed safely if adequate precautions are taken. The NIH Registry contains no deaths or serious morbidity associated with pulmonary angiography.

Maintenance of adequate oxygenation by the administration of supplemental oxygen and the avoidance of vasovagal reactions (and rapid treatment of those that occur with intravenous atropine) should reduce the associated risk in this patient group. Placement of an arterial line for continuous arterial pressure monitoring is advised, and nonionic contrast agents appear to be better tolerated. Injections are preferably limited to the individual lungs or specific lobes to reduce

Figure 53-11 Perfusion lung scans in patients with pulmonary hypertension. *A,* Patient with primary pulmonary hypertension (PPH). *B,* Patient with pulmonary thromboembolism causing pulmonary hypertension (PTE). Both perfusion scans are abnormal. The scan on the patient with PPH shows a mottled distribution in a nonsegmental, nonanatomical manner. The scan on the patient with PTE reveals lobar, segmental, and subsegmental defects highly suggestive of an anatomical obstruction to pulmonary blood flow.

TABLE 53-2 -- APPLICATIONS OF CATHETERIZATION IN ESTABLISHING THE ETIOLOGICAL DIAGNOSIS OF PULMONARY HYPERTENSION

CONDITION	TEST APPLIED	FINDING

Congenital heart disease	Step-up in O_2 saturation in right heart Step-down in O_2 saturation in left heart Cardiac angiography	Left-to-right shunt and location of shunt Right-to-left shunt and location of shunt Anatomical definition
Peripheral pulmonary artery stenoses	Intrapulmonary arterial pressure Pulmonary angiogram	Intrapulmonary arterial pressure gradients Pulmonary arterial branch stenoses
Proximal pulmonary arterial occlusion by clot or tumor*	Selective or main pulmonary angiography	Intravascular filling defect or narrowing, webs, poststenotic dilatation
Mitral stenosis Cor triatriatum Supravalvular mitral ring	Simultaneous wedge and left ventricular pressure recording	An elevated wedge pressure and mean mitral valve diastolic pressure gradient >3 mm Hg at rest, both of which increase with exercise
Mitral regurgitation	Simultaneous wedge and left ventricular pressure recording Left ventriculogram	Large systolic pressure wave in wedge tracing. Regurgitation of contrast from left ventricular angiogram into the left atrium
Left ventricular diastolic dysfunction Restrictive cardiomyopathy	Left ventricular pressure Right ventricular pressure	LVEDP >15 mm Hg LVEDP response to intravenous fluid challenge: normalization of LVEDP with marked reduction in pulmonary artery pressure with intravenous nitroprusside

LVEDP=left ventricular end-diastolic pressure.

*Ventilation=perfusion lung scans precede catheterization.

the contrast load. Pulmonary wedge angiography using a segmental angiographic technique with hand injection of small amounts of angiographic contrast through the terminal lumen of a balloon flotation catheter while the balloon is inflated is not a substitute for pulmonary angiography.

COMPUTED TOMOGRAPHY OF THE CHEST.

Chest radiographs, as well as chest CT scans, have been used to determine the presence and severity of pulmonary hypertension based on the diameter of the main pulmonary arteries.[129] [132] This information may be useful when performing chest CT to investigate the lung parenchyma in patients with pulmonary hypertension who are undergoing diagnostic evaluation. In addition, high-resolution chest CT scans have been used successfully in diagnosing chronic thromboembolic pulmonary hypertension.[132] In addition to visualization of thrombi in the pulmonary vasculature with contrast enhancement, a mosaic pattern of variable attenuation compatible with irregular pulmonary perfusion can be determined in the unenhanced CT scan. Marked variation in the size of segmental vessels is also a specific feature of chronic thromboembolic disease. In some institutions, high-resolution CT scanning has replaced lung scintigraphy as a test to make this diagnosis.

EXERCISE TESTING.

The use of a symptom-limited exercise test can be very helpful in the evaluation of patients with pulmonary hypertension. Besides allowing objective assessment of the severity of symptoms, exercise testing has been shown to also be predictive of survival. Two types of exercise testing have recently become popularized. The Naughton protocol uses a treadmill with increases in work of 1-MET increments at 2-minute stages to allow patients with very limited exercise tolerance to perform. In the 6-minute walk test, patients are instructed to walk down a 100-ft corridor and cover as much ground as possible within the 6 minutes. The total distance walked is determined by a tester. The application of exercise testing has been particularly helpful in evaluating the efficacy of drug therapy.[133]

CARDIAC CATHETERIZATION.

The diagnosis of PPH cannot be confirmed without cardiac catheterization (Table 53-2) . Besides allowing the exclusion of other causes, it also establishes the severity of disease and allows an assessment of prognosis. By definition, patients with PPH should have a low or normal pulmonary capillary wedge pressure. Although it has often been stated that one may be unable to obtain an accurate wedge pressure in these patients, such is rarely the case in experienced hands.[76] However, when an increased wedge pressure is obtained, it must be correlated with left ventricular end-diastolic pressure and not attributed to a "falsely elevated" reading.[134] It has been shown that left ventricular diastolic compliance becomes significantly impaired in PPH and parallels the severity of the disease; thus, pulmonary capillary wedge pressure tends to rise slightly in the late stages of PPH, although it rarely exceeds 16 mm Hg. Measurements of all right-sided pressures are properly made at expiration to avoid incorporating negative intrathoracic pressures.

It can be extremely difficult to pass a catheter into the pulmonary artery in patients with pulmonary hypertension because of the tricuspid regurgitation, dilated right atrium and ventricle, and low cardiac output. Flow-directed thermodilution balloon catheters, which are the proper devices to use, also lack stiffness and can be difficult to place. A specific flow-directed thermodilution balloon catheter has been developed for patients with pulmonary hypertension (American Edwards Laboratories, Irvine, CA); it has an extra port for the placement of a 0.32-inch guidewire to provide better stiffness to the catheter. The risk associated with cardiac catheterization in patients with PPH is extremely low in experienced hands, but deaths have been reported.[76]

DIAGNOSIS (Table 53-3)

It is essential that diagnostic efforts be pursued vigorously in patients with severe pulmonary hypertension to ensure that no patient with secondary pulmonary hypertension is erroneously classified as having PPH. Patients with PPH may tolerate diagnostic procedures poorly. These individuals can experience sudden cardiovascular collapse and even death during or shortly after the induction of general anesthesia for surgical procedures and during cardiac catheterization and angiography.

The *differential diagnosis* of PPH includes a number of well-defined causes of secondary pulmonary hypertension (Table 53-4) . Exclusion of mitral stenosis, congenital cardiac defects (including cor triatriatum, pulmonary thromboembolism, and pulmonary venous obstruction by means of catheterization and angiography is imperative. "Silent" mitral stenosis, i.e., without the characteristic diastolic murmur, can be excluded by means of echocardiographic visualization of the motion of the mitral valve and the absence

TABLE 53-3 -- DIAGNOSTIC STUDIES USEFUL FOR ELUCIDATING CAUSES OF PULMONARY HYPERTENSION

POTENTIAL CAUSE OF PULMONARY HYPERTENSION	DIAGNOSTIC STUDIES
Pulmonary thromboembolic disease	Ventilation/perfusion scans, computed tomography of chest, pulmonary angiography
Pulmonary venous thrombosis or obstruction	Chest x-ray, angiography, computed tomography, magnetic resonance imaging
Congenital intracardiac shunts	Transesophageal echocardiography with contrast
Increased left atrial pressure secondary to mitral or aortic valve disease, left ventricular dysfunction, or systemic hypertension	Pulmonary artery wedge pressure or left atrial pressure (via patent foramen ovale) (>15 mm Hg and LVEDP)
Pulmonary airway disease (e.g., chronic bronchitis and emphysema)	Respiratory function tests (FVC/FEV, chest x-ray)
Hypoxic pulmonary hypertension associated with (1) impaired ventilation, either central (CNS) or peripheral (chest wall problems or upper airway obstruction) and (2) residence at high altitude	Sleep apnea studies and respiratory function tests

Interstitial lung disease, pneumoconioses, and fibrosis (e.g., silicosis, rheumatoid disease, and sarcoidosis)	Chest x-ray, spirometry and carbon monoxide diffusion, high-resolution chest computed tomography
Collagen-vascular disease (e.g., SLE, polyarteritis nodosa, scleroderma)	Serological and immunogenetic studies; skin, muscle, or other tissue biopsy; esophageal motility studies
Parasitic disease (schistosomiasis or filariasis)	Rectal biopsy, complement fixation, skin tests, blood smears
Cirrhosis with portal hypertension	Liver function tests, ultrasonography, computed tomography
Peripheral pulmonary artery stenosis (including Takayasu disease and fibrosing mediastinitis)	Selective pulmonary angiography or pressure gradient at catheterization
Sickle cell disease	Erythrocyte morphology, hemoglobin electrophoresis

CNS=central nervous system; FEV_1 =forced expiratory volume in 1 second; FVC=forced vital capacity; SLE=systemic lupus erythematosus.

Modified from Weir EK: Diagnosis and management of primary pulmonary hypertension. In Weir EK, Reeves JT: Pulmonary Hypertension. Mt Kisco, NY, Futura, 1984, p 141.

of a transvalvular pressure gradient (see Chap. 46) . *Congenital cardiac defects* with Eisenmengers syndrome can usually be ruled out if significant left-to-right or right-to-left shunts are absent, although occasional patients with equal pulmonary and systemic vascular resistance may have no detectable shunt at rest. Transesophageal echocardiography can reliably detect congenital cardiac defects and distinguish an atrial septal defect from a patent foramen ovale.[135] *Cor triatriatum* (see Chaps. 43 and 44) is recognized by appropriate hemodynamic studies and angiographic visualization of the left atrial membrane. This entity has a characteristic left atrial echocardiogram with normal mitral valve motion. Cardiac catheterization reveals a hemodynamic pattern similar in some ways to mitral stenosis, i.e., a diastolic pressure gradient between the left ventricle and the pulmonary capillary bed. *Pulmonary embolism* (see Chap. 52) can be excluded by pulmonary angiography, and *sickle cell disease with in situ pulmonary vascular thrombosis* (see Chap. 69) can be evaluated by hemoglobin electrophoresis. The presence of severe *pulmonary parenchymal disease* can be recognized by the characteristic physical findings, chest radiograph, pulmonary function tests, and high-resolution chest CT. *Collagen-vascular disease* is suggested by the involvement of other organ systems or the presence of abnormal immunological phenomena such as antinuclear antibodies and LE cells (see Chap. 67) .

TABLE 53-4 -- DIAGNOSTIC CLASSIFICATION OF PULMONARY HYPERTENSION

Pulmonary arterial hypertension	Interstitial lung disease
Primary	Sleep-disordered breathing
Sporadic	Alveolar hypoventilation disorders
Familial	Chronic exposure to high altitude
Secondary	Neonatal lung disease
Collagen-vascular disease	Alveolar-capillary dysplasia
Congenital systemic-to-pulmonary shunts	Other
Portal hypertension	Pulmonary hypertension from chronic thrombotic and/or embolic disease
HIV infection	
Drugs/toxins	Thromboembolic obstruction of proximal pulmonary arteries
Anorexigens	Obstruction of distal pulmonary arteries
Other	Obstruction of distal pulmonary arteries
Persistent pulmonary hypertension of the newborn	Pulmonary embolism (thrombus, tumor, ova and/or parasites, foreign material)
Other	In situ thrombosis
Pulmonary venous hypertension	Sickle cell disease
Left-sided atrial or ventricular heart disease	Pulmonary hypertension caused by disorders directly affecting the pulmonary vasculature
Left-sided valvular heart disease	
Extrinsic compression of central pulmonary veins	Inflammatory
Fibrosing mediastinitis	Schistosomiasis
Adenopathy/tumors	Sarcoidosis
Pulmonary venoocclusive disease	Other
Other	Pulmonary capillary hemangiomatosis
Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxemia	
Chronic obstructive pulmonary disease

TREATMENT (Fig. 53-12)

LIFE STYLE CHANGES.

The diagnosis of PPH does not necessarily imply total disability for the patient. However, physical activity can be associated with elevated pulmonary artery pressure inasmuch as marked hemodynamic changes have been documented to occur early in the onset of increased physical activity.[136] For that reason, graded exercise activities, such as bike riding or swimming, in which patients can gradually increase their workload and easily limit the extent of their work, are thought to be safer than isometric activities. Isometric activities such as lifting weights or stair climbing can be associated with syncopal events and should be limited or avoided.

The subject of pregnancy should also be discussed with women of childbearing age. The physiological changes that occur in pregnancy can potentially activate the disease and result in death of the mother and/or the child. Besides the increased circulating blood volume and oxygen consumption that will increase right ventricular work, circulating procoagulant factors and the risk of pulmonary embolism from deep vein thrombosis and amniotic fluid are serious concerns. Syncope and cardiac arrest have also been reported to occur during active labor and delivery, and a syndrome of postpartum circulatory collapse has been described.[137] For these reasons, surgical sterilization should be given strong consideration by women with PPH or their husbands.

DIGOXIN.

Animal studies performed on the utility of digoxin in right ventricular systolic overload show that prior administration helps prevent the reduction in contractility of the right ventricle. Recently, it has been shown that digoxin can exert a favorable hemodynamic effect when given acutely to patients with right ventricular failure from pulmonary hypertension.[138] An increase in resting cardiac output of approximately 10 percent was noted, which is similar to observations made in patients with left ventricular systolic failure. In addition, it was also observed that digoxin causes a significant reduction in circulating norepinephrine, which was markedly increased.

Digitalis toxicity in patients with pulmonary hypertension and normal renal function is uncommon. Consequently, digoxin appears to be a potentially useful medication for patients who have right ventricular failure, either with isolated pulmonary hypertension or in combination with left ventricular systolic failure.

DIURETIC THERAPY.

Diuretics appear to be of marked benefit in symptom relief of patients with PPH. Their traditional role has been limited to patients manifesting right ventricular failure and systemic venous congestion. However, patients with advanced PPH can have increased left ventricular filling pressures that contribute to the symptoms of dyspnea and orthopnea, which can be relieved with diuretics. Diuretics may also serve to reduce right ventricular wall stress in patients with concomitant tricuspid regurgitation and volume overload. The fear that diuretics will induce systemic hypotension is unfounded because the main factor limiting cardiac output is pulmonary vascular resistance and not pulmonary blood volume. Patients with severe venous congestion may require high doses of loop diuretics or the use of combined diuretics. In these instances, electrolytes need to be carefully watched to avoid hyponatremia and hypokalemia.

SUPPLEMENTAL OXYGEN THERAPY.

Hypoxic pulmonary vasoconstriction can contribute to pulmonary vascular disease in patients with alveolar hypoxia from parenchymal lung disease. Supplemental low-flow oxygen alleviates arterial hypoxemia and attenuates the pulmonary hypertension in these disorders; in contrast, most patients with PPH do not exhibit resting hypoxemia and derive little benefit from supplemental oxygen therapy. Patients who experience arterial oxygen desaturation with activity, however, may benefit from ambulatory supplemental oxygen because increased oxygen extraction develops in the face of fixed oxygen delivery. Patients with severe right-sided heart failure and resting hypoxemia resulting from markedly increased oxygen extraction at rest should be treated with continuous oxygen therapy to maintain their arterial oxygen saturation above 90 percent.[139] Patients with hypoxemia caused by a right-to-left shunt via a patent foramen ovale do not improve their level of oxygenation to an appreciable degree with supplemental oxygen.

VASODILATOR TREATMENT.

Because of early reports showing a reduction in pulmonary artery pressure following the acute administration of vasodilators, it has been presumed that vasodilators are the mainstay of treatment in patients with PPH. This presumption, however, is not supported by the published literature over the past two decades. Vasodilators appear to be effective in a subset of patients with PPH, but many complexities regarding vasodilator administration make their use in these patients very difficult.

The first principle in using vasodilators in patients with PPH is to establish accurate baseline hemodynamics. Because substantial hemodynamic variability has been reported to exist in the pulmonary vascular bed and will produce changes in cardiac output and pulmonary artery pressure from moment to moment, serial baseline recordings are required to evaluate the magnitude of change in hemodynamics that may be attributed to variability rather than to drug effect.[140] The practice of attributing "peak" effect of the drug to an administered agent introduces bias into the assessment. Thus, by choosing the highest level of pulmonary artery pressure as the baseline and the subsequent lowest one as drug effect, one may be misled to attribute a favorable influence from a medication when in fact no effect or even an adverse one is occurring.

It must also be emphasized that hemodynamic assessment of the entire circulatory system is essential when determining the influence of drugs in these patients. Small changes in pulmonary artery pressure are probably due to variability and are not related to direct drug influence. Changes in pulmonary vascular resistance cannot be directly measured but are computed by the change in pulmonary pressure and cardiac output simultaneously. Because thermodilution cardiac output, the method that is most commonly used in these patients, can be associated with large errors in reproducibility, particular care should be taken in the methodology of thermodilution used in these patients. In addition, when an underlying right-to-left shunt exists or severe tricuspid regurgitation is a concern, the Fick determination of cardiac output is preferred.

Changes in pulmonary capillary wedge pressure can have important influences on the determination of pulmonary vascular resistance. A rising capillary wedge pressure secondary to increased cardiac output may be the first sign of impending left ventricular failure and an adverse effect of a drug, whereas the calculated pulmonary vascular resistance may become lower and suggest a beneficial effect. Right atrial pressure also reflects the filling characteristics of the right ventricle. A right atrial pressure increase in the face of rising cardiac output suggests right ventricular diastolic dysfunction.[141] The resting heart rate is a physiological parameter of marked importance in patients with congestive heart failure, and treatments that cause an increased heart rate are likely to yield deleterious long-term results. Finally, the systemic arterial oxygen content should be evaluated in patients with PPH. Effective vasodilator drugs can result in vasodilatation of blood vessels supplying poorly ventilated areas of the lung and worsen hypoxemia. This effect is particularly noticeable in patients with underlying chronic lung disease. For all these reasons it has been advocated that vasodilators be initiated only in the hospital setting with central catheter placement for direct hemodynamic recordings and never initiated in the outpatient setting.[139] [142]

ACUTE TESTING WITH INTRAVENOUS VASODILATORS(Table 53-5)

Intravenous vasodilators may be of value in the short-term assessment of pulmonary vasodilator reserve in patients with PPH.[139] Historically, tolazoline received attention as an agent to acutely test the responsiveness of the pulmonary vascular bed in patients with pulmonary hypertension from several causes. However, it is poorly tolerated acutely because of its side effects and has largely been replaced by other agents. Acetylcholine was one of the first medications used to evaluate patients with PPH. It is rapidly inactivated by the lung, which explains why intravenous administration seems to produce selective pulmonary vasodilator effects. Although it has been reported to produce substantial acute reductions in pulmonary artery pressure in some patients, chronic therapy with this drug is not feasible. Isoproterenol is a potent beta-adrenergic agent that affects both the systemic and pulmonary vascular beds and increases cardiac output by chronotropic and inotropic mechanisms. It is considered a pulmonary vasodilator because it results in lowering of the calculated pulmonary vascular resistance. However, it rarely results in substantial lowering of pulmonary artery pressure in patients with pulmonary hypertension because of its more direct effect in increasing cardiac output. Phentolamine is a potent alpha-adrenergic blocker that has been shown to cause pulmonary vasodilatation in animals and humans. Its widespread use is limited by the profound systemic hypotension that occurs upon administration, and it is not generally used in the evaluation of PPH. Sodium nitroprusside is a potent vasodilator that acts on arterial and venous beds. Its short half-life is also an advantage because the effects rapidly dissipate when infusion of the drug is stopped. Like phentolamine, its use as a test of vasodilator reserve is limited by the marked lowering of systemic blood pressure that occurs.

ADENOSINE.

This substance is an intermediate product in the metabolism of adenosine triphosphate that has potent vasodilator properties through its action on specific vascular receptors. In addition to pulmonary vasodilatation, it can also produce systemic and coronary vasodilatation. It is believed to stimulate the endothelial cell and vascular smooth muscle receptors of the A_2 type, which induce vascular smooth muscle relaxation by increasing cyclic adenosine monophosphate.[143] In patients with PPH, adenosine has been shown to be an extremely potent vasodilator and predictive of the subsequent effects of intravenous prostacyclin and oral calcium channel blockers.[144] [145] Adenosine has an extremely short half-life (less than 5 seconds), which provides a safety net by its rapid dissolution should any adverse side effects occur. It is administered intravenously in doses of 50 ng/kg/min and titrated upward every 2 minutes until uncomfortable symptoms develop (such as chest tightness or dyspnea). It should be noted that adenosine is given as an infusion and not as an

TABLE 53-5 -- HEMODYNAMIC ASSESSMENT OF VASODILATORS IN PULMONARY HYPERTENSION

PARAMETER MEASURED	DESIRED ACUTE CHANGES	COMMENTS
Mean pulmonary artery pressure	>25% fall; ideally mean PAP below 30 mm Hg	Must not be any associated significant fall in systemic blood pressure
Pulmonary vascular resistance	>33% fall; ideally, PVR below 6 units	Should be associated with a fall in PA pressure *and* an increase in cardiac output. An increase in cardiac output alone may lead to future RV failure
Right atrial pressure	No change or fall	An increase in RA pressure signals impending RV failure
Pulmonary capillary wedge pressure	No change	An increase in wedge pressure suggests pulmonary venoocclusive disease or coexisting LV dysfunction
Systemic blood pressure	Minimal fall; mean arterial pressure should remain above 90 mm Hg	A significant hypotensive response makes chronic vasodilator therapy contraindicated

Cardiac output	Increase	The increase should be related to increased stroke volume and not solely due to increased heart rate
Heart rate	No significant change	A chronic increased heart rate will result in RV failure. Watch for bradycardia if high doses of diltiazem are used
Systemic arterial oxygen saturation	Increase if reduced on room air, little change if normal	A fall in systemic arterial oxygen saturation suggests lung disease or right-to-left shunting and prohibits chronic use
Pulmonary artery (mixed venous)oxygen saturation	Increase	Should reflect the increase in cardiac output and improved tissue oxygenation

LV=left ventricular; RA=right atrial; RV=right ventricular.

intravenous bolus as is used to treat supraventricular tachyarrhythmias.

PROSTACYCLIN.

This substance (epoprostenol sodium, or PGI_2) is a metabolite of arachidonic acid that is synthesized and released from vascular endothelium and smooth muscle. Its vasodilatory effects are thought to be mediated by activation of specific membrane PGI_2 receptors that are also coupled to the adenylate cyclase system.[28] Other effects include inhibition of platelet activation and aggregation, as well as leukocyte adhesion to the endothelium.[146] Prostacyclin has been used as an acute test of vasodilator reserve in patients with PPH. Like adenosine, its short half-life allows use of the drug to be discontinued if any acute adverse effects result. Also similar to adenosine, it is administered incrementally, at 2 ng/kg/min and increased every 15 to 30 minutes until systemic effects such as headache, flushing, or nausea occur, which limits the acute dose titration. Favorable acute effects from prostacyclin appear to be predictive of a favorable response to oral calcium channel blockers.[147]

Adenosine and prostacyclin possess potent inotropic properties, in addition to their ability to vasodilate the pulmonary vascular bed. When using these drugs for the acute testing of patients, one needs to pay particular attention to changes in cardiac output that occur in association with the changes in pulmonary arterial pressure. An increase in cardiac output with no change in pulmonary arterial pressure will result in a reduction in calculated pulmonary vascular resistance and may be erroneously interpreted as a vasodilator response. Instead, one should look at the magnitude of change of each individual parameter to determine the effects that the drug is having on the pulmonary circulation, as well as the type of response that it elicits.

NITRIC OXIDE.

This substance, whose activity is identical to that of endothelium-derived relaxing factor, is produced from L-arginine by NO synthase.[148] NO diffuses to vascular smooth muscle and mediates vasodilatation by stimulating soluble guanylate cyclase to produce cyclic GMP. Because it binds very rapidly to hemoglobin with high affinity and is thereby inactivated, inhalation of NO gas results in selective pulmonary vascular effects without influencing the systemic circulation. Inhalation of NO by patients with PPH has been shown to produce a reduction in pulmonary vascular resistance acutely, similar to that achieved with intravenous adenosine, and to also predict the effectiveness of calcium channel blockers.[149] [150] NO has also been shown to be effective in patients with pulmonary hypertension secondary to congenital heart disease and the adult respiratory distress syndrome.[151] Although NO seems to have similar acute effects on pulmonary arterial pressure that are predictive of the chronic response to oral vasodilator agents, it differs importantly from adenosine and prostacyclin in that it has little effect on cardiac output.

Chronic Treatment

CALCIUM CHANNEL BLOCKERS.

Of the vasodilators tested in patients with PPH, calcium channel blockers appear to have the widest usage. Early studies using conventional doses failed to demonstrate a chronic sustained benefit. Moreover, calcium channel blockers have properties that could worsen the underlying pulmonary hypertension, including negative inotropic effects on right ventricular function (Fig. 53-13) and reflex sympathetic stimulation, which may increase the resting heart rate.[141] It has been reported that patients with PPH who are challenged with very high doses of calcium channel blockers may manifest a dramatic reduction in pulmonary artery pressure and pulmonary vascular resistance, which upon serial catheterization has been maintained for over 5 years.[122] Importantly, the patient's quality of life is restored with improved functional class, and survival (94 percent rate at 5 years) is improved when compared with nonresponders and historical control subjects (36 percent rate) (Fig. 53-14 *A*). This experience suggests that some patients with PPH have the ability to have their pulmonary hypertension reversed and their quality of life and survival enhanced. It is unknown whether the response to calcium channel blockers identifies two subsets of patients with PPH, different stages of PPH, or a combination of both. However, it is essential to point out that patients who do not exhibit a dramatic hemodynamic response to calcium channel blockers do not appear to benefit from their long-term administration. Unfortunately, it is becoming common practice for physicians to prescribe calcium channel blockers at conventional doses to all patients with pulmonary hypertension, often without hemodynamic guidance. This unfortunate practice may result in quicker deterioration in these patients and should be strongly discouraged.

CHRONIC PROSTACYCLIN INFUSION THERAPY.

Continuous-infusion prostacyclin therapy has now been shown in prospective randomized trials to improve quality of life and symptoms related to PPH, exercise tolerance, hemodynamics, and survival.[133] [152] [153] [154] [155] (Fig. 53-14 *B*). The initial enthusiasm for prostacyclin was based on the demonstration of pulmonary vasodilator effects when administered to experimental animals with acute pulmonary vasoconstriction and when subsequently administered to patients with PPH. The long-term effects of prostacyclin in PPH include its vasodilator and antithrombotic effects, but its effects may also be importantly related to its ability to restore the integrity of the pulmonary vascular endothelium. A recent study revealed that significant reductions in pulmonary vascular resistance that go beyond acute vasodilation were the rule in the patients treated with intravenous prostacyclin for 1 year.[155] On average, patients had a reduction in pulmonary vascular resistance of greater than 50 percent which occurred even if no acute hemodynamic effects were noted (Fig. 53-15) .

Prostacyclin is generally administered through a central venous catheter that is surgically implanted and delivered by an ambulatory infusion system. The delivery system is complex and requires patients to learn the techniques of sterile drug preparation, operation of the pump, and care of the intravenous catheter. Most of the serious complications that have occurred with prostacyclin therapy have been attributable to the delivery system and include catheter-related infections and thrombosis and temporary interruption of the infusion because of pump malfunction. Anecdotal reports of rebound pulmonary hypertension occurring in patients in whom the infusion was interrupted suggest

Figure 53-13 Adverse effects of calcium channel blockers in pulmonary hypertension. The hemodynamic effects of verapamil and nifedipine in patients with pulmonary hypertension are shown. An increase in right atrial pressure in association with no significant change in cardiac index as produced by nifedipine suggests that right ventricular dysfunction is occurring. The increased right atrial pressure associated with a fall in cardiac index, as produced by verapamil, suggests that negative inotropic effects are producing overt right ventricular failure. (Adapted from Packer M, Medina N, Yushak M: Adverse hemodynamic and clinical effects of calcium channel blockade in pulmonary hypertension secondary to obliterative pulmonary vascular disease. Am Coll Cardiol 4:890, 1994.)

Figure 53-14 *A,* Effect of high doses of calcium channel blockers on survival over 5 years in patients with primary pulmonary hypertension (PPH). Patients who responded to the high-dose regimen (open circles) had a 95 percent 5-year survival rate, as opposed to the nonresponders (solid line), who had a 36 percent 5-year survival rate. Rates were similar in patients studied in the National Institutes of Health (NIH) Registry on PPH (triangles), as well as patients from the University of Illinois only (solid circles). *B,* Effect of intravenous prostacyclin (PGI_2) on survival in patients with PPH. The survival of patients given a chronic infusion of prostacyclin and monitored for 5.5 years is compared with that of functional Class III and IV patients from the NIH Registry (historical controls). *C,* Effects of anticoagulation on survival in patients with PPH who did not respond to calcium channel blockers. Patients who received warfarin (open circles) had a marked survival advantage over those who received no warfarin. (*A* and *C* from Rich S, Kaufmann E, Levy PS: The effects of high doses of calcium channel blockers on survival of primary pulmonary hypertension. N Engl J Med 327:76,

that great care must be taken to ensure that the infusion is never stopped.

Side effects related to prostacyclin therapy include flushing, headache, nausea, diarrhea, and a unique type of jaw discomfort that occurs with eating. In most patients, these symptoms are minimal and well tolerated. Chronic foot pain and a poorly defined gastropathy with prolonged use develop in some patients. Tachyphylaxis to the drug develops at low doses and therefore may require a periodic dose increase to maintain its efficacy. To date, chronic prostacyclin has been given to patients with PPH for over 10 years with continued favorable effectiveness. In some patients (Class IV) who are critically ill, it serves as a bridge to lung transplantation by stabilizing the patient to a more favorable preoperative state. Patients who are less critically ill may do so well with prostacyclin therapy that they may delay the need to consider transplantation, perhaps indefinitely.

A high-cardiac output state has been reported in a large series of patients with PPH receiving chronic prostacyclin therapy and is consistent with the drug having positive inotropic effects.[156] Whether the effect is a direct one on the myocardium or indirect via neurohormonal activation has not been determined. Although most patients with PPH have reduced cardiac output on initial examination, the development of a chronic high-output state could have long-term detrimental effects on underlying cardiac function. The follow-up assessment of patients receiving intravenous prostacyclin is quite variable from medical center to medical center, but it does appear important to determine the cardiac output response to therapy periodically to optimize dosing.[157]

Figure 53-15 Long-term reduction in pulmonary vascular resistance (PVR) with chronic therapy with epoprostenol (prostacyclin) for primary pulmonary hypertension (PPH) in relation to the short-term reduction after the administration of adenosine. Although patients with the greatest short-term reduction in PVR had the greatest long-term reduction, patients who had little or no reduction acutely still had a significant reduction in PVR with long-term therapy. This finding suggests that mechanisms other than acute vasodilatation are responsible for the long-term benefit of intravenous prostacyclin therapy in PPH and supports the notion that reversal of pulmonary vascular remodeling is occurring. (From McLaughlin VV, Genthner DE, Panella MM, et al: Reduction in pulmonary vascular resistance with long-term epoprostenol (prostacyclin) therapy in primary pulmonary hypertension. N Engl J Med 338:273-277, 1998. Copyright © 1998 Massachusetts Medical Society. All rights reserved.)

ANTICOAGULANTS.

Oral anticoagulant therapy is widely recommended for patients with PPH, although its clinical efficacy as a therapy is difficult to prove. A retrospective review of patients with PPH monitored over a 15-year period at the Mayo Clinic suggested that patients who received warfarin had improved survival over those who did not.[57] The influence of warfarin therapy has been investigated in patients with PPH who failed to respond to high doses of calcium channel blockers.[119] Significant improvement in survival was observed in patients who received anticoagulation, with a 1-year survival rate of 91 percent and 3-year survival rate of 47 percent as compared with 1- and 3-year rates of 62 and 31 percent, respectively, in patients who did not receive anticoagulants (Fig. 53-14 *C*). The current recommendation is to use warfarin in relatively low doses, as has been recommended for prophylaxis of venous thromboembolism, with the international normalized ratio maintained at 2.0 to 2.5 times control.[156] Given its inhibitory effects on smooth muscle proliferation, heparin might be a suitable anticoagulant in PPH, although its use is more difficult. With the recent advent of low-molecular-weight heparins requiring once-a-day administration without the need for adjusting the dose to its antithrombotic effect, treatment with these agents is becoming a more viable alternative. They may be particularly useful in patients who are believed to be at increased risk for pulmonary thromboembolism.

ATRIAL SEPTOSTOMY

The rationale for the creation of an atrial septostomy in PPH is based on experimental and clinical observations suggesting that an intraatrial defect allowing right-to-left shunting in the setting of severe pulmonary hypertension might be of benefit. Although over 60 patients have undergone this procedure worldwide, it should still be considered investigational.[159] [160] [161] [162] Nonetheless, atrial septostomy may represent a real alternative for selected patients with severe PPH. Indications for the procedure include recurrent syncope and/or right ventricular failure despite maximum medical therapy, as a bridge to transplantation if deterioration occurs in the face of maximum medical therapy, or when no other option exists.[162] Because the disease process in PPH appears to be unaffected by the procedure, the long-term effects of atrial septostomy must be considered palliative.

The procedure-related mortality with atrial septostomy in patients with PPH is high, and thus it should be attempted only in institutions with an established track record in the treatment of advanced pulmonary hypertension and experience in performing atrial septostomy with low morbidity.[161] It should not be performed in a patient with impending death and severe right ventricular failure or a patient receiving maximum cardiorespiratory support. Predictors of procedure-related failure or death have been identified and include a mean right atrial pressure of greater than 20 mm Hg, a pulmonary vascular resistance index of greater than 55 units m^2 or a predicted 1-year survival rate of less than 40 percent.

The mechanisms responsible for the beneficial effects of atrial septostomy remain unclear. Possibilities include increased oxygen delivery at rest and/or with exercise, reduced right ventricular end-diastolic pressure or wall stress, improvement in right ventricular function by the Frank Starling mechanism, or relief of ischemia.

HEART-LUNG AND LUNG TRANSPLANTATION. (see also Chap. 20) .

Heart-lung transplantation has been performed successfully in patients with PPH since 1981.[163] Because these patients have pulmonary vascular disease and severe right ventricular dysfunction, it was originally believed that heart-lung transplantation was the only transplantation option. Widespread application of heart-lung transplantation, however, has been limited by the number of centers with expertise to perform the procedure, the scarcity of suitable donor organs, and the very long waiting times required for

TABLE 53-6 -- GENERAL GUIDELINES FOR SELECTION OF LUNG TRANSPLANT RECIPIENTS

Indications
Advanced obstructive, fibrotic, or pulmonary vascular disease with a high risk of death within 2 to 3 yr
Lack of success or availability of alternative therapies
Severe functional limitation but preserved ability to walk
Age 55 yr or less for candidates for heart-lung transplantation, age 60 yr or less for candidates for bilateral lung transplantation, and age 65 yr or less for candidates for single-lung transplantation
Absolute Contraindications
Severe extrapulmonary organ dysfunction, including renal insufficiency with a creatinine clearance below 50 ml/min, hepatic dysfunction with coagulopathy or portal hypertension, and left ventricular dysfunction or severe coronary artery disease (consider heart-lung transplantation)
Acute, critical illness
Active cancer or recent history of cancer with substantial likelihood of recurrence (except for basal cell and squamous cell carcinoma of the skin)
Active extrapulmonary infection (including infection with HIV, hepatitis B, hepatitis C)
Severe psychiatric illness, noncompliance with therapy, and drug or alcohol dependence
Active or recent (preceding 3 to 6 mo) cigarette smoking
Severe malnutrition (<70% of ideal body weight) or marked obesity (>130% of ideal body weight)
Inability to walk, with poor rehabilitation potential
Relative Contraindications
Chronic medical conditions that are poorly controlled or associated with target organ damage
Daily requirement for more than 20 mg of prednisone (or equivalent)
Mechanical ventilation (excluding noninvasive ventilation)
Extensive pleural thickening from prior thoracic surgery or infection
Active collagen-vascular disease
Preoperative colonization of the airways with pan-resistant bacteria (in patients with cystic fibrosis)

From Arcasoy SM, Kotloff RB: Lung transplantation. N Engl J Med 340:1081-1091, 1999. Copyright © 1999 Massachusetts Medical Society. All rights reserved.

patients with end-stage right-sided heart failure. More recently, bilateral or double-lung transplantation and single-lung transplantation have been performed successfully in patients with PPH.[164] Hemodynamic studies have shown an immediate reduction in pulmonary artery pressure and pulmonary vascular resistance associated with improvement in right ventricular function.[165]

The ages of recipients of heart-lung and lung transplantation for pulmonary hypertension have ranged from 2 months to 61 years.[166] Operative mortality ranges between 16 and 29 percent and is somewhat higher for recipients of a single-lung transplant. The 1-year survival rate is between 70 and 75 percent, the 2-year survival rate is between 55 and 60 percent, and the 5-year survival rate is between 40 and 45 percent. Transplantation should be reserved for patients with pulmonary hypertension who have progressed in spite of optimal medical management.[167] (Table 53-6) .

Patients should be referred for evaluation for transplantation at the appropriate time.[168] The course of the disease and the waiting time must be taken into account, as well as other factors such as the anticipated waiting time before transplantation in the region and the expected survival after transplantation. It is generally accepted that patients should be considered for transplantation when they are New York Heart Association Functional Class III or IV in spite of medical therapy or when treatment with prostacyclin is failing or causing intolerable side effects.

The major long-term complications in patients who survive the operation are the high incidence of bronchiolitis obliterans in the transplanted lungs, acute organ rejection, and opportunistic infection.[169] Although several studies have documented significant improvement in quality of life after heart-lung and lung transplantation for pulmonary hypertension, cost-effectiveness has not yet been addressed. In many patients, prostacyclin may prove to be an ideal bridge to keep patients alive and stable until organs become available.[170]

Secondary Pulmonary Hypertension

Although PPH is relatively rare, with an estimated incidence of 1 to 2 per million in the population, severe pulmonary arterial hypertension associated with other conditions is more common[171] [172] [173] [174] [175] [176] [177] (Table 53-7) . The most common etiology is associated with collagen-vascular disease states, primarily scleroderma, including the CREST syndrome (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia), and mixed connective tissue disease.[172] Pulmonary arterial hypertension is also relatively common in patients with congenital heart defects, especially those with ventricular septal defects or a patent ductus arteriosus.[174] Other major etiologies include cirrhosis with portal hypertension and HIV infection.[97] [177] In some instances, increased resistance to pulmonary blood flow downstream leads to what has been referred to as "passive" pulmonary hypertension because in many cases, elevation in pulmonary artery pressure but no significant elevation in pulmonary vascular resistance is observed. Reactive pulmonary hypertension often coexists in these states, with pulmonary artery pressure and pulmonary vascular resistance elevated to levels higher than can be accounted for purely by increased downstream resistance to blood flow. In some instances, relieving the downstream obstruction results in normalization of pulmonary artery pressure and pulmonary vascular resistance, whereas in other instances it may not. Failure of normalization has been believed to be related to chronicity of the reactive pulmonary hypertension leading to irreversible vascular changes, although this hypothesis has never been proved. When reactive pulmonary hypertension occurs, it often results in right ventricular failure, which can predominate in the patient's clinical symptomatology and lead to marked deterioration in functional class and death.

PULMONARY HYPERTENSION ASSOCIATED WITH COLLAGEN-VASCULAR DISEASES (see also Chap. 67)

Scleroderma, either from progressive systemic sclerosis or the CREST syndrome, is the most common etiology of pulmonary hypertension in collagen-vascular disease states.[171] [172] Scleroderma is associated with pulmonary hypertension in as many as one-third of patients, and CREST syndrome in as many as 50 percent.[172] [178] The high incidence suggests that periodic screening with echocardiography in these patients may be a reasonable practice. Although pulmonary hypertension may occur as a result of entrapment and obstruction of the pulmonary microvasculature by interstitial inflammation or fibrosis, patients initially seen with severe pulmonary hypertension usually do not have evidence of interstitial lung disease and have a pulmonary vasculature with histological features that resemble those of PPH.[179] Patients with systemic lupus erythematosus may also have pulmonary hypertension, although less common than in scleroderma. On occasion, pulmonary hypertension may precede the clinical diagnosis of lupus by several years. Mixed connective tissue disease is a less common form of collagen-vascular disease, but pulmonary hypertension may occur in as many as two-thirds of these patients. Pulmonary hypertension has also been described in patients with polymyositis, dermatomyositis, and rheumatoid arthritis.

Because collagen-vascular diseases may have an insidious onset and slowly progressive course, early recognition of the symptoms of pulmonary hypertension may be difficult. Although easy fatigability may be a feature of the collagen-vascular disease, it may also be an initial symptom of pulmonary hypertension. Dyspnea is still the most common initial symptom and should not be attributed to advancing age. Syncope, presyncope, or peripheral edema represents advanced pulmonary hypertension and right-sided heart failure. Physical findings of an elevated jugular venous pressure and an increased pulmonic component of the second heart sound along with a right ventricular fourth heart sound are typical features of pulmonary hypertension and warrant an evaluation for pulmonary hypertension. A murmur of tricuspid regurgitation generally reflects more advanced disease. Arterial hypoxemia is characteristic and should also prompt an evaluation of possible pulmonary hypertension in these patients.

The prognosis of patients with collagen-vascular disease in whom pulmonary hypertension develops is very poor.[179] Conventional therapy with digitalis, diuretics, and supplemental oxygen is used, and

TABLE 53-7 -- ADVANCED PULMONARY HYPERTENSION BY DISEASE CATEGORY

DISEASE	PREVALENCE	PERCENTAGE OF PATIENTS WITH PH	ESTIMATED NUMBER IN NORTH AMERICA AND EUROPE
Systemic sclerosis	190/million	33	37,620
Congenital heart defects (ASD/VSD/PDA)	300/million	15-20	31,500

HIV related	2500/million	0.5	7500
Primary PH	7/million	100	4200

ASD=atrial septal defect; PDA=patent ductus arteriosus; PH=pulmonary hypertension; VSD=ventricular septal defect.

Figure 53-16 Mean pulmonary artery pressure (*top*) and pulmonary vascular resistance (*bottom*) before and after prostacyclin therapy in patients with secondary pulmonary hypertension. White bars indicate patients with congenital heart disease, striped bars indicate patients with collagen-vascular disease, and black bars indicate patients with portopulmonary hypertension. *$p<0.01$. $p<0.05$ versus baseline. For all groups combined, mean pulmonary artery pressure fell 23% and pulmonary vascular resistance 50% after chronic (1 year) therapy. (From McLaughlin VV, Genthner DE, Panella MM, et al: Compassionate use of prostacyclin in the management of secondary pulmonary hypertension: A case series. Ann Intern Med 130:740-743, 1999.)

anticoagulation has been recommended to provide a survival benefit similar to the practice in PPH. Although the use of oral vasodilators has been disappointing, intravenous prostacyclin therapy has demonstrated therapeutic efficacy manifested by improved exercise tolerance, hemodynamics, and sense of well-being.[180] [181] Prostacyclin should be considered as a therapeutic intervention as early as possible in patients with pulmonary hypertension secondary to collagen-vascular disease. In patients with associated Raynaud phenomenon, it may provide relief of digital ischemia (Fig. 53-16) .

INCREASED RESISTANCE TO PULMONARY VENOUS DRAINAGE

PATHOPHYSIOLOGY.

Increased resistance to pulmonary venous drainage is a mechanism common to several conditions of diverse cause in which pulmonary arterial hypertension occurs. Altered resistance to pulmonary venous drainage may be the result of diseases affecting the left ventricle or pericardium, mitral or aortic valvular disease, or rare entities such as cor triatriatum, left atrial myxoma, or pulmonary venoocclusive disease (see below).

The magnitude of pulmonary hypertension depends, in part, on the performance of the right ventricle. In response to an acute stress such as pulmonary embolism, the normal right ventricle of an adult living at sea level can achieve systolic pulmonary pressures of 45 to 50 mm Hg, above which right ventricular failure supervenes. Systolic pressures of 80 to 100 mm Hg can be generated only by a hypertrophied right ventricle that is normally perfused. If right ventricular infarction or ischemia has occurred or if the right and left ventricles are both affected by a myopathic process, right ventricular failure occurs at lower pulmonary vascular pressure and severe

pulmonary hypertension may not develop despite an increase in pulmonary vascular resistance.

In the presence of a healthy, nonischemic right ventricle, an increase in left atrial pressure from subnormal levels up to 7 mm Hg results in a fall in both pulmonary vascular resistance and the pressure gradient across the lungs. These reductions may reflect distention of a population of compliant small vessels, recruitment of additional vascular channels, or both. With further increases in left atrial pressure, pulmonary arterial pressure rises along with pulmonary venous pressure; i.e., at a constant pulmonary blood flow, the pressure gradient between the pulmonary artery and veins and pulmonary vascular resistance remains constant. Finally, when pulmonary venous pressure approaches or exceeds 25 mm Hg on a chronic basis, a disproportionate elevation in pulmonary artery pressure occurs; i.e., the pressure gradient between the pulmonary artery and veins rises while pulmonary blood flow remains constant or falls, which is indicative of an elevation in pulmonary vascular resistance that is due, in part, to pulmonary vasoconstriction. The latter occurs to a variable extent in response to passive elevations in pulmonary venous pressure and probably reflects the reactivity of the pulmonary vasculature, which may be variable between and within species.

Considerable variability in pulmonary arterial vasoconstriction is listed in response to pulmonary venous hypertension. Marked reactive pulmonary hypertension with pulmonary artery systolic pressures in excess of 80 mm Hg occurs in somewhat less than one-third of patients with pulmonary venous pressures elevated chronically in excess of 25 mm Hg. The fact that severe reactive pulmonary hypertension develops in less than one-third of patients with severe mitral stenosis also argues in favor of a spectrum of pulmonary vascular reactivity to chronic increases in pulmonary venous pressure.

The mechanism involved in elevating pulmonary vascular resistance is unclear. A neural component may be present; also, an elevation in pulmonary venous pressure may narrow or close airways, which may diminish ventilation and lead to hypoxia and, in turn, elevate pulmonary artery pressure. Finally, interstitial pulmonary edema secondary to pulmonary venous hypertension may encroach on the vascular lumen and contribute to the pulmonary arterial hypertension.

PATHOLOGY.

Structural changes in the pulmonary vascular bed develop in association with chronic pulmonary venous hypertension, irrespective of its etiology. At the ultrastructural level, these changes include swelling of pulmonary capillary endothelial cells, thickening of their basal lamina, and wide separation of groups of connective tissue fibrils, indicative of interstitial edema. With persistence of the edema, reticular and elastic fibrils proliferate and the alveolar capillaries become embedded in dense connective tissue. The permeability of interendothelial junctions depends on pulmonary capillary pressure, with leakage of large molecules (40,000 to 60,000 daltons) occurring at capillary pressures in excess of approximately 30 mm Hg.

Light microscopic examination of the lungs of patients with pulmonary venous hypertension shows distention of pulmonary capillaries, thickening and rupture of the basement membranes of endothelial cells, and transudation of erythrocytes through these ruptured membranes into the alveolar spaces, which contain fragments of disintegrating erythrocytes. Pulmonary hemosiderosis is commonly observed and may progress to extensive fibrosis. In the late stages of pulmonary venous hypertension, areas of hemorrhage may be scattered throughout the lungs, edema fluid and coagulum may collect in the alveolar spaces, and widespread organization and fibrosis of pulmonary alveoli may be present. Occasionally, particularly in patients with chronic pulmonary venous hypertension caused by mitral valve disease, the alveolar spaces become ossified. Pulmonary lymphatics may become markedly distended and give the appearance of lymphangiectasis, particularly when pulmonary venous pressure chronically exceeds 30 mm Hg. Structural alterations in the small pulmonary arteries, arterioles,

and venules include medial hypertrophy, intimal fibrosis, and rarely, necrotizing arteritis. However, plexiform lesions are not seen. The latter characterize the "irreversible" forms of pulmonary arterial hypertension.

PULMONARY HYPERTENSION SECONDARY TO ELEVATION IN LEFT VENTRICULAR DIASTOLIC PRESSURE

LEFT VENTRICULAR DIASTOLIC FAILURE.

This condition may result from hypertension: aortic stenosis; ischemic heart disease; hypertrophic, restrictive, and congestive cardiomyopathies; and constrictive pericarditis. Chronic increases in mean left ventricular filling pressure exceeding 25 mm Hg are uncommon, and the resulting pulmonary arterial hypertension is usually moderate unless reactive pulmonary hypertension also occurs.

Increased pulmonary artery pressure in patients with left ventricular dysfunction is a marker of poor prognosis. Pulmonary hypertension is associated with more frequent episodes of congestive heart failure and excess mortality after heart transplantation.[182] Pulmonary hypertension may result from an increase in left atrial pressure and pulmonary vascular resistance and possibly from the loss of endothelium-dependent vasodilatation of the pulmonary arterial bed. The severity of pulmonary hypertension in patients with left ventricular dysfunction is widely variable and independent of the degree of left ventricular dysfunction or associated functional mitral regurgitation. Many patients will improve considerably if effective medical therapy can be identified that will lower left ventricular end-diastolic pressure.[183] Identifying the basis for the increase in this pressure is essential.

PULMONARY HYPERTENSION SECONDARY TO LEFT ATRIAL HYPERTENSION

Mitral Valve Disease (see also Chap. 46) .

MITRAL STENOSIS.

This valvular lesion represents an important cause of pulmonary hypertension. Although the pulmonary hypertension associated with mitral stenosis is initially a result of an increase in resistance to pulmonary venous drainage and backward transmission of the elevated left atrial pressure, many patients subsequently exhibit marked pulmonary vasoconstriction and anatomical changes in vessels, so the pulmonary hypertension is "reactive" as well as "passive." The elevation in pulmonary vascular resistance and the associated pulmonary hypertension may come to dominate the clinical picture in mitral stenosis. Thus, patients with mitral stenosis often have what might be considered to be a more proximal obstruction at the level of the pulmonary arterioles and small muscular arteries, with resultant pulmonary hypertension equal to or exceeding systemic arterial pressure during exertion and sometimes even at rest. The clinical picture in such patients is characterized by right ventricular failure with distended neck veins, hepatomegaly, and ascites. These patients exhibit marked fatigue, occasionally a more serious complaint than dyspnea. The murmur of mitral stenosis may be soft or even inaudible, and the opening snap of the stenotic mitral valve may be indistinguishable from a loud pulmonic component of S_2 as a result of narrowing of the S_2 opening snap interval. Pulmonary congestion and edema may not be prominent clinically. Cardiac output is usually markedly reduced. This constellation of findings may obscure the underlying diagnosis of mitral stenosis and suggest instead either PPH or pulmonary hypertension secondary to some other disorder.

Diagnostic Studies.

The echocardiogram shows left atrial enlargement and thickened mitral valve leaflets whose mobility is markedly reduced. At cardiac catheterization, the pulmonary arterial hypertension is associated with substantial elevations in pulmonary wedge pressure, and a sizable (>10 mm Hg) pressure gradient is generally noted between pulmonary capillary wedge and left ventricular diastolic pressure. These findings are of key importance in distinguishing mitral stenosis from pulmonary arterial hypertension, a condition in which left atrial size and the wedge pressure are normal and in which no diastolic pressure gradient can be found between the wedge and left ventricular pressure.

Protection Against Pulmonary Edema.

At least three mechanisms that tend to protect against pulmonary edema formation are operative in patients with mitral stenosis and chronic elevations in pulmonary venous pressure in excess of 25 mm Hg (see Chap. 17) . First, lymphatic drainage of the pulmonary interstitium increases abruptly when pulmonary venous pressure is increased to 25 mm Hg. Acute increases in pulmonary lymph flow of up to 8 times the resting level occur when pulmonary venous pressure is raised to 30 mm Hg for a 10-minute interval, and the increased lymphatic flow persists at high levels for 30 to 60 minutes after pulmonary venous pressure has returned to normal. In models of *chronic* pulmonary venous pressure elevation, increases in pulmonary lymph flow of up to 28 times normal have been observed.

Diminished permeability of the capillary-alveolar barrier is a second protective mechanism that might be operative in patients with *chronic* pulmonary venous

hypertension in excess of 25 mm Hg. There is morphological evidence of thickening of the layer between the capillary lumen and the alveolar space.[184] A third mechanism operating in patients with chronic increased resistance to pulmonary venous drainage is the reactive constriction of small muscular pulmonary arteries and arterioles. This constriction, which results in considerable elevation in pulmonary artery pressure, is usually associated with a significant decline in right ventricular output and therefore pulmonary blood flow). The lower pulmonary blood flow tends to diminish the formation of pulmonary edema because it results in substantially lower left atrial and pulmonary venous pressure at any given size of the mitral valve orifice or for any given impairment in left ventricular function.

Effects of Surgery.

After corrective surgery on the mitral valve or after mitral balloon valvuloplasty (see Chap. 46) , both pulmonary vascular resistance and pulmonary hypertension decline,[185] the major extent of which is noted within the first postoperative week. The extent of reversal of pulmonary vascular obstruction has varied depending on the adequacy of the procedure in producing an increase in mitral orifice area and whether mitral valve restenosis.[186]

MITRAL REGURGITATION.

Although pulmonary hypertension is widely recognized as developing in patients with left atrial hypertension caused by mitral stenosis, it can also occur in patients with pure mitral regurgitation.[187] In one series, nearly half of a cohort of 41 patients with severe mitral regurgitation had pulmonary artery systolic pressures in excess of 50 mm Hg. In this subgroup of patients, pulmonary vascular resistance was three times normal and cardiac output was substantially depressed when compared with that in patients in whom severe mitral regurgitation was associated with only minimal pulmonary artery pressure elevation.[187] Presumably, the pulmonary hypertension in these patients is reversible, just as it is in mitral stenosis, although data on this point have not been reported.

COR TRIATRIATUM (see also Chap. 43) .

In this malformation, partitioning of the left atrium creates two left atrial subchambers. The posterior subchamber receives the pulmonary venous inflow, which then drains through an opening in the partition into the anterior subchamber and then through the mitral orifice into the left ventricle. When the opening in the partition separating the two left atrial subchambers is small, severe pulmonary venous and pulmonary arterial hypertension result.

INCREASED RESISTANCE TO FLOW THROUGH THE PULMONARY VASCULAR BED

Pulmonary Parenchymal Disease

This important cause of pulmonary hypertension is discussed in Chapter 54 .

Eisenmenger Syndrome (see also Chaps. 43 and 44)

Decreased cross-sectional area of the pulmonary arteriolar bed with irreversible pulmonary hypertension characterizes the so-called Eisenmenger syndrome. This term was used by Wood[188] to refer to patients with congenital cardiac lesions and severe pulmonary hypertension in whom reversal of a left-to-right shunt has occurred. Left-to-right shunts are usually due to congenital cardiovascular malformations (e.g., atrial and ventricular septal defects, patent ductus arteriosus).

PATHOPHYSIOLOGY.

Pulmonary hypertension in congenital heart disease may occur simply because of increased pulmonary blood flow. When chronic, the increased pulmonary flow is often associated with a passive reduction in pulmonary resistance and little elevation in pulmonary vascular pressure. In a normal adult with pulmonary blood flow (PBF) of 5 liters/min, pulmonary vascular resistance (PVR) of 60 dyne-sec cm^{-5} , and mean left atrial pressure (LA) of 6 mm Hg, the pulmonary artery mean pressure (PA) may be calculated from the expression

If PBF is doubled, a reduction in pulmonary vascular resistance to 30 dyne-sec cm^{-5} maintains pulmonary artery mean pressure at a normal level of 10 mm Hg. However, if PBF is increased fourfold to

sixfold, the reserve capacity of the pulmonary vascular bed is exceeded, and pulmonary artery pressure rises. Thus, if the pulmonary vascular resistance is 30 dyne-sec cm^{-5} , a PBF of 30 liters/min is associated with a mean pulmonary artery pressure that is only minimally elevated at 17 mm Hg, although the high right ventricular stroke volumes associated with the augmentation in PBF result in considerably higher values (40 to 45 mm Hg) for pulmonary artery and right ventricular systolic pressure. If no underlying arteriolar vascular disease exists, abolition of the shunt by corrective surgery restores PBF and pulmonary artery pressure to normal.

If a congenital cardiovascular defect causes pulmonary hypertension from the time of birth, the small, muscular arteries of the fetal lung may undergo delayed or only partial involution, with subsequent persistently high levels of pulmonary vascular resistance. This is especially true in lesions in which a left-to-right shunt enters the right ventricle or pulmonary artery directly (i.e., a posttricuspid valve shunt, such as ventricular septal defect or patent ductus arteriosus); these patients experience a higher incidence of severe and irreversible pulmonary vascular damage than do those in whom the shunt is proximal to the tricuspid valve (pretricuspid shunts, as in atrial septal defect and partial anomalous pulmonary venous drainage). In the latter category, pulmonary hypertension may result from a large pretricuspid left-to-right shunt, which enhances the risk of pulmonary vascular damage.

PATHOLOGY.

The extent of reversibility of pulmonary vascular obstructive disease in the presence of congenital heart disease varies. From an anatomical point of view, reversible conditions are those in which the decreased pulmonary arteriolar cross-sectional area is the result of medial hypertrophy and vasoconstriction; irreversibility is associated with the presence of necrotizing arteritis and plexiform lesions in these small vessels. The classification by Heath and Edwards[3] of six grades of structural change is widely used to assess the potential reversibility of pulmonary vascular disease and is summarized as follows: *Grade I* is characterized by hypertrophy of the media of small muscular pulmonary arteries and arterioles. In *grade II,* intimal cellular proliferation is added to the medial hypertrophy. *Grade III* is characterized by advanced medial thickening with hypertrophy and hyperplasia, together with progressive intimal proliferation and concentric fibrosis that result in obliteration of many arterioles and small arteries. In *grade IV,* dilatation and so-called plexiform lesions of the muscular pulmonary arteries and arterioles are observed. The latter consist of a plexiform network of capillary-like channels within a dilated segment of a muscular pulmonary artery. The channels are separated by proliferating endothelial cells that often contain thrombi; indeed, the network of capillary channels may constitute recanalization of a thrombus. *Grade V* changes include complex plexiform, angiomatous, and cavernous lesions and hyalinization of intimal fibrosis. Finally, *grade VI* is characterized by the presence of necrotizing arteritis.

The Heath-Edwards classification implies that the morphological alterations are sequential, with grade I being the earliest stage and grade VI being the "end stage" of pulmonary vascular obliterative disease. That such an orderly progression may not in fact occur is suggested by the findings of Wagenvoort, which indicate that plexiform lesions develop gradually in areas affected by necrotizing arteritis. Fibrinoid necrosis of a small segment of a pulmonary arterial branch has been suggested to lead to medial destruction and subsequent aneurysmal dilatation of the vessel, as well as the formation of a fibrin clot in the lumen, often with an admixture of platelets. Organization of the fibrin clot by strands of intimal cells leads to formation of the plexus; the small capillary-like channels within the plexus provide continuity to the distal portion of the artery, which undergoes poststenotic dilatation. With time, the inflammatory component of the process subsides, fibrin disappears, and the strands of intimal cells become fibrotic. Wagenvoort's view is supported by animal experiments in which end-to-end systemic-pulmonary anastomoses resulted in arteritis and fibrinoid necrosis before the appearance of plexiform lesions. Thus, although Heath-Edwards grades I, II, and III may represent chronological progression, evidence exists that grade VI (necrotizing arteritis) changes appear next, followed by grades IV and V as end-stage alterations.

CLINICAL CONSIDERATIONS.

Eisenmenger syndrome is applied to any anomalous circulatory communication that leads to obliterative pulmonary vascular disease, including pretricuspid and posttricuspid shunts. Health-Edwards grade IV to VI changes are usual in these patients; occasionally, lesser anatomical changes predominate and may be reversible

after successful corrective surgery. The long-term prognosis of patients with the Eisenmenger syndrome is substantially better than that of patients with other conditions associated with pulmonary hypertension.[189] Patients with the Eisenmenger syndrome have an 80 percent survival rate at 10 years, a 77 percent survival rate at 15 years, and a 42 percent survival rate at 25 years.[190] [191] Survival is typically related to mean right atrial pressure and pulmonary vascular resistance.

When pulmonary vascular resistance has increased so that it equals or exceeds systemic resistance and the anatomical changes of the pulmonary vessels are predominantly those of grades IV to VI, surgical closure of the anomalous circulatory communication will be associated with a prohibitive immediate risk and, if the patient survives, will usually fail to relieve pulmonary hypertension. Surgery may in fact hasten death in most survivors who had either balanced shunts or predominant right-to-left shunts because closure of the right-to-left communication merely increases the load on an already overburdened right ventricle. Structural changes in the pulmonary vascular bed are evident in pulmonary arteriograms, which reveal dilated central pulmonary arteries and narrowing of the peripheral branches. These changes can be evaluated by means of quantitative analysis of the pulmonary wedge angiogram.[192]

Intravenous prostacyclin therapy is highly effective and has been shown to improve exercise tolerance, quality of life, and hemodynamics in patients with congenital heart disease irrespective of the severity or duration of the condition[181] [193] (see Fig. 53-16) . It is effective in patients who have had previous surgical repair of their defect and in those who have not. No increased incidence of systemic side effects has been noted in patients who have a persistent right-to-left shunt. Long-term prostacyclin therapy may slow the progression of Eisenmenger syndrome and render some patients eligible for partial surgical repair consisting of atrial septostomy.[193] In patients who have bidirectional shunts, the use of prostacyclin may be a therapeutic strategy to enable a patient who is considered inoperable to become eligible for surgery at a later date.

Other Conditions Associated with Decreased Cross-Sectional Area of the Pulmonary Vascular Bed

PERSISTENT FETAL CIRCULATION IN THE NEWBORN (see also Chap. 43) .

This condition has been reported as a cause of severe pulmonary hypertension.[194] [194A] Affected infants exhibit cyanosis, tachypnea, acidemia, normal pulmonary parenchymal markings on chest radiography, and anatomically normal hearts. Cyanosis is the result of right-to-left shunting across the foramen ovale and through a patent ductus arteriosus. The condition may be due to persistence of extremely muscular small pulmonary arteries, a diminution in the absolute number of these resistance vessels, or a combination of the two.[195]

PULMONARY THROMBOEMBOLISM.

This important cause of pulmonary hypertension is discussed in Chapter 52 .

Chapter 54 - Cor Pulmonale

VALLERIE V. McLAUGHLIN
STUART RICH

Cor pulmonale is defined as right ventricular hypertrophy and dilatation secondary to pulmonary hypertension caused by diseases of the lung parenchyma and/or pulmonary vasculature, unrelated to the left side of the heart. Chronic cor pulmonale traditionally implies pulmonary hypertension related to either obstructive or restrictive lung disease, whereas acute cor pulmonale usually refers to the development of acute pulmonary hypertension from massive pulmonary embolism. The basic anatomy and physiology of the pulmonary circulation is reviewed in Chapter 53 . In this chapter the focus is on chronic pulmonary hypertension primarily related to disorders of the respiratory system and/or hypoxemia, chronic thromboembolic disease, and disorders directly affecting the pulmonary vasculature (see Table 53-4 , p. 1922). The pathogenic mechanisms that can lead to pulmonary arterial hypertension and cor pulmonale are shown in Table 54-1 .

THE EFFECTS OF ALVEOLAR GAS TENSION ON THE PULMONARY CIRCULATION

HYPOXIA

(see also p. 1909). The hypoxic pulmonary vasoconstrictor response is an important adaptive mechanism in human physiology. [1] Alveolar hypoxia results in local vasoconstriction so that blood flow is shunted away from hypoxic regions toward better-ventilated areas of the lung, improving the ventilation-perfusion matching within the lung.[2] Although the acute effects of this response are undoubtedly beneficial, chronic hypoxemia can result in sustained elevation of pulmonary artery pressure, vascular remodeling, and the development of cor pulmonale.

Hypoxic pulmonary vasoconstriction can be observed in isolated pulmonary vascular smooth muscle cells.[3] The mechanism of hypoxic pulmonary vasoconstriction involves the inhibition of potassium currents and pulmonary vascular smooth muscle membrane depolarization as a result of changes in the membrane sulfhydryl redox status. Potassium, calcium, and chloride channels all play important roles in determining pulmonary vascular tone and are altered by changes in local oxygen tension in the pulmonary circulation.

Increased calcium (Ca^{2+}) entry into the vascular smooth muscle cells appears to mediate hypoxic pulmonary vasoconstriction.[4] The concentration of Ca^{2+} in the vicinity of the contractile machinery represents a balance between inflow and outflow across the cell membrane and intracellular release and uptake. Within the cell, Ca^{2+} can be mobilized from the sarcoplasmic reticulum and mitochondrial membrane, or the inner aspect of the cell membrane.[5] Although most of the evidence favors an influx of Ca^{2+} from extracellular fluid, the relative contribution of differential mobilization from intracellular stores is unsettled. The mechanism responsible for intracellular mobilization of Ca^{2+} is also unclear.[6] [7]

Mechanisms of Hypoxic Vasoconstriction.

The mechanism of acute hypoxic pulmonary vasoconstriction is multifactorial, but the vascular endothelium plays a central role as a mediator of hypoxia-induced pulmonary vasoconstriction. Balanced release of nitric oxide[8] and endothelin [9] by endothelial cells is a key factor in the regulation of tone in the pulmonary circulation. A reduction in nitric oxide production has been demonstrated in the chronically hypoxic piglet[10] and rat,[11] whereas prolonged inhalation of nitric oxide attenuates hypoxic pulmonary vasoconstriction[12] and pulmonary vascular remodeling[13] in rats. Conversely, plasma levels of endothelin-1 are increased in association with hypoxemia in humans.[14] It is believed that endothelin-1 induces a decrease in the calcium-activated potassium current, contributing to hypoxia-induced pulmonary hypertension.[15] Endothelin receptor antagonists have been demonstrated to reduce hypoxic pulmonary vasoconstriction in animals.[16] [17] [18] [19] [20] [21]

Pulmonary vascular remodeling in response to hypoxia is also meditated by a number of growth factors. Platelet-derived growth factor-A (PDGF-A) and PDGF-B are elevated in hypoxic rats,[22] and vascular endothelial growth factor (VEGF), which is an endothelial cell-specific mitogen, is upregulated during exposure to chronic hypoxia.[23] [24] [25] VEGF is likely involved in pulmonary vascular injury and endothelial cell proliferation in the setting of chronic hypoxic pulmonary vascular remodeling because of its permeability, angiogenesis, proinflammatory properties,[26] and specificity for endothelial cells (Fig. 54-1) .

The roles of angiotensin-converting enzyme (ACE) and angiotensin II in the pulmonary circulation are becoming more established. Local increases in right ventricular ACE activity and expression likely play an important role in the pathogenesis of right ventricular hypertrophy secondary to hypoxic pulmonary hypertension. In chronically hypoxic rats the development of pulmonary hypertension and right ventricular hypertrophy is associated with a significant increase in membrane-bound right ventricular ACE activity.[27] ACE inhibitors attenuate the development of pulmonary hypertension in rats exposed to chronic hypoxia,[28] [29] and acute hypoxic pulmonary vasoconstriction is attenuated by type 1 angiotensin II receptor blockade.[30] Treatment of chronically hypoxic rats with ACE inhibitors also reduces right ventricular hypertrophy and fibrosis.[31]

Hypoxia inducible factor-1 (HIF-1)[32] represents a vital link between oxygen sensing, gene transcription, and the

TABLE 54-1 -- POTENTIAL PATHOGENETIC MECHANISMS LEADING TO PULMONARY ARTERIAL HYPERTENSION AND COR PULMONALE

MECHANISMS	EXAMPLE
Primary	
Anatomical decrease in crosssectional area (vessel destruction; encroachment on lumen by hypertrophy) of the pulmonary resistance vessels	Interstitial fibrosis and granuloma
Vasoconstriction of pulmonary resistance vessels	Hypoxia and acidosis
Contributory	
Large increments in pulmonary blood flow	Exercise

Increased pressures on the left side of the heart and pulmonary veins	Left ventricular failure or pulmonary venoocclusive disease
Increased viscosity of the blood	Secondary polycythemia or chronic hypoxia
Unproved	
Compression of pulmonary resistance vessels by raised alveolar pressures in their vicinity	Asthmatic bronchitis
Bronchial arterial-pulmonary arterial anastomoses	Expanded bronchial circulation

From Fishman AP: Pulmonary hypertension and cor pulmonale. In Fishman AP: Pulmonary Diseases and Disorders. 2nd ed. New York, McGraw-Hill, 1988, p 1001.

physiological adaptation to chronic hypoxia in vivo. One of the classic adaptations to chronic hypoxia is an increased rate of erythropoiesis that is mediated by the glycoprotein growth hormone erythropoietin. HIF-1 has been identified as a nuclear factor that is induced by hypoxia and bound to a site in the erythropoietin response element. HIF-1 expression is tightly regulated by cellular oxygen tension.

Changes in alveolar oxygenation affect the oxygenation of small pulmonary arteries and arterioles by direct gaseous diffusion from the alveoli, respiratory bronchioles, and alveolar ducts in the pulmonary arterioles, even though the latter are "upstream" in relation to the alveoli. This fact, taken together with evidence for a reduction in pulmonary arterial blood volume during hypoxia,[33] supports the view that the small pulmonary arteries and arterioles are the main sites of vasoconstriction and increased resistance in the pulmonary circulation during hypoxia.[33] [34] Although alveolar oxygen tension is a major physiological determinant of pulmonary arteriolar tone, a reduction in the oxygen tension in the mixed venous blood flowing through the small pulmonary arteries and arterioles may also contribute to pulmonary arterial vasoconstriction.[35]

Acidosis significantly increases pulmonary vascular resistance and acts synergistically with hypoxia.[36] In contrast, an increase in arterial P_{CO_2} seems to exert no direct effect but rather operates by way of the induced increase in hydrogen-ion concentration. Hypoxia and acidemia frequently coexist; and their interaction, which is clinically important, follows a predictable pattern.

ALTITUDE.

Life at high altitudes is associated with pulmonary hypertension of variable severity, reflecting the range of reactivities of different persons due to the pulmonary vasoconstrictive effect of hypoxia.[37] Altitude decreases the inspired partial pressure of oxygen (P_{IO_2}) because of a decrease in barometric pressure. At sea level, P_{IO_2} is on average 150 mm Hg. At high altitudes (3000 to 5500 m) P_{IO_2} decreases to 80 to 100 mm Hg, and at extreme altitudes,

Figure 54-1 This diagram demonstrates the existence of phenotypically unique cell subpopulations in the normal vascular media and their contribution to injury-induced vascular remodeling. In response to vascular injury, select cell subpopulations may be activated to migrate, proliferate, and/or change their production of specific matrix proteins. In addition, these cells may also produce autocrine or paracrine growth factors. The selectively activated cell population thus not only expands but also induces changes in other smooth muscle cell subpopulations in the vessel wall. Thus, the final vascular lesion observed in response to physiological stimuli is the collective product of many cell types and several cellular processes. *(From Stenmark KR, Frid MG: Smooth muscle cell heterogeneity: Role of specific smooth muscle cell subpopulations in pulmonary vascular disease. Chest 114:82S-90S, 1998.)*

5500 to 8840 m, P_{IO_2} decreases to 40 to 80 mm Hg. Corresponding alveolar P_{O_2} (P_{AO_2}) and arterial P_{O_2} (Pa_{O_2}) depend on the hypoxic ventilatory response and associated respiratory alkalosis. Mild pulmonary hypertension in adult natives at high altitude occurs at rest and may increase substantially with exercise. It is not immediately reversed by breathing of oxygen, does not seem to limit exercise capacity, and is rarely the cause of right ventricular failure.[38] [39] Severe pulmonary hypertension may occur with high altitude pulmonary edema, with infantile or adult forms of subacute mountain sickness, and with chronic mountain sickness. Subacute and chronic mountain sickness may be associated with right-sided heart failure. Subjects susceptible to high-altitude pulmonary edema often present with a slight increase in pulmonary vascular resistance at rest and exercise at sea level and with an enhanced pulmonary vascular reactivity to hypoxia. Transient right ventricular dysfunction has also been described with strenuous exercise at high altitude. In one study, 5 of 14 runners who completed an ultra-marathon at high altitude developed marked right ventricular dilation and hypokinesis, paradoxical septal motion, and pulmonary hypertension.[40] These echocardiographic abnormalities had all normalized at 1-day follow-up.

ASSESSMENT OF PATIENTS WITH COR PULMONALE SECONDARY TO LUNG DISEASE

CLINICAL EXAMINATION.

The clinical examination is a relatively insensitive means of detecting pulmonary hypertension

Figure 54-2 Upright chest radiograph in the posteroanterior (PA) projection in a man with severe COPD and pulmonary artery hypertension (mean pulmonary artery pressure = 47 mm Hg). The arrows indicate the widest dimensions of the enlarged right descending pulmonary artery. Note also the enlarged main pulmonary artery in the central left hemithorax. An enlarged right descending pulmonary artery (>16 mm Hg) and an enlarged main pulmonary artery on the PA projection are indicative of pulmonary artery hypertension in patients with COPD.

or right ventricular dysfunction in patients with chronic obstructive pulmonary disease (COPD), because clinical signs are often obscured by hyperinflation of the chest. The jugular venous pressure may also be difficult to assess in patients with COPD because of large swings in intrathoracic pressure. A systolic left parasternal heave indicates right ventricular hypertrophy, whereas the murmur of tricuspid regurgitation suggests right ventricular dilatation, but these are not always present and may be modified by hyperinflation. Accentuation of the pulmonic component of the second heart sound indicating pulmonary hypertension is a specific but insensitive finding in patients with COPD. Peripheral edema can be due to other causes (such as hypoalbuminemia) and does not always occur in patients with pulmonary hypertension. A progressive decrease in exercise tolerance in the absence of worsening pulmonary function should suggest a cardiovascular cause and prompt a thorough evaluation.

CHEST RADIOGRAPH

(Fig. 54-2) . The presence of pulmonary arterial hypertension in patients with COPD has been shown to be related to the width of the right descending pulmonary artery. A right descending pulmonary artery ranging from greater than 16 mm Hg in its widest dimension[41] to greater than 20 mm Hg has been reported to identify patients with pulmonary arterial hypertension.[42] In addition, a high value for the cardiothoracic ratio was 95 percent sensitive and 100 percent specific for the presence of pulmonary hypertension in patients with COPD.[42] Although measurements on plain chest radiography may be useful as an initial screening test for the presence of pulmonary arterial hypertension, they cannot be used to predict the level of pulmonary arterial pressure in individual patients. Dilatation of the right ventricle gives the heart a globular appearance, but right ventricular hypertrophy or dilatation is not easily discernible on a plain chest radiograph. Encroachment of the retrosternal air space on the

lateral film may be a helpful sign to confirm that the enlarged silhouette is a result of right ventricular dilatation.

ELECTROCARDIOGRAPHY.

The detection of right ventricular hypertrophy by the electrocardiogram (ECG) is highly specific but has a low sensitivity (see Chap. 5). Frequently used criteria for the diagnosis of right ventricular hypertrophy are outlined in Table 54-2 . However, these ECG abnormalities are usually less pronounced in COPD than other forms of pulmonary hypertension because of the relatively modest degree of pulmonary hypertension that occurs and because of the effects of hyperinflation (Fig. 54-3) . Butler and coworkers have introduced three criteria for right ventricular hypertrophy: (1) P wave amplitude <0.25 mV in II, III, aVF, and V_1 or V_2 ; (2) R wave amplitude
0.2 mV in I; and (3) A+R -PL
0.7 mV (A = R or R
in V_1 or V_2 ; R = S in I or V_6 ; PL = S in V_2).[43] These three criteria achieve 66 percent sensitivity in a group with right ventricular hypertrophy caused by mitral stenosis and 95 percent specificity in normal controls. When these criteria were evaluated in a population with cor pulmonale, their sensitivity was found to be even higher at 89 percent.[44]

ECHOCARDIOGRAPHY.

Although echocardiography is an invaluable tool in the evaluation of most forms of pulmonary hypertension (see Chap. 7), its utility is more limited in COPD because hyperinflation of the lungs and marked respiratory variations in intrathoracic pressures often result in suboptimal images. Delayed opening of the pulmonic valve, midsystolic closure, and an increase in the ratio of right ventricular preejection time to total ejection time have been described in patients with pulmonary hypertension.[45] Measurement of the velocity of blood flow in the main pulmonary artery can be used to estimate the pulmonary artery pressure.[46] The interval between the onset of right ventricular ejection and peak velocity, known as the time to peak velocity, correlates fairly well with the mean pulmonary artery pressure in patients with COPD (r = 0.7).[47] However, an adequate recording of the flow velocity from the pulmonary valve may be difficult to obtain. The addition of Doppler echocardiography has improved the assessment of right ventricular systolic ejection flow as an estimate of pulmonary artery systolic pressure[48] by adding the mean right atrial pressure to the peak systolic gradient between the right atrium and right ventricle. It is also possible to estimate the pulmonary end-diastolic pressure noninvasively by summing the mean right atrial pressure and the end-diastolic gradient between the pulmonary artery and the right ventricular outflow track using the pulmonary regurgitation jet. Because obtaining the estimates of peak tricuspid regurgitation velocities in patients with COPD can be difficult at times, saline contrast medium enhancement should be used to improve the accuracy of the measurements.[49]

Two-dimensional echocardiography can be used to assess right ventricular dimensions and wall thickening and right ventricular volume overload in patients with COPD. Detection of right ventricular hypertrophy by echocardiography

Figure 54-3 Electrocardiogram in a patient with emphysema and diffuse lung disease; there is right-axis deviation, "P pulmonale," a qR pattern in V_1 and an rS pattern in V_6 . *(From McGowan FX, Wagner GS: The electrocardiogram in chronic lung disease. In Rubin LJ [ed]: Pulmonary Heart Disease. Boston, Martinus Nijhoff, 1984, p 117.)*

is limited by the ability to differentiate the right ventricular wall from its surrounding structures. Moreover, correlations between the thickness of the right ventricular wall and the right ventricular mass are poor, even when measured at autopsy.[50] Measurement of the right ventricular diastolic diameter by echocardiography may be useful in detecting right ventricular enlargement. Right ventricular dysfunction is difficult to quantitate echocardiographically, but the position and curvature of the intraventricular septum gives an indication of right ventricular afterload. The utility of transesophageal echocardiography in the evaluation of pulmonary hypertension has yet to be fully explored, but this technique will usually provide satisfactory imaging of the right-sided heart structures in patients whose transthoracic images are of poor quality.

RADIONUCLIDE VENTRICULOGRAPHY (See also Chap. 9).

Radionuclide ventriculography can provide useful information regarding right ventricular function, provided that adequate separation of the cardiac chambers can be accomplished. Because radioactive counts are proportional to volume, variations in the geometric configuration of the ventricles are less important. Although pulmonary artery pressure can not be estimated with this technique, there is an inverse relationship between pulmonary artery pressure and right ventricular ejection fraction in COPD.[51] In most patients with pulmonary vascular disease caused by COPD, the right ventricular ejection fraction is preserved at rest but fails to increase appropriately during exercise.[51] Contractility appears to be maintained until late in the course of the disease, and the abnormal right ventricular response during exercise is most likely due to increased afterload. Patients in whom the right ventricular ejection fraction is reduced usually have more severe pulmonary hypertension or overt signs of right-sided heart failure.

COMPUTED TOMOGRAPHY (See also Chap. 10).

CT determined pulmonary arterial cross-sectional diameter correlates well with mean pulmonary artery pressure.[52] A high-resolution CT scan of the chest is also the most accurate noninvasive means of detecting emphysema in vivo.[53] The principal manifestation of emphysema is a hyperlucent region of lung tissue with no or only a very thin visible wall. Because CT has 10 times the density resolution of conventional radiography, it more readily distinguishes the emphysematous spaces from surrounding lung tissue. Other findings on high-resolution CT include ground-glass opacity, bullae, bronchial wall thickening, mucous plugging of bronchi and bronchioles, overinflation, air trapping (manifest as a lack of expected increase in lung capacity on exhalation scans), central arterial dilatation reflecting pulmonary arterial hypertension, and modest mediastinal lymphadenopathy. CT may demonstrate emphysema in patients with little or no abnormality on pulmonary function tests. Because the aggregate cross-sectional area is so large, the respiratory bronchioles contribute only a small portion of the total resistance to air flow, which causes poor sensitivity of pulmonary function tests.

MAGNETIC RESONANCE IMAGING (See also Chap. 10).

MRI is becoming the reference standard for measuring ventricular dimensions because it produces the best images of the right ventricle. This technique is noninvasive and does not impose a radiation burden on the patient, but it is expensive and available only in specialized centers. Studies in patients with COPD have demonstrated a correlation between the right ventricular free-wall volume and both pulmonary artery pressure (r = 0.72, $p > 0.01$) and pulmonary vascular resistance (r = 0.65, $p > 0.01$).[54] Interestingly, the right ventricular free-wall volume as an estimate of wall mass correlates with the Pa_{CO_2} but not with the Pa_{O_2} .[54] MRI can be used to diagnose right ventricular hypertrophy in patients with COPD and to study the effect of therapeutic interventions. It can also be used to quantify regional right ventricular function to determine the impact of chronic pulmonary hypertension on right ventricular performance.[55]

PULMONARY HYPERTENSION ASSOCIATED WITH RESPIRATORY DISORDERS

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease is the fourth leading cause of death in the United States, affecting over 14 million people.[56] The incidence, morbidity, and mortality from COPD is rising and varies widely among countries. In fact, the mortality attributed to COPD in the United States rose by 32 percent during the past decade.[56] This may be related to differences in exposure to risk factors as well as to large variations in individual susceptibility. COPD is a heterogeneous group of diseases that share a common feature: the airways are narrowed, which causes the inability to exhale completely. Although there are numerous disorders that fall under the heading of COPD, the two largest components are emphysema and chronic bronchitis. The American Thoracic Society defines COPD as a disorder characterized by abnormal tests of expiratory flow that do not change markedly either spontaneously over short periods of time or after administration of a bronchodilator.[57] Although clear-cut distinctions can often be made, there is considerable overlap as to the dominant abnormality in the individual patient in whom features of both may be manifest. *Chronic bronchitis* is a condition associated with excessive tracheal bronchial mucous production sufficient to cause cough with

expectoration for at least 3 months of the year for more than 2 consecutive years. *Emphysema* is defined as the permanent, abnormal distention of the air spaces distal to the terminal bronchial with destruction of the alveolar septa. In lungs from patients with COPD studied at postmortem, the major site of air flow obstruction has been shown to be in the small airways.

Cigarette smoking is the most commonly identified correlate with COPD and accounts for 80 to 90 percent of the

risk of developing COPD.[58] It has been estimated that 15 percent of one-pack-per-day smokers and 25 percent of two-pack-per-day smokers will eventually develop COPD during their lifetime.[58] [59] Why the proportion is so small is not known, but underlying host factors may play a role. Other potential environmental causes include air pollution, occupational exposures, and infection. Individuals who are homozygous for alpha$_1$ -antitrypsin deficiency develop severe emphysema in the third and fourth decades of life. Dusty occupational environments are well-established risks but probably not major factors in North America.

PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION.

Most commonly, pulmonary hypertension in COPD is due to multiple factors, which include pulmonary vasoconstriction caused by alveolar hypoxia, acidemia, and hypercarbia; the mechanical effects of the high lung volume on pulmonary vessels; the loss of small vessels in the vascular bed in regions of the emphysema and lung destruction; and the increased cardiac output and blood viscosity from polycythemia secondary to hypoxia. Of these causes, hypoxia is undoubtedly the most important and is associated with pathological changes that occur characteristically in the peripheral pulmonary arterial bed.[60] The small pulmonary arteries develop accumulations of vascular smooth muscle cells in their intima that are laid down longitudinally along the length of the vessels. Intimal thickening appears to be an early event that occurs in association with progressive air flow limitation.[61] Medial hypertrophy in the muscular pulmonary arteries, and less commonly fibrinoid necrosis in these vessels, has also been reported in patients with COPD with chronic pulmonary arterial hypertension. Thus, structural change, rather than hypoxic vasoconstriction, is required for the development of sustained pulmonary hypertension in patients with COPD.[62]

Changes in airway resistance may augment pulmonary vascular resistance in patients with COPD by affecting the alveolar pressure. The normal linear relationship between pressure and flow in the pulmonary circulation changes when alveolar pressure is increased. The effect of airway resistance on pulmonary artery pressure may be particularly important when ventilation increases (such as in acute exacerbation of COPD). In patients with COPD, even the small increases in flow that occur during mild exercise may increase pulmonary artery pressure significantly. Alveolar hypoxia is a potent arterial constrictor in the pulmonary circulation, which reduces perfusion with respect to ventilation in an attempt to restore Pa_{O_2} . In patients with COPD there is a positive correlation between the Pa_{CO_2} and the pulmonary artery pressure. Polycythemia, which may develop in response to chronic hypoxemia, increases the blood viscosity, which may also contribute to the severity of pulmonary arterial hypertension. Pulmonary arterial thrombosis may also occur in patients with COPD and may be a result of peripheral airway inflammation.

HEMODYNAMIC CHANGES.

The elevation in pulmonary artery pressure tends to be rather mild in patients with COPD. Naeije studied 74 patients with severe, but clinically stable COPD. All presented with episodes of acute and chronic respiratory failure in the past, and almost half presented with peripheral edema.[63] They all had severe air flow limitations (FEV_1 25.7 ± 1 percent of predicted) and hypoxemia (Pa_{O_2} mean 43 mm Hg, range 23 to 67 mm Hg), and the majority were also hypercapnic (Pa_{CO_2} mean 51 mm Hg, range 33 to 68 mm Hg). However, the pulmonary artery pressure was only modestly raised to a mean of 35 mm Hg in this group. Although the pulmonary artery pressure may be normal or only slightly elevated when measured at rest in patients with COPD, it may increase to abnormal levels during exercise.[64]

The progression of pulmonary hypertension seems to be related to hypoxemia. In 93 patients with COPD observed for 5 years, hemodynamic worsening, defined as an increase in mean pulmonary artery pressure by more than 5 mm Hg, was observed in 29 percent of patients.[65] In these patients there was a marked worsening of hypoxemia that was not observed in the others. In patients with mild COPD, right ventricular end-diastolic pressure and right ventricular stroke work, which were normal at rest, increased during exercise due to an increase in work against a higher pulmonary artery pressure.[66]

Severe pulmonary arterial hypertension is uncommon in the presence of COPD. In a review of 500 patients referred with cor pulmonale, only 6 were found to have severe elevation in mean pulmonary artery pressure (>50 mm Hg), which was not related to the severity of their underlying lung disease.[67] This observation suggests that a different biological mechanism results in changes in the pulmonary vascular bed in susceptible patients and that pulmonary hypertension occurs in the presence of lung disease rather than as a *result* of the lung disease. This has important implications with respect to treatment. Patients who present with severe pulmonary hypertension should be evaluated for another disease process that is responsible for the high pulmonary arterial pressures before attributing it to the COPD.

PROGNOSIS AND PREDICTORS OF SURVIVAL.

Although pulmonary arterial hypertension progresses slowly in patients with COPD, its presence confers a poor prognosis. Weitzenblum and coworkers showed a 72 percent 4-year survival rate in those with normal pulmonary artery pressure compared with a 49 percent survival rate in those with an elevated pulmonary artery pressure (mean > 20 mm Hg).[68] Burrows and colleagues studied 50 patients with chronic airway obstruction over 7 years and showed that the pulmonary vascular resistance was the hemodynamic parameter that correlated best with mortality.[69] In this study, none of the patients whose pulmonary vascular resistance exceeded 7 Wood Units survived for more than 3 years. France and colleagues, in a study of 115 patients with COPD, found that a number of variables correlated significantly with mortality, including Pa_{O_2} , Pa_{CO_2} , $FEV_{1,}$ and the presence of peripheral edema.[70] Others have reported that patients with COPD who develop peripheral edema have a 5-year survival rate of only 27 to 33 percent.[71]

A 10-year follow-up study conducted on a cohort of 870 patients with severe COPD concluded that (1) patients with COPD have a high mortality rate from acute respiratory failure, cor pulmonale, and lung cancer; (2) patients' age at the time of diagnosis influences the death hazard; (3) patients who need long-term oxygen treatment have a higher death hazard than those who do not; (4) the higher the FEV_1 or Pa_{O_2} at the time of diagnosis, the lower the death hazard; (5) patients who need and use long-term oxygen treatment have a lower death hazard compared with those who need it but do not use it properly; and (6) patients with a partial reversible airway obstruction who regularly attend the clinic for planned checkups have a lower death hazard compared with those who have the same characteristics but do not show adherence to the care program.[72] In another study, among a cohort of 270 patients with COPD, the median survival was 3.1 years. Death was predicted by the following variables: age, ECG signs of right ventricular hypertrophy, chronic renal failure, ECG signs of myocardial infarction or ischemia, and FEV_1 less than 590 ml.[73] Among 166 patients treated with long-term oxygen therapy, the overall survival rates were 78.3 percent and 67.1 percent at 2 and 3 years, respectively. A multivariate analysis showed an independent predictive power for right ventricular systolic pressure, age, and FEV_1 .[74] Once endotracheal intubation is necessary, the prognosis is usually poor and the survival after 1 year is usually lower than 40 percent.[75] Pulmonary embolism is a common cause of death, with the frequency estimated to be approximately 11 percent.[76]

Among patients with COPD in the intensive care unit, pulmonary embolism was the most frequent cause of death at 40.6 percent.

Treatment

Management goals in COPD are to ameliorate air flow obstruction and improve symptoms, to avoid secondary complications, to maintain functional capacity, and to improve the quality of life. Recent advances in smoking cessation strategies and surgical techniques (lung volume reduction surgery and lung transplantation) and renewed interest in noninvasive positive-pressure ventilation have expanded treatment options to meet the patient's needs. In addition to the specific therapies discussed here, all patients should receive a yearly influenza vaccination and the 23-valent pneumococcal vaccination at least once in their lifetime. For patients who do not receive influenza vaccine and are at risk for influenza type A infection, amantadine, 200 mg/d, or rimantadine, 100 mg twice per day, should be prescribed until the risk of infection has subsided.

SMOKING CESSATION.

The importance of smoking cessation cannot be overemphasized. The annual rate of decline of FEV_1 in smokers is approximately 80 ml per year, in contrast to 25 to 30 ml per year in nonsmokers. The Lung Health Study reported that patients who stopped smoking had a small improvement in FEV_1 (57 ml) after 1 year. [77]

Thereafter, the rate of decline in lung function is similar to age-matched nonsmokers. The short-term success rates with smoking cessation are variable (18-77 percent), but success is more likely if the patient abstains from smoking within the first 2 weeks of entry into a program. The use of nicotine replacement therapy should always include a structured behavioral modification program to increase the likelihood of success. Pharmacological methods to reduce addictive behavior have not been found to be effective in controlled clinical trials.[78] Recently, the novel antidepressant bupropion (Zyban), which enhances noradrenergic activity, was reported to have a successful smoking cessation rate of 44 percent, compared with 19 percent in the placebo group.[79]

PULMONARY REHABILITATION.

Patients with advanced COPD often lead a sedentary lifestyle because of breathlessness during mild to moderate exercise. The lack of exercise leads to deconditioning and worsening dyspnea, even with low levels of activity. The overall goal of a pulmonary rehabilitation program is to maintain the individual's maximal level of independence and functioning in the community. Pulmonary rehabilitation can improve exercise endurance and decrease the sense of breathlessness. Several studies have demonstrated that pulmonary rehabilitation can improve exercise capacity, subjective symptoms, and quality of life.

Because of hyperinflation, deconditioning, and malnutrition, patients with advanced air flow obstruction have weakened ventilatory muscles. Moreover, because of the increased work of breathing, the inspiratory muscles are prone to fatigue. Fortunately, the respiratory muscles can be trained to improve their strength and endurance. Strength training can be achieved by high-intensity, low-frequency stimuli such as inspiring against a closed glottis or shutter valve. Endurance training may also improve inspiratory muscle strength.

OXYGEN.

Hypoxemia is a common finding in patients with advanced COPD and is easily corrected with low-flow supplemental O_2 . In key clinical trials sponsored by the National Institutes of Health (NIH, Nocturnal Oxygen Therapy Trial [NOTT] Group, 1980) and the British Medical Research Council (1981) long-term oxygen therapy clearly improved the survival of hypoxemic patients with COPD (Fig. 54-4) .[80] [81] The British study compared the effect of treatment with oxygen for approximately 15 hours per day with the effects of no oxygen therapy, whereas the NIH

Figure 54-4 Survival curves in the MRC (British) and NIH (US) long-term oxygen therapy trials in patients with severe hypoxemia and cor pulmonale. *(From Flenley DC, Muir AL: Cardiovascular effects of oxygen therapy for pulmonary arterial hypertension. Clin Chest Med 4:297, 1983.)*

study compared nocturnal oxygen therapy (about 12 hours per day) to "continuous" oxygen therapy (at least 19 hours per day). In each study, the mean baseline Pa_{O_2} when the patients were breathing ambient air was 51 mm Hg; the mean FEV_1 was 0.7 to 0.8 liter.

Oxygen therapy was beneficial in both studies (see Fig. 54-4). In the British study, 19 of 42 (45 percent) oxygen-treated patients died within 5 years, whereas 30 of 45 (67 percent) untreated patients died. In the NIH study, the mortality rate after a year was 20.6 percent in the group receiving nocturnal oxygen and 11.9 percent in the group receiving continuous oxygen therapy; and after 2 years, mortality was 40.8 percent and 22.4 percent, respectively. The relative risk of death for nocturnal oxygen therapy compared with continuous oxygen was 1.94. Oxygen therapy is therefore effective, and continuous therapy is more effective than nocturnal therapy only.

HEMODYNAMIC EFFECTS OF OXYGEN.

How oxygen therapy improves survival is unknown. Two major hypotheses have been proposed: (1) oxygen relieves pulmonary vasoconstriction, decreasing pulmonary vascular resistance and thus enabling the right ventricle to increase stroke volume, and (2) oxygen therapy improves arterial oxygen content, providing enhanced oxygen delivery to the heart, brain, and other vital organs. These two hypotheses are not mutually exclusive, and each one has supporting evidence. Oxygen therapy clearly alleviates the progressive pulmonary hypertension of untreated COPD. Patients who exhibit a significant decrease in pulmonary artery pressure (>5 mm Hg) after acute oxygen therapy (28 percent oxygen for 1 day) have better survival than patients who do not respond acutely when both groups of patients are subsequently treated with long-term continuous oxygen therapy.[82] Enhanced right ventricular performance during short-term oxygen therapy may also be the direct result of improved tissue (e.g., myocardial) oxygenation rather than decreased pulmonary vascular resistance.[83]

RECOMMENDATIONS.

Criteria for chronic home O_2 therapy are shown in Table 54-3 . Long-term oxygen therapy is warranted if the resting Pa_{O_2} remains less than 55 mm Hg after a 3-week stabilization period on maximal medical therapy (e.g., bronchodilators, antimicrobial agents, diuretics). Patients with a Pa_{O_2} above 55 mm Hg should be considered for oxygen therapy if they are polycythemic or have clinical evidence (e.g., ECG, physical examination) of pulmonary hypertension.[84] Hypoxemia should be documented after the stabilization period to avoid the cost of long-term

TABLE 54-3 -- INDICATIONS FOR HOME OXYGEN

Absolute

oxygen therapy in patients who do not require it. In the NOTT study,[81] 45 percent of hypoxemic patients initially selected for study improved enough during 3 to 4 weeks of observation and treatment to suspend plans for long-term oxygen therapy. An even longer observation period of 2 or 3 months may be necessary to exclude patients who eventually achieve acceptable Pa_{O_2} values on medical therapy alone. For sedentary patients already on supplemental O_2 , the resting O_2 requirement may be increased by 1 liter/min during mild activities. Oxygen has been shown to delay the onset of fatigue in exercising muscles, thus improving ventilatory endurance and exercise capacity.[85] In addition, it also decreases dyspnea and minute ventilation for a given workload.[86] Nocturnal oxygen therapy may be important in patients with sleep desaturation. Daily activities, such as walking, washing, and eating, are associated with transient oxygen desaturation in patients with moderate to severe COPD, even in the absence of resting hypoxemia.[87] Ambulatory oxygen therapy in patients with COPD and exercise hypoxemia may improve exercise capacity and breathlessness.[88]

Carbon dioxide retention may occur with supplemental O_2 , especially with higher O_2 concentrations, and is thought to be due to blunting of hypoxemia driven central respiratory drive. This observation may lead some physicians to withhold O_2 therapy. It is now believed that the main mechanism for CO_2 retention in these patients is worsening ventilation-perfusion inequality due to O_2 -induced pulmonary vasodilatation in areas of the lung with poorer ventilation. Ambier and colleagues show that

central respiratory drive is normal or slightly increased in patients who develop hypercapnia while on O_2 therapy.[89] If CO_2 retention is associated with systemic acidosis (pH 7.25 or less) and the patient requires high O_2 flow to maintain satisfactory PaO_2 , mechanical ventilation should be considered.

ANTICHOLINERGICS.

Anticholinergics are the bronchodilators of choice in the management of COPD and appear to be more effective than $beta_2$ agonists. [90] Anticholinergic drugs, typified by atropine, cause bronchodilatation by blocking cholinergic mediated increases in bronchomotor tone. In addition, they also block the afferent limb of the vagally mediated bronchoconstriction induced by nonspecific airway irritants such as cigarette smoke, dust, and fumes. Ipratropium bromide can achieve similar, if not greater, degrees of bronchodilatation than beta agonists and has fewer side effects. It has been suggested that ipratropium bromide should be the initial agent in the chronic therapy for COPD.[91] Combination therapy with anticholinergic and $beta_2$ agonists has been shown to be more effective than either drug alone.[92] Unlike beta agonists, anticholinergic drugs have a slower onset of action and a longer half-life. The usual dose of ipratropium bromide is two puffs every 4 to 6 hours. An investigational agent, ipatropium bromide, gives prolonged bronchodilatation lasting over 24 hours and has the advantage of improved compliance with once-daily dosing.[93]

BETA-ADRENERGIC AGONISTS.

These are important drugs in the management of chronic air flow obstruction. In contrast to asthma, however, a lesser degree of bronchodilatation is seen in COPD. The absence of a significant bronchodilator response on a single spirometry (post-bronchodilator increase in FEV_1 by greater than 15 percent) does not preclude the delayed effectiveness of beta agonists. As many as 70 percent of patients who show no initial response to a beta agonist will show greater than 15 percent improvement in FEV_1 on subsequent spirometry.[91] The increases in vital capacity are usually higher than those observed for FEV_1 , and they are often associated with symptomatic improvement.[94] Recent studies have shown that the long-acting inhaled $beta_2$ agonists salmeterol and formoterol are beneficial in patients with COPD, resulting in improved lung function and symptom control.[95] [96] The side effects of properly used inhaled beta agonists are minimal and limited to skeletal muscle tremors and tachycardia. Although there is no evidence that the regular use of a beta agonist increases mortality in patients as alluded to in asthma, it is generally recommended that a beta agonist should be used on an "as needed" basis. In patients with severe COPD, regularly dosed beta agonists may improve symptoms.[97]

THEOPHYLLINE.

The use of theophylline in COPD has been tempered by its frequent side effects, variable hepatic metabolism, and studies showing little symptomatic benefit. However, theophylline is an effective bronchodilator in COPD and will cause a small improvement in results of pulmonary function tests.[98] [99] Long-term use has been associated with an overall 10 to 20 percent increase in the FEV_1 from baseline, and an improvement in minute ventilation and gas exchange has also been observed.[98] [100] In addition to improving FEV_1 , theophylline reduces dyspnea,[98] [101] improves exercise performance,[102] and is associated with a subjective sense of well-being in patients with severe COPD, even if the reduction in dyspnea is not accompanied by a change in functional indices such as FEV_1 or arterial blood gases.[101]

CORTICOSTEROIDS.

Because there is continued neutrophilic inflammation in COPD, it was thought that inhaled corticosteroids might prevent the progression of disease. However, there is little evidence that inhaled corticosteroids are of benefit to a large percentage of patients.[103] The few patients (approximately 10 percent) who have some response to corticosteroids have asthma. A large study (the European Respiratory Society Study on Chronic Obstructive Pulmonary Disease [EUROSCOP]) in patients with mild COPD showed no overall effect of an inhaled corticosteroid (budesonide, 400 mug twice daily) on the annual rate of decline in lung function, although some subgroups appear to benefit.[104] A recent trial of even higher doses of inhaled budesonide, 1600 mug/d, versus placebo showed no physiological or functional benefit in patients with advanced COPD after 6 months.[105] A 3-year placebo-controlled, parallel group, randomized, double-blinded trial of inhaled budesonide demonstrated no clinical benefit in COPD patients.[106]

The effects of oral corticosteroids are similarly disappointing. Only 10 to 20 percent of COPD patients with judicious use of oral corticosteroids will show improvement in pulmonary symptoms and FEV_1 by 20 to 25 percent,[107] as well as decreasing the number of acute exacerbations[108] and airway responsiveness. Clinical criteria that may be useful in predicting corticosteroid responders from nonresponders includes a significant bronchodilator response

to a beta agonist, presence of eosinophils in the sputum or blood, and a history of atopy.

DIGITALIS.

The effects of digitalis in cor pulmonale are complex. The cardiac glycosides increase the contractility of the RV myocardium, but they also can produce pulmonary vasoconstriction. Furthermore, Sylvester and associates[109] showed that, in dogs, digitalis can reduce venous return, which may adversely affect cardiac output. Intravenous digoxin may also improve diaphragm strength and blood flow in patients with COPD with acute respiratory failure.[110]

Digitalis therapy is indicated in patients with cor pulmonale and coexistent left ventricular failure. In patients with severe COPD and biventricular failure, an improvement in right ventricular ejection fraction has been observed with digoxin,[111] but not in patients with a reduced right ventricular ejection fraction and normal left ventricular function.[112] Recently, it was demonstrated that short-term intravenous digoxin improved cardiac output and reduced circulating norepinephrine[113] in patients with right ventricular dysfunction due to primary pulmonary hypertension. Digitalis therapy may cause an increased incidence of adverse side effects (e.g., cardiac arrhythmias) in patients with obstructive lung disease, presumably in part owing to the effect of hypoxia.

VASODILATORS.

No agent other than oxygen has been shown convincingly to vasodilate the pulmonary circulation in patients with COPD. Nonselective beta-adrenergic antagonists may reduce systemic arterial oxygen saturation from intrapulmonary shunting associated with an increase in dyspnea in these patients. Hydralazine and calcium channel blockers have been shown to have essentially no effect on pulmonary hemodynamic measurements in patients with COPD. Currently, there is no role for oral vasodilators in the management of COPD.

NITRIC OXIDE.

Inhaled nitric oxide (NO) has been used as a selective pulmonary vasodilator due to its short duration of action and inactivation in the systemic circulation,[114] but it is difficult to use over a prolonged period. A recent study demonstrated that the combined inhalation of NO and O_2 was associated with reductions of the mean pulmonary artery pressure and pulmonary vascular resistance and a remarkable improvement in arterial oxygen saturation.[115] Other studies have suggested that inhaled NO worsens oxygenation in the setting of COPD, potentially by overriding hypoxic pulmonary vasoconstriction.[116] [117] The role of NO in the therapy for COPD has yet to be defined.

ACE INHIBITORS.

Angiotensin II is a potent pulmonary and airway constrictor acting through angiotensin II receptors. The role of ACE inhibitors and angiotensin II receptor antagonists is still emerging. In one trial, enalapril reduced pulmonary hypertension and improved renal blood flow in 30 patients with COPD.[118] The angiotensin receptor blocker losartan also reduces pulmonary artery pressure in patients with COPD[119] and therefore may be useful in preventing the progression of pulmonary hypertension and cor pulmonale in patients with severe COPD. Further investigation needs to be completed before making generalized recommendations regarding these agents in patients with COPD.

NONINVASIVE VENTILATION.

Noninvasive positive-pressure ventilation (NPPV) has been reported to improve gas exchange, sleep efficiency, quality of life, and functional status in patients with restrictive lung disease and chronic respiratory failure. Its usefulness in patients with COPD is not as well established. The initial interest in using intermittent noninvasive ventilation for patients with severe COPD arose from physiological studies on respiratory muscle function. Hyperinflation in patients with COPD was found

to place the respiratory muscles at a mechanical disadvantage. The flattened diaphragms had shortened sarcomere lengths, diminished maximal force, increased muscle tension, and compromised blood supply. Based on these considerations, investigators hypothesized that noninvasive ventilation would be of value to patients with severe COPD because it would rest the chronically fatigued muscles. Periods of intermittent rest would permit recovery of muscle function, increasing muscle strength, reducing the tendency to fatigue, and improving pulmonary function and gas exchange.

An alternative hypothesis was generated based on sleep studies in COPD. Patients with severe COPD have a high prevalence of sleep-disordered breathing, including not only obstructive sleep apnea but also episodes of hypoventilation associated with oxygen desaturations.[120] Large retrospective analyses have examined outcomes of patients treated with NPPV for periods ranging up to 5 years.[121] [122] Patients with COPD were less likely to continue NPPV treatment than patients with neuromuscular disorders or chest wall deformities, but the average duration of continuation was still 2 to 3 years. Although the survival of patients with COPD treated with long-term NPPV appears to be comparable to that of patients treated with tracheostomies or long-term oxygen therapy, the retrospective and uncontrolled nature of these trials greatly limits any conclusions that can be drawn.

A recent consensus conference suggested that patients with severe CO_2 retention, particularly those with nocturnal oxygen desaturation, appear most likely to respond favorably to NPPV.[123] The statement specifically recommends consideration of NPPV for those patients with COPD and symptoms such as fatigue, dyspnea, and morning headache despite optimal medical management and one of the following physiological criteria: Pa_{CO_2} greater than or equal to 55 mm Hg; Pa_{CO_2} of 50 to 54 mm Hg and nocturnal desaturation (oxygen saturation < 88 percent for 5 continuous minutes while receiving 2 L/min or more of nasal O_2); or Pa_{CO_2} of 50 to 54 mm Hg and hospitalization (two or more times in a 12-month period) related to recurrent episodes of hypercapnic respiratory failure.

LUNG VOLUME REDUCTION SURGERY.

Volume reduction surgery, which was originally described by Brantigan, has been advocated in selected patients with advanced emphysema. The surgical technique involves removing 20 to 30 percent of the volume of each lung by means of sternotomy, sequential thoracotomy, or thoracoscopy to reduce the severe hyperinflation commonly seen in patients with severe COPD. The physiological improvement after excision of large bullae in patients with severe emphysema is easy to understand. The compressed normal lung parenchyma expands after bullaectomy, resulting in improved lung function and exercise capacity. In patients with diffuse emphysema, the exact mechanism of these physiological improvements is less clear. The proposed benefits of surgery include the following: restoration of elastic recoil on small airways leading to decreased airway resistance; restoration of normal outward chest recoil; improved ventilation-perfusion matching; and a reduction in end-expiratory lung volume, thereby returning the diaphragm to a more favorable length-tension precontraction length for optimal pressure generation. There are, however, very strict criteria for lung volume reduction surgery (Table 54-4) . Although the medical selection criteria are less stringent for lung volume reduction surgery than for lung transplantation, the disease-specific criteria are more restrictive. The residual volume to total lung capacity ratio is the single most important determinant of improvement in pulmonary function after lung volume reduction surgery.[124]

Patients with COPD who are thought to respond best to surgery have the following characteristics: heterogeneous bullous changes within the lung as detected by CT and ventilation-perfusion scan; presence of severe hyperinflation; reduced diaphragmatic excursion; and absence of hypercapnia and pulmonary hypertension. Long-term follow-up data are still not available, and it is not clear how long

TABLE 54-4 -- CRITERIA FOR LUNG VOLUME REDUCTION SURGERY

No age restriction
Marked disability after completing pulmonary rehabilitation (see text)
No tobacco use for at least 4 months
Imaging must show heterogeneous disease (homogeneous disease has more stringent criteria)
Pulmonary function tests (all after bronchodilator administration; lung volumes measured by plethysmography)
Forced expiratory volume in 1 second (FEV_1)
45% if age >70 years, an FEV_1
15% predicted)
Total lung capacity
110%
Residual volume
150%
Diffusing capacity of the lung for carbon monoxide
70%
Absence of bronchodilator response (FEV_1) change
30% and 300 ml
Pa_{CO_2} <60 mm Hg
Pa_{O_2} >45 mm Hg on room air
Mean pulmonary artery pressure
35 mm Hg or peak systolic pressure
45 mm Hg

the improvement in lung function seen after lung volume reduction will persist. Maximal improvement in lung function indices are seen at 6 months after surgery; and although improvements are maintained at 1 year, there may be a trend toward falling indices compared with the 6-month values.[125] Lung volume reduction is palliative to a procedure that does not halt but only slows the rate of functional decline for COPD. The disease will still progress, and symptoms will likely worsen.

LUNG TRANSPLANTATION.

COPD is the most common indication for lung transplantation worldwide. In 1995, approximately 60 percent of single lung and 30 percent of bilateral lung transplants were performed on patients with COPD.[126] Lung transplantation is a viable treatment option in patients with advanced pulmonary parenchymal or pulmonary vascular disease who have exhausted medical management. Both the number of patients waiting for lung transplantation and the waiting period have increased. Because of the scarcity of organ donors, the waiting time is now approximately 18 to 24 months in the United States. Patient selection and timing of referral for lung transplantation should take into account this waiting period. Selection criteria are outlined in Table 54-5 , although they may differ among lung transplant centers. Currently, both single-lung transplantation and bilateral lung transplantation result in significant improvement in postoperative lung function, exercise capacity, and quality of life.[127] The choice of the procedure needs to be individualized. In general, single-lung transplantation is used for emphysema because of the scarcity of organ donors, lower perioperative morbidity and mortality, and comparable improvement in exercise capacity compared with bilateral lung transplantation.[128] However, postoperative spirometry, single breath diffusing capacity, and arterial oxygen tension are all significantly higher in bilateral lung transplantation compared with single-lung transplantation, which may benefit young patients with emphysema because the higher pulmonary reserve will offset any decline in lung function due to infection or rejection. In most centers, bilateral lung transplantation is reserved for patients with suppurative lung disease or pulmonary vascular disease. The 1-year and 5-year survival for single and bilateral lung transplantation for emphysema is approximately 80 percent and 40 percent, respectively.

Complications associated with lung transplantation recipients are due to infections (i.e., bacterial, viral, or fungal), chronic rejection (bronchiolitis obliterans), and

TABLE 54-5 -- CRITERIA FOR LUNG TRANSPLANTATION FOR COPD

Ambulatory with rehabilitation potential 80-120% of ideal body weight
Approximate maximum age (years)

65 (single-lung recipients)
60 (double-lung recipients)
55 (heart-lung recipients)
Severely ill despite optimal medical therapy
NYHA Class III
FEV_1 <20% of predicted
Rapid decline in FEV_1
Hypoxia
Hypercapnia
Minimal corticosteroid use (15-20 mg qd)
Creatinine clearance >50 mg ml/min
Contraindications
Recent or current malignancy
Significant disease affecting other organ systems
Extrapulmonary infections
Substance abuse (including cigarettes) for more than 6 months
Ventilator dependence

noninfectious complications due to prolonged immunosuppression. Chronic rejection, manifest clinically as progressive deterioration in lung function and pathologically as bronchiolitis obliterans, can occur in 40 percent of lung transplant recipients and is now the most common cause of death among long-term survivors.[129]

Interstitial Lung Disease

Interstitial lung diseases represent a variety of conditions that involve the alveolar walls, perialveolar tissue, and other contiguous supporting structures. Cor pulmonale occurs in a variety of interstitial lung diseases and is often associated with obliteration of the pulmonary vascular bed by lung destruction and fibrosis. The mechanism for pulmonary hypertension may be related to hypoxemia or a loss of effective pulmonary vasculature from lung destruction and/or by indirectly triggering a pulmonary vasculopathy. Interstitial lung disease may be due to environmental inhalant exposures, such as to asbestos, drugs, and chemotherapeutic agents, to radiation, and to recurring aspiration pneumonias. A large number of patients have interstitial lung disease of unknown etiology, the most common being idiopathic pulmonary fibrosis (IPF) and interstitial lung disease associated with collagen vascular diseases.

IDIOPATHIC PULMONARY FIBROSIS.

IPF can be associated with pulmonary hypertension, which is difficult to manage because the current medical therapy for IPF is only minimally effective. Most patients are older than 50 years of age and usually report an insidious onset of progressive dyspnea and cough from months to years. The physical findings are typified by inspiratory crackles on chest examination and clubbing of the fingers. The chest radiograph may show bilateral peripheral-based opacities and honeycombing predominantly involving the lower lung zones. Pulmonary function tests show reduced lung volumes with restrictive physiology and a diminished diffusing capacity for carbon monoxide. IPF is a diagnosis of exclusion, and other forms of diffuse parenchymal lung disease need to be ruled out. A definitive diagnosis of IPF requires an open-lung biopsy.[130] Other lung diseases that need to be distinguished include bronchiolitis obliterans with organizing pneumonia, nonspecific interstitial pneumonia, desquamative interstitial pneumonia, acute interstitial pneumonia, lymphocytic interstitial pneumonia, respiratory bronchiolitis-associated

Figure 54-5 Pathogenesis of pulmonary fibrosis. There are numerous pathways that can lead to pulmonary fibrosis, and none is mutually exclusive. This scheme poses a problem in that specific targeted therapy would likely be ineffective because of the redundancy of pathways toward fibrosis. However, it is likely that only a few of these pathways are critical in human idiopathic pulmonary fibrosis. Studies with keratinocyte growth factor (KGF) in rats and gene deletion studies in mice indicate that a single growth factor or receptor might be highly effective. Therapy need not be directed at the whole inflammatory response as is the current rationale for corticosteroids and cytotoxic agents. IL-4 = interleukin-4; FGF-2 = fibroblast growth factor-2, basic FGF; TGF-beta = transforming growth factor-beta; TNF = tumor necrosis factor; PDGF = platelet-derived growth factor; IL-1 = interleukin-1; IGF-1 = insulin-like growth factor-1; HB-EGF = heparin binding epidermal-like growth factor; IFN = interferon gamma; PGE_2 = prostaglandin E_2 . *(From Mason RJ, Schwarz MI, Hunninghake GW, Musson FA: Pharmacological therapy for idiopathic pulmonary fibrosis. Am J Respir Crit Care Med 160:1171-1177, 1999.)*

interstitial lung disease, and chronic hypersensitivity pneumonitis.

The pathogenesis of pulmonary fibrosis has not been well defined because there are numerous pathways that can lead to pulmonary fibrosis that are not mutually exclusive.[131] Although it is believed that inflammatory cells acting directly on fibroblasts in the lung through a variety of inflammatory mediators play a key role, the interaction of the inflammatory cascade with parenchymal lung cells is also important (Fig. 54-5) .

Initial symptoms include dyspnea, effort intolerance, and dry cough without obvious cause. A "ground glass" appearance on high-resolution chest CT is equated histologically with a cellular reaction.[132] A "reticular nodular" appearance denotes more advanced, less cellular fibrotic areas. However, the high-resolution chest CT is normal in approximately 12 percent of biopsy specimen-proven cases of interstitial lung disease.[133]

The major targets of therapy have focused on the inflammatory cells, and this has led to the use of antiinflammatory agents.[134] [135] However, corticosteroids and cytotoxic drugs are only occasionally effective in IPF. Pulmonary hypertension is a complication of pulmonary fibrosis that may warrant more aggressive therapy. Pulmonary hypertension can become the limiting factor in the dyspnea and exercise limitation of patients with IPF and contributes to its mortality. The therapy for pulmonary hypertension should be directed at the underlying disease process and not toward lowering pulmonary artery pressure. Oxygen is indicated in the presence of hypoxemia. Worsening gas exchange and heart failure can be induced by the use of vasodilators, which appear to have no role in disease management. In such patients, therapy with digitalis and diuretics would be appropriate.

ADULT CYSTIC FIBROSIS.

Cystic fibrosis (CF) is the most common lethal genetic disease in whites and occurs in approximately 1 of every 2000 live births. As the disease progresses, patients develop disabling lung disease and eventually respiratory failure, pulmonary hypertension, and cor pulmonale. The pathophysiology of pulmonary hypertension and cor pulmonale in CF is believed to be related to progressive destruction of the lung parenchyma and the pulmonary vasculature and to pulmonary vasoconstriction secondary to hypoxemia.[136] The development of cor pulmonale in patients with CF carries a grave prognosis. The mean survival time from the onset of cor pulmonale has been reported to be as short as 8 months. Typically, the patients have severe hypoxemia, which may be a result of and a causative factor of the pulmonary hypertension (Fig. 54-6) .

One recent study evaluated patients with CF and cor pulmonale in depth.[137] Right ventricular hypertrophy appears to be a precursor of right ventricular failure and an indicator of the onset of pulmonary hypertension. The severity of the pulmonary hypertension appeared to correlate significantly with declining pulmonary function, as well as with the degree of oxygen desaturation on exercise. In this study, patients who developed pulmonary hypertension had a much worse prognosis (average survival 15 months) compared with those without pulmonary hypertension (average survival 33 months). Once lung function is severely limited (FEV_1 <40 percent predicted), the prevalence of pulmonary hypertension may be as high as 40 percent. Because hypoxemia is universally found, supplemental oxygen

Figure 54-6 The correlation between pulmonary artery systolic pressure (PASP) and FEV_1 , mean oxygen saturation during wakefulness (Sa_{O_2} W), mean oxygen saturation during sleep (Sa_{O_2} S), and mean oxygen saturation at the end of a 6-minute walk test (Sa_{O_2} WT). *(From Fraser KL, Tullis E, Sasson Z, et al: Pulmonary hypertension and cardiac function in adult cystic fibrosis: Role of hypoxemia. Chest 115:1321-1328, 1999.)*

is considered to be the mainstay of treatment in this group.

Sleep-Disordered Breathing

Sleep apnea, defined as repeated episodes of obstructive apnea and hypopnea during sleep together with daytime sleepiness or altered cardiopulmonary function, is common. Epidemiological studies estimate that the condition affects 2 to 4 percent of middle-aged adults.[138] Only a small proportion of the cases in this group of adults have been diagnosed, which is believed to be related to insufficient awareness of sleep apnea among physicians and the public at large.

The incidence of pulmonary hypertension in the setting of obstructive sleep apnea without clinically significant lung disease ranges from 17 to 41 percent, with most studies suggesting an incidence of 20 percent.[139] [140] Pulmonary hypertension is rarely observed in the absence of daytime hypoxemia, and the severity of nocturnal events (i.e., apnea and hypopnea) does not appear to be the determining factor of pulmonary hypertension (Fig. 54-7) (Figure Not Available) . Some studies have demonstrated that a reduced FEV_1 also contributes to pulmonary hypertension in these patients.[141] In most cases, the pulmonary hypertension is mild, similar to COPD.

Patients with sleep apnea also have an increased risk of diurnal hypertension, nocturnal dysrhythmias, right and left ventricular failure, myocardial infarction, and stroke.[142] Symptoms such as sleepiness, fatigue, irritability, and personality change have been attributed to nocturnal desaturation and the chronic sleep deprivation caused by sleep fragmentation. Sleep fragmentation may be the most important predictor of daytime sleepiness. Patient characteristics associated with sleep apnea include male sex, age older than 40 years, habitual snoring, nocturnal gasping, choking, or resuscitative snoring, observed apnea, and a history of systemic hypertension.[143] Symptoms of daytime somnolence, unrefreshed sleep, morning headaches, cognitive impairment, depression, nocturnal esophageal reflux, and nocturia are commonly reported but do not distinguish sleep apnea from other common nonpulmonary, sleep disorders. A sleep study should be performed to confirm the presence of upper airway closure during sleep and to access the patient's level of risk.

Therapeutic strategies for patients with sleep apnea may be grouped into three general categories: behavioral, medical, and surgical. The goals of treatment are to establish normal nocturnal oxygenation and ventilation, abolish snoring, and eliminate disruption of sleep due to upper airway closure. Avoiding factors that increase the severity of upper airway obstruction such as sleep deprivation, the use of alcohol, sedatives, hypnotic agents, and increased weight should be discussed with the patient. In obese patients, weight loss can significantly reduce the severity of the apnea.[144] However, the most important advancement in the medical treatment is positive airway pressure. Positive airway pressure delivered through a mask is the initial treatment of choice in clinically important sleep apnea. Continuous positive pressure is applied to the upper airway with the nasal mask, nasal prongs, or mask that covers both the nose and mouth. The level of positive pressure required to sustain patency of the upper airway during sleep should be determined in the sleep laboratory. Supplemental oxygen can also be used in conjunction with positive airway pressure and assist in maintaining saturation above 90 percent.[145] Patients treated with continuous positive airway pressure delivered nasally have repeatedly demonstrated improvement in neuropsychiatric function and a lessening of daytime sleepiness.[146] Nocturnal desaturation, ventilatory related arousals, nocturnal dysrhythmias, pulmonary hypertension, and right-sided heart failure have also been effectively treated. Retrospective studies suggest that patients

Figure 54-7 (Figure Not Available) Mean pulmonary artery pressure (P_{pa}) and oxygen saturation by pulse oximetry (SpO_2) is shown during wakefulness in each sleep stage in patients with obstructive sleep apnea. Mean pulmonary artery pressure appears to be highest during rapid-eye-movement sleep, at a time that oxygen saturation is lowest. During wakefulness, when oxygen saturation is higher, the mean pulmonary artery pressures are considerably lower. *(From Niijma M, Kimura H, Edo H, et al: Manifestation of pulmonary hypertension during REM sleep in obstructive sleep apnea syndrome. Am J Respir Crit Care Med 159:1766-1772, 1999.)*

treated with nasally delivered continuous positive pressure or tracheostomy have improved survival.[147] Side effects reported by patients usually involve discomfort or irritation related to the nasal mask.

Surgical treatment includes tracheostomy and palatal surgery. For those with severe apnea who cannot tolerate positive airway pressure, tracheostomy can provide dramatic improvement and be life saving, although additional medical and psychosocial morbidity may be associated with this treatment. The most commonly performed palatal surgery, uvulopalatopharyngoplasty, is curative in less than 50 percent of patients. Of 25 patients observed for 4 to 8 years, about half of the patients were clinically and objectively improved over the long term.[148]

The approach to the patient with severe pulmonary hypertension associated with sleep apnea is controversial. Although it is unlikely a result of hypoxemia alone, it is recommended that these patients have documented effective therapy for at least 3 months, before treating the pulmonary arterial hypertension as a separate entity. In this subset, prostacyclin may prove helpful.

Alveolar Hypoventilation Disorders

CHEST WALL DISORDERS.

Thoracovertebral deformities that can result in restrictive pulmonary syndromes and chronic alveolar hypoventilation include idiopathic kyphoscoliosis, spinal tuberculosis, congenital spinal developmental abnormalities, spinal cord injury and other childhood myelopathies, ankylosing spondylitis, or other congenital and acquired muscular skeletal conditions, such as pectus excavatum. Kyphoscoliosis is a relatively common disorder of the spine in its articulations. When severe, it can have a profound impact on pulmonary function, characterized by a severe restrictive pattern on pulmonary function testing (Fig. 54-8) . In addition, there can be associated inspiratory muscle weakness that appears related to the increased elastic load from reduced lung and chest wall compliance. Scoliosis that appears before the age of 5 years has the worst respiratory prognosis. An angulation of greater than 100 degrees is considered very severe and is strongly associated with chronic alveolar hypoventilation.[149] Pulmonary compliance is often reduced by 50 percent or more as a result of lung underdevelopment and chronic lung hypoinflation. Patients can also have both central and obstructive apneas and hypopneas.

Pulmonary hypertension and chronic cor pulmonale frequently occur in patients with thoracovertebral deformities. Pulmonary hypertension is related to the reduction of the vascular bed because of hypoventilation and hypoxia. Symptoms are commonly slowly progressive. Hypoxemia may be seen from ventilation-perfusion mismatch or underlying atelectasis. When severe, the hypoxemia can also lead to cor pulmonale. In patients with advanced disease, intermittent positive-pressure breathing and noninvasive ventilation have been used successfully, as well as supplemental oxygen in patients who are hypoxemic.[150]

NEUROMUSCULAR DISEASE.

The development of right-sided heart failure is an unusual manifestation of respiratory failure solely due to respiratory muscle weakness. It usually develops in response to the hypoxic and hypercapnic stimuli in patients with chronic forms of these disorders. Weakness of the respiratory muscles can be caused by either generalized muscle diseases, such as myopathic infiltrating diseases or muscular dystrophy (see Chap. 71), or more commonly by such neurological disorders as a cord lesion at or below the third cervical vertebrae, amyotrophic

Figure 54-8 Pathogenesis of pulmonary hypertension and cor pulmonale in kyphoscoliosis and disorders of ventilatory control. *(From Fishman AP: Pulmonary hypertension and cor pulmonale. In*

Fishman AP [ed]: Pulmonary Diseases and Disorders. 2nd ed. New York, McGraw-Hill Book Co, 1988, p 1033.)

lateral sclerosis, myasthenia gravis, poliomyelitis, and Guillain-Barre syndrome. The diagnosis of respiratory muscle weakness is confirmed by the finding of a restrictive ventilatory defect and a marked impairment of maximal respiratory pressures. Nocturnal ventilatory support, with either positive or negative pressure, has become established as effective therapy in appropriate cases, and its beneficial effects are well recognized.[151]

DIAPHRAGMATIC PARALYSIS.

Bilateral diaphragmatic paralysis is an uncommon and rarely recognized cause of cor pulmonale. Diaphragmatic paralysis is a result of phrenic nerve injury, which can be traumatic or secondary to an underlying motor neuron disease. It may occur after cardiac surgery, as a manifestation of Lyme disease,[152] after radiation therapy,[153] or as a manifestation of other neurological disorders. When an affected patient is upright, ventilation may be normal or almost so, but when the patient is supine, gas exchange deteriorates. The diagnosis may be suspected in a patient with supine breathlessness, a disturbed sleep pattern, paradoxical motion of the abdomen on inspiration, and a low vital capacity in the upright position.

Patients with nontraumatic bilateral diaphragmatic paralysis may go unrecognized until they present either with respiratory failure or cor pulmonale. The diagnosis can be suspected when the vital capacity is reduced greater than 40 percent of predicted and paradoxic motion of the hemidiaphragms is noted on fluoroscopy.[154] Patients can also have unilateral paralysis of the diaphragm, which is more common but associated with less symptoms and physiological abnormalities. The treatment should always be directed toward correcting the underlying chronic neuromuscular disease, if present, and addressing nocturnal hypoventilation with noninvasive ventilatory techniques. Intermittent positive airway pressure is an effective therapy.[155]

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Three forms of persistent pulmonary hypertension of the newborn (PPHN) have been described. In the hypertrophic type, the muscular tissue of the pulmonary arteries is hypertrophied and extends peripherally to the acini. Medial hypertrophy causes narrowing of the arteries and an increase in pulmonary pressure and reduction in pulmonary blood flow. It is believed to be the result of sustained fetal hypertension from chronic vasoconstriction due to chronic fetal distress. In the hypoplastic type, the lungs including the pulmonary arteries are underdeveloped, usually as the result of a congenital diaphragmatic hernia or prolonged leakage of amniotic fluid.[156] [157] The cross-sectional area of the pulmonary vascular bed is inadequate for normal neonatal pulmonary blood flow. In the reactive type, lung histology is presumably normal but vasoconstriction causes pulmonary hypertension. High levels of vasoconstrictive mediators such as thromboxane, norepinephrine, and leukotrienes may be responsible and may result in a streptococcal infection or acute asphyxia at birth.

Although PPHN can vary in severity, severe cases are usually life threatening. It is usually associated with severe hypoxemia and the need for mechanical ventilation. Echocardiographic findings of severe pulmonary hypertension and right-to-left shunting at the level of the ductus arteriosus or foramen ovale are common. Inhaled nitric oxide has provided encouraging results through improvement in oxygenation in these patients (Fig. 54-9) . Intravenous prostacyclin has also been used and may even have additive effects to that of inhaled nitric oxide.[158]

Figure 54-9 The short-term effect of inhaled nitric oxide on systemic oxygenation in infants with severe hypoxemia and persistent pulmonary hypertension of the newborn. As compared with conventional treatment with oxygen and mechanical ventilation without nitric oxide (open bars), nitric oxide therapy (solid bars) rapidly increased postductal Pa_{O_2} from baseline (panel A) and decreased the oxygenation index (a value calculated as $100 \times Fi_{O_2} \times$mean airway pressure and postductal Pa_{O_2}). *(From Roberts JD Jr, Fineman JR, Morin FC III, et al: Inhaled nitric oxide and persistent pulmonary hypertension of the newborn. N Engl J Med 336:605-610, 1997.)*

ALVEOLAR CAPILLARY DYSPLASIA.

Alveolar capillary dysplasia is a very rare cause for PPHN and is characterized by a developmental abnormality in the pulmonary vasculature. The antemortem diagnosis can only be made with open-lung biopsy. Despite aggressive treatment with nitric oxide, prostacyclin, and even extracorporeal membrane oxygenation, survival in the setting of alveolar capillary dysplasia is rare.[159]

PULMONARY HYPERTENSION DUE TO CHRONIC THROMBOEMBOLIC DISEASE

Thromboembolic Obstruction of the Proximal Pulmonary Arteries (see also Chap. 62)

Pulmonary thromboembolism, as a single event or as repeated events, rarely leads to the development of chronic pulmonary hypertension.[160] However, in a subset of patients (believed to be less than 0.1 percent of all patients suffering from pulmonary embolism), the outcome is unusual.[161] Rather than having inherent fibrinolytic resolution of the thromboembolism with restoration of vascular patency, the thromboemboli in these patients fails to resolve adequately. They undergo organization and incomplete recanalization and become incorporated into the vascular wall. Commonly, they are in the subsegmental, segmental, and lobar vessels, although it is believed that chronic thromboembolism tends to propagate retrograde, leading to slowly progressive vascular obstruction.[160] It appears that the vast majority of these patients have suffered one major thromboembolic event rather than multiple recurrences.

The slowly progressive nature of the course of chronic thromboembolic pulmonary hypertension (CTEPH) allows right ventricular hypertrophy to ensue and compensate for the increased pulmonary vascular resistance. However, owing to either progressive thrombosis or vascular changes in the "uninvolved" vascular bed,[161] the pulmonary hypertension becomes progressive and the patient manifests the clinical symptoms of dyspnea, fatigue, hypoxemia, and right-sided heart failure.

DIAGNOSIS.

The physical examination of a patient with CTEPH is typical of any patient with pulmonary hypertension, with the exception of the following features. These patients tend to have lower cardiac outputs than patients with PPH, which is often reflected by the carotid arterial pulse volume. In addition, on occasion, bruits may be heard over areas of the lung that represent vessels with partial occlusions, but they must be carefully looked for. It is important to make the diagnostic distinction between patients with CTEPH and those with other forms of pulmonary hypertension because the treatment is so different. For the former group, a potentially curative therapy through thromboendarterectomy is available, whereas for the latter group effective pharmacological regimens are now evolving. The symptoms and physical findings of CTEPH are nonspecific and similar to those patients with primary pulmonary hypertension.

The perfusion lung scan is usually adequate to identify patients with this entity and is an important reason why lung scans are recommended for all patients who present with pulmonary hypertension. However, the lung scan typically underestimates the severity of the central pulmonary arterial obstruction.[162] Therefore, patients who present with one or more mismatched segmental or larger defect should undergo pulmonary angiography. Pulmonary angiography can be performed safely in these patients if careful attention is given to the hemodynamic state. Nonionic contrast medium has been demonstrated to cause no major hemodynamic effects even in patients with severe chronic thromboembolic pulmonary hypertension[163] and is preferred. Hypotension and/or bradycardia should be immediately treated with atropine.

Figure 54-10 Chest CT scans in a patient with chronic thromboembolic pulmonary hypertension. In *A*, a helical scan with contrast medium enhancement of the pulmonary vasculature shows a marked disparity in vessel size between the involved vessels (A), which are enlarged from thrombus, and the uninvolved vessels (B). In *B*, a non-contrast medium-enhanced high-resolution scan illustrates a marked mosaic pattern manifest by differences in density of regions of the lung parenchyma reflecting the perfused areas (B) and the nonperfused areas (A), also consistent with underlying thromboembolic disease.

CT can be a great aid in diagnosing CTEPH (Fig. 54-10) . Using high-resolution nonenhanced CT, areas of increased attenuation that do not obscure the vessels and that have a ground-glass appearance have been characterized as a mosaic pattern corresponding to hypoperfusion of the lung. Although this pattern is consistent with CTEPH, it may also be seen in cystic fibrosis, bronchiectasis, and the lungs of lung transplant recipients. It is virtually never seen in PPH.[164] Marked variation in the size of the segmental vessels is more specific for CTEPH and is believed to represent involvement of the segmental vessels due to thromboemboli. It has been reported that these findings might also be mimicked in patients with fibrosing mediastinitis.

On cardiac catheterization, patients with CTEPH tend to have higher right atrial pressures and lower cardiac outputs than comparable patients with PPH for the same level of pulmonary artery pressure. Because this is a disease that generally is progressive, the hemodynamic indication for

surgical intervention would be an elevation of pulmonary artery pressure and pulmonary vascular resistance for a period of more than 3 months.

TREATMENT.

Patients suitable to undergo pulmonary thromboendarterectomy must have thrombi that are accessible to surgical removal and demonstrate a significant increase in the pulmonary vascular resistance.[161] The operative mortality is fairly high, approximately 12 percent in experienced centers.[165] The postoperative management of these patients can be extremely challenging. Patients in whom a large volume of central thrombus is removed, associated with back-bleeding from the distal vascular segments and an immediate fall in the pulmonary artery pressure, usually have an extremely good postoperative course and long-term follow-up. Patients in whom small amounts of thrombus can be removed, in whom the thrombus becomes fragmented at the time of thromboendarterectomy, or in whom there is no distal back-bleeding from the segment where the thrombus was removed usually have a difficult postoperative course. In addition, a lack of significant fall in pulmonary artery pressure and an increase in cardiac output portends a difficult postoperative recovery.

These patients may need mechanical ventilation and inotropic support for days to weeks during periods of slow recovery. Much of their mortality appears to be related to severe right ventricular dysfunction, which actually becomes initially worsened during the surgical procedure. Reperfusion injury, which is manifest by profound hypoxemia and pulmonary infiltrates corresponding to the segments where thrombus was removed, has been reported and can be extensive. The only effective management of this complication is sustained assisted ventilation and oxygen supplementation. Attempts to reverse this with corticosteroids or other agents have not been successful.

Those survivors who have a good result, with a significant reduction in postoperative pulmonary vascular resistance at 48 hours, can expect to realize an improvement in functional class and exercise tolerance.[166] [167] Life-long anticoagulation with a goal international normalized ratio of 2.5 to 3.5 is indicated postoperatively. Right ventricular dysfunction of any magnitude is not considered a contraindication to surgery, because right ventricular function has been noted to improve once the obstruction of the pulmonary blood flow is removed. Certain hypercoagulable states such as lupus anticoagulant may be associated with CTEPH.[168] Some of these patients have also been successfully treated with pulmonary thromboendarterectomy.[169]

Sickle Cell Disease

Cardiovascular system abnormalities are prominent as part of the clinical spectrum of sickle cell disease. Evidence of right ventricular dysfunction, presumably resulting from pulmonary hypertension, is a poorly characterized complication. The incidence of pulmonary hypertension in the setting of sickle cell disease in one series of 60 consecutive patients undergoing echocardiography was 20 percent.[170] The mortality was also significantly greater in patients with pulmonary hypertension than those without (42 percent vs. 8 percent, $p = 0.03$). One must always consider left ventricular dysfunction as a cause of pulmonary hypertension in sickle cell disease because the elevation of pulmonary artery pressure is most often associated with elevation of the pulmonary capillary wedge pressure.[171] Patients with sickle cell disease may also have an increased risk of thromboembolism, and pulmonary thromboendarterectomy may be indicated in certain situations.[172] Sickle cell disease can also affect the lungs by causing embolization of bone marrow elements. Generally, the smaller pulmonary arteries, arterioles, and capillaries are affected. It can be associated with pulmonary infarction or local perivascular fibrosis.

PULMONARY HYPERTENSION DUE TO DISORDERS DIRECTLY AFFECTING THE PULMONARY VASCULATURE

SCHISTOSOMIASIS

Although schistosomiasis is extremely rare in North America, hundreds of millions of people are affected worldwide, particularly in developing countries. The development of pulmonary hypertension almost always occurs in the setting of hepatosplenic disease and portal hypertension.[173] Clinical features appear when ova embolize to the lungs, where they induce formation of delayed hypersensitivity granulomas. In addition, deposition of fibrous tissue causes narrowing, thickening, and occlusion of the pulmonary arterioles. Histologically, focal changes related directly to the presence of schistosome ova may be located either within the alveolar tissue or within the pulmonary arteries, and plexiform or angiomatoid lesions may be found. Fibrosis surrounds most focal lesions.[174] The clinical symptoms and radiographic findings in these patients who develop pulmonary hypertension are not distinctive. In developing countries this condition can be confused with primary pulmonary hypertension.

The diagnosis of schistosomiasis-induced cor pulmonale is confirmed by finding the parasite ova in the urine or stools of persons with symptoms. However, the insidious onset of pulmonary vascular disease years after infection makes finding these parasite ova difficult. Active infections are treated with praziquantel, which kills the adult worms and stops further destruction of tissue by ova deposition.[175] Reversal of pathological lesions in the lungs after therapy has not been documented.

SARCOIDOSIS

Sarcoidosis is a multisystemic granulomatous disease of unknown origin characterized by an enhanced cellular immune response at the sites of involvement.[176] Although any organ can be involved, it most commonly affects the lungs and intrathoracic lymph nodes.[177] The clinical presentation and natural history of sarcoidosis varies greatly, but the lung is involved in over 90 percent of the patients. The most common presenting symptoms are cough and shortness of breath, which is of a progressive nature.[178] As the disease progresses in the lung parenchyma, extensive interstitial fibrosis is the result. In addition, obstructive airway disease, fibrocystic disease, bronchiectasis, endobronchial granulomas, and lobar atelectasis are common consequences of lung involvement.

Cardiac involvement from sarcoidosis appears to be more common than previously thought and may be present in up to one third of the cases (see Chap. 48).[179] Consequently, patients presenting with dyspnea should have a thorough cardiac evaluation for the possibility of cardiac involvement. Noncaseating granulomas may infiltrate the myocardium and leave fibrotic scars; and if enough of the myocardium is involved, the patients will develop clinical features of a restrictive cardiomyopathy. Patients with cardiac involvement from sarcoidosis may also present with varying degrees of heart block, arrhythmias, and/or clinical features of biventricular diastolic heart failure. Sudden death can be a common manifestation of cardiac sarcoid, and it is one of the most feared sequelae. The prognosis of patients with cardiac involvement from sarcoidosis is variable but can be quite poor. Usually a trial of corticosteroids is given in the hope that it will alter the natural history of the disease.

An echocardiogram will often demonstrate either diffuse or regional wall motion abnormalities in patients with cardiac involvement. It is not uncommon, however, to find the features of pulmonary hypertension. Pulmonary hypertension detected by echo-Doppler techniques may be the result of restrictive cardiomyopathy from sarcoid and needs to be clearly distinguished from patients with pulmonary hypertension from direct pulmonary vascular involvement, because their clinical management will differ dramatically.

Cor pulmonale is most commonly the result of chronic severe *fibrocystic* sarcoidosis.[180] Patients have chronic progressive dyspnea with effort, a chest radiograph demonstrating severe diffuse interstitial fibrotic lung disease, and pulmonary function tests that reflect severe restrictive physiology and hypoxemia. In these cases the resulting cor pulmonale is usually mild to moderate and typical of patients presenting with restrictive lung disease of any etiology. The treatment is generally focused on reversing any acute exacerbations of their lung disease and supplemental oxygen when indicated. Some patients with sarcoidosis, however, have mild to moderate restrictive lung disease with severe pulmonary hypertension, presumed from granulomatous vasculitis of the pulmonary vessels. It is critically important in the cardiopulmonary evaluation of the patient presenting with underlying sarcoidosis and dyspnea to distinguish whether the symptoms are from chronic interstitial lung disease, restrictive cardiomyopathy, or pulmonary vascular disease.[181] Although the traditional treatment of these patients has been unsatisfactory, it has recently been demonstrated that some patients have a very favorable response to intravenous prostacyclin therapy.[182] Although interstitial

lung involvement from the sarcoidosis can result in mild pulmonary hypertension, a subset of patients present with severe pulmonary hypertension believed to be due to direct pulmonary vascular involvement. It appears that, as with other secondary causes, these patients are predisposed to the development of pulmonary vascular disease that is triggered in some way by the sarcoid disease process. Although the use of intravenous prostacyclin chronically may reverse the right-sided heart failure and dramatically improve their pulmonary hemodynamics, it will have no impact on any underlying fibrotic lung disease and/or hypoxemia, which still may render the

patients symptomatic and dyspneic.

PULMONARY CAPILLARY HEMANGIOMATOSIS

Pulmonary capillary hemangiomatosis (PCH) was first described in 1978 as a very rare cause of pulmonary hypertension.[183] Because of the few reports in the medical literature it is hard to characterize this abnormality. The typical chest radiographic appearance is a diffuse bilateral reticular nodular pattern associated with enlarged central pulmonary arteries.[184] Ventilation-perfusion scans are often abnormal and may show matched or unmatched defects. The most characteristic finding on high-resolution CT is diffuse bilateral thickening of the interlobular septa and small centrilobular poorly circumscribed nodular opacities.[185] Diffuse ground-glass opacities have also been described. Histological findings often include irregular small nodular foci of thin-walled capillary sized vessels, which diffusely invade the lung parenchyma, the bronchiolar walls, and the adventitia of large vessels. These nodular lesions are often associated with alveolar hemorrhage. Changes of hypertensive arteriopathy manifest by intimal fibrosis and medial hypertrophy are also common. Most patients appear to be young adults and present with dyspnea and/or hemoptysis. It is very difficult to distinguish PCH from PPH clinically. A hereditary form with probable autosomal recessive transmission has been reported.

The clinical course of these patients is usually one of progressive deterioration leading to severe pulmonary hypertension, right-sided heart failure, and death. Intravenous prostacyclin has been used, but it has been reported with the association of the development of severe pulmonary edema.[186] The only definitive treatment for these patients is bilateral lung transplantation.

Part VI - MOLECULAR BIOLOGY AND GENETICS

Chapter 55 - Principles of Cardiovascular Molecular Biology and Genetics

JEFFREY M. LEIDEN

During the first half of the 20th century revolutionary studies of human and animal physiology led to an elegant understanding of the anatomical, electrical, and mechanical properties of the cardiovascular system. As we enter the new millennium, we are in the midst of a second and equally exciting revolution in cardiovascular medicine--one that involves the application of recent advances in molecular and cellular biology to understanding both normal cardiovascular function and the pathophysiological bases of human cardiovascular disease.

Applications of modern molecular and cellular biology already permeate both cardiovascular diagnostics and therapeutics. During the past 10 years a rapidly expanding list of genes that are involved in the etiology of cardiovascular diseases, including hypertrophic and dilated cardiomyopathies, hypertension, and atherosclerosis, have been identified. Recombinant proteins and antibodies made from cloned genes such as tissue plasminogen activator (t-PA) and glycoprotein IIb/IIIa monoclonal antibodies are currently used to treat or prevent acute coronary thrombosis. Novel gene therapies are being tested for the treatment of ischemic cardiomyopathies and vascular proliferative syndromes such as restenosis after balloon angioplasty or arterial stenting.

Although significant, these advances represent just the beginning of a new era of molecular medicine that promises to fundamentally change the way we practice cardiovascular medicine over the coming decades. In 2000, the sequences of all of the genes in the human genome were reported. This enormous accomplishment will provide a wealth of new information about basic cardiovascular biology as well as large numbers of new diagnostic tools and potential drug targets. Given this rapidly expanding mass of molecular information, it is clear that the practicing cardiologist will soon need to understand as much about the basic principles of molecular biology and human genetics as he or she currently knows about coronary anatomy or cardiac hemodynamics.

In this chapter an overview is provided of the basic terminology, principles, and techniques of molecular and cellular biology. The reader is referred to several excellent texts and in-depth reviews for more detailed information about these topics.[1] [2] [3] [4] [5]

ANATOMY OF THE MAMMALIAN CELL

The mammalian cell is a highly dynamic, compartmentalized, and specialized structure that has evolved to carry out a number of functions that are important for survival, replication, and the proper functioning of individual organs and the organism as a whole (Fig. 55-1) (see also Chap. 14). [6] [7]

All human cells share a number of common structures and properties. The outer cell membrane (plasma membrane) is composed of a lipid bilayer studded with extracellular receptors. This membrane provides protection from the extracellular environment while simultaneously enabling the cell to respond to extracellular signals such as hormones, drugs, toxins, or other cells that bind to or otherwise perturb membrane-associated receptors. Mitochondria are specialized subcellular organelles present in all human cells that generate energy in the form of adenosine triphosphate from the oxidation of carbon-containing compounds such as sugars or fats.

The genomic deoxyribonucleic acid (DNA) organized into chromosomes is contained within the membraneencapsulated cell nucleus. The chromosomes are collections of genes that store the genetic information needed to synthesize all of the component proteins that constitute the

Figure 55-1 Anatomy of the mammalian cell. Schematic illustration of an idealized mammalian cell demonstrating structures that are common to most cell types. Note that lineage-specific cell structures, such as sarcomeres, are not included in this illustration. See Figure 14-1 (Figure Not Available) for the latter.

cell and its organelles. As described in more detail later, this DNA is copied or transcribed into ribonucleic acid (RNA) in the nucleus. This RNA is then transported to the cytoplasm (i.e., the nonnuclear portion of the cell), where it is used as a template to direct the synthesis of proteins on specialized synthetic organelles called ribosomes. Newly synthesized proteins are sorted into the cytoplasmic compartment, inserted into membranes, or incorporated into specialized granules for secretion from the cell. These proteins play diverse roles in the physiology of the cell, including functioning as major structural elements; serving as enzymes that catalyze biochemical reactions; and functioning as cell surface receptors that sense and send extracellular signals and as hormones, growth factors, cytokines, or other secreted molecules that help integrate the function of multiple cells and organs within the organism.

In addition to these common structures and organelles, many cells express cell lineage-specific proteins and structures that enable them to carry out their specialized functions within the organism. Thus, for example, striated cardiac muscle cells express a set of contractile proteins assembled into sarcomeres that allow their rhythmic contraction whereas neurons express lineage-specific neurotransmitters and receptors that allow them to interpret and respond to diverse environmental stimuli.

GENETIC MACHINERY AND FLOW OF INFORMATION IN THE CELL

DNA

Despite its remarkably simple structure and limited four-letter alphabet, deoxyribonucleic acid represents one of the most sophisticated and foolproof information storage systems ever discovered.[7] [8] Given its elegant simplicity, it is not surprising that the basic structure and information storage rules of DNA have been highly conserved during evolution from the most simple viruses and bacteria to humans.

DNA is composed of two long strands of polynucleotides wound around each other in a clockwise double helix (Fig. 55-2 *A*). Each strand can contain an unbroken array of millions of nucleotides. The backbone of each strand of the DNA helix is composed of a linked array of identical deoxyribose phosphate groups, with the phosphate group forming a 5
-3
 phosphodiester bond between the fifth carbon of one pentose ring and the third carbon of the adjacent ring. Each deoxyribose sugar on each strand is attached to one of four nucleic acid bases: two purines, adenine and guanine (A and G), and two pyrimidines, cytosine and thymine (C and T). These nucleic acids project at right angles toward the center of the DNA helix and pair with each other according to a very specific set of rules: an A from one strand can only pair with a T from the opposite strand, whereas a C from one strand can only pair with a G from the opposite strand. This nucleic acid pairing, which is stabilized by hydrogen bonding between the two complementary nucleic acids, serves to hold the two strands of the helix together. Of equal importance, the two strands of the helix, which have opposite polarities (one is oriented in the 5
 to 3
direction, whereas the other is oriented in a 3
 to 5
 direction), are complementary copies of each other. Therefore, the sequence of one strand of the helix can be used to easily predict or program the sequence of the opposite strand. This important property of complementarity allows the enzymatic machinery of the nucleus to copy faithfully one strand of DNA into a daughter strand during cell replication and also allows the DNA sequence of a gene to be easily copied into RNA that can be used to program the synthesis of cellular proteins (Fig. 55-2 *B*) (see later).

Chromosomes and Genes

Within the nucleus, the DNA is compacted by being wound around specialized structures called nucleosomes and organized into packages called chromosomes.[9] [10] [11] The human genome contains approximately 3×10^9 pairs of nucleotides (called base pairs) organized into 23 pairs of chromosomes.[12] [13] [14] One member of each pair of chromosomes is inherited from each parent. Remarkably, almost all of the cells in the human body contain a copy of the entire human genome or all of the instructions necessary to specify the entire organism (erythrocytes and platelets are notable exceptions).

Within a single chromosome, the DNA is organized into individual packets of information called genes[12] [13] [14] (Fig. 55-3) .

Figure 55-2 Flow of genetic information within a eukaryotic cell. *A,* Schematic illustration of the structure of eukaryotic DNA. The double helix at the right edge of the illustration is unfolded to allow visualization of the deoxyribose-phosphate backbone of each strand as well as base pairing between complementary nucleotide bases. *B,* Schematic illustration of transcription and translation of a eukaryotic gene. *Top right,* Genomic DNA being transcribed into messenger ribonucleic acid (mRNA) in the nucleus. *Bottom right,* mRNA being translated into a polypeptide in the cytoplasm. Transfer RNAs (tRNAs) loaded with amino acids are shown binding to the mRNA on a ribosome.

Each gene is composed of a unique sequence of nucleotides that comprises the information needed to encode one protein. The capacity of a unique sequence of bases within a gene to encode a unique protein is somewhat analogous to the letters of the alphabet that when assembled in different combinations uniquely define the meaning of individual sentences. The human genome contains an estimated 80,000 to 150,000 distinct genes.[14] The protein coding information contained within a single gene is not continuous but instead is encoded in multiple discontinuous packets called exons.[15] Between these exons are variable-sized stretches of DNA called introns. The function of these introns, which can be thought of as "junk" DNA and which are interspersed in the genes of all eukaryotic cells, remains unclear. However, it has been suggested that they may have facilitated the creation of new genes during evolution by enabling the duplication, shuffling, and divergence of functional domains of different genes.[15]

In addition to its coding sequence (i.e., the sequence that determines the structure of its encoded protein), each gene also contains regulatory DNA sequences that control its spatial and temporal patterns of expression within different cell types and in response to different extracellular signals. These regulatory sequences, called promoters, enhancers, and silencers, are recognized and bound by a set of specialized nuclear proteins called transcription factors that can promote or inhibit the copying of a gene into an RNA template that can then program the synthesis of its encoded protein.[16] [17] [18] [19] [20] [21] [22] [23] Promoters are typically located immediately upstream (or 5
) of the coding region of the gene. Enhancers on the other hand can be located upstream (5
), downstream (3
), or even within the introns of a gene.

Figure 55-3 Transcription and processing of eukaryotic RNA. *Top,* Structure of a prototypical eukaryotic gene with a 5
promoter, three exons (exons 1-3), and a 3
 enhancer. This gene is transcribed into a primary RNA transcript, which is then processed by splicing and addition of a 5
 cap and 3
 polyA tail. The resulting mature mRNA molecule is exported to the cytoplasm where it is translated into protein on a ribosome.

From Genes to Proteins

TRANSCRIPTION.

The genes themselves can be thought of as the code stored in a basic computer program. To be functional, these genes must first be interpreted or translated into the proteins that they specify. This is a complex and highly regulated process that involves (1) the initial copying of the DNA copy of the gene into RNA in the nucleus, (2) processing and transport of this RNA copy to the cytoplasmic compartment (i.e., across the nuclear membrane), (3) translation of the RNA into its encoded protein on ribosomes, and, in some cases, (4) posttranslational modifications of the proteins themselves (see Figs. 55-2 and 55-3). In the first of these steps the antisense strand (3
-5
 strand) of the gene is copied base by base into a single-stranded complementary RNA molecule by cellular RNA polymerases.[19] Like DNA, RNA is a polynucleotide strand composed of a backbone of ribose sugars linked to one of four nucleic acid bases (A, G, C, and U [uracil], instead of T [thymidine]). Thus the sequence of the RNA copy of the antisense strand is identical to the sense strand of the DNA (except that *U*s replace the *T*s). Because this RNA copy contains both the exons (protein coding blocks) and introns (interspersed junk DNA) it must be processed (spliced) to remove all intron sequences and precisely join the exons into a single messenger RNA (mRNA) containing a contiguous region of sequence encoding its cognate protein.[24] Both ends of this single-stranded mRNA are then modified (a cap is added to the 5
 end of the mRNA while the 3
 end has a string of adenine bases added to produce a polyA tail), and the RNA is exported from the nucleus into the cytoplasm, where it is bound by ribosomes in preparation for translation into protein.[25] [26] [27]

THE GENETIC CODE.

Because DNA and RNA are linear arrays of nucleotides, whereas proteins are linear arrays of amino acids, there must be a code by which the linear sequence of the four nucleotides of the RNA molecule can be translated into the linear sequence of amino acids of its encoded protein. This "genetic code" turns out to be remarkably simple and has been conserved in most (but not all) organisms from viruses to humans.[28] [29] Every three contiguous nucleotides or triplets in the RNA specify a single amino acid (Fig. 55-4) . Because there are four nucleotide possibilities at each position, there are 4×4×4 or 64 different triplet possibilities. One of the triplets, AUG, specifies methionine, which is the amino acid that starts each protein; three other triplets, UAA, UGA, and UAG, program the ribosome to end translation and are therefore called stop codons. The remaining 60 triplets or codons specify one of the 20 amino acids. Because there are 60 codons and only 20 amino acids some amino acids can be specified by two or more different triplets (e.g., cysteine=UGU or UGC). Thus, it is possible to read the sequence of the protein encoded by a gene by simply reading its triplets in order (e.g., ATG TCC TGG TCC=Met Ser Trp Ser).

TRANSLATION.

The conversion of the single-stranded mRNA into protein on the ribosome requires special adapter molecules called transfer RNAs (tRNAs) (see Fig. 55-3). One portion of these tRNAs is complementary to the triplet corresponding to the single amino acid it adds to the growing protein chain (e.g., the tRNA for methionine contains a triplet RNA sequence, UAC, that can base pair with the triplet AUG that encodes methionine in the mRNA). A second portion of the tRNA molecule can bind specifically to that amino acid. By docking on the triplet in the mRNA by base pairing, the tRNA brings the correct amino acid into proximity with the growing protein chain, allowing the ribosome to specifically couple it to the carboxy terminus of the nascent polypeptide. The ribosome and tRNAs can therefore be thought of as a reading machine that scans the sequence of the mRNA and converts it into a protein.

EVOLUTIONARY CONSERVATION.

The remarkable evolutionary conservation of the structures of DNA, RNA, and

Figure 55-4 The genetic code. The amino acids corresponding to each nucleotide triplet in the mRNA are shown. Note that there are three stop codons (UAG, UAA, and UGA) and a single start codon (AUG).

proteins as well as the genetic code and much of the machinery for RNA and protein production has profound implications for molecular geneticists. It means, for example, that human genes can be transferred into bacteria, yeast, or insect cells where they will be faithfully replicated and copied into RNA and protein. This property constitutes the basis of the recombinant DNA technology used to produce many therapeutic proteins such as t-PA. Similarly, human genes can be spliced into viruses that can be used to infect human cells to transfer genes for therapeutic purposes. Finally, many of the genes involved in human cardiovascular development and function have been highly conserved in mice, fish, and even flies. Thus, these simple organisms can serve as powerful model systems for studying human cardiovascular development and function and for testing novel genetic or pharmacological therapies for human cardiovascular diseases.

Regulation of Gene Expression

Only a small fraction of the genes within the human genome is expressed in any given cell at any given time. These genes can be divided into several subsets based on their patterns of expression. One subset of genes is constitutively expressed in most, if not all, cells. The products of these so-called housekeeping genes are necessary for basic functions of cell survival, replication, and energy generation. A second subset of genes is expressed in a lineage-restricted fashion, for example, only in a cardiomyocyte or an endothelial cell. In fact, it is the precise regulation of expression of this subset of lineage-specific genes that determines the unique identity and function of a particular cell type. A final subset of genes is expressed only in response to a specific environmental stimulus. Given the necessity for these complex and dynamic patterns of differential gene expression, human cells have evolved sophisticated molecular mechanisms to regulate lineage-specific gene expression and to allow rapid and precise changes of gene expression in response to various organismal and environmental signals.

The expression of a specific gene can be regulated at many levels including transcription of the gene into RNA,[16] [17] [18] [19] [20] [21] [22] [23] processing and transport of the mRNA into the cytoplasm,[24] [25] [26] [27] stability of the cytoplasmic mRNA,[30] translation of the mRNA into protein,[31] [32] posttranslational modification of the protein,[33] [34] [35] [36] [37] subcellular localization of the protein, [38] and protein stability.[37] Although each of these mechanisms plays important roles in regulating some genes, two of these, the regulation of gene transcription and protein phosphorylation (and dephosphorylation), appear to represent the major mechanisms used by the cell to control the expression and activity of proteins. Indeed, in many cases these two mechanisms have been linked into distinct signaling pathways that allow cells to respond to developmental, environmental, and organismal signals with complex and precisely orchestrated changes in gene expression. An example of one such signaling pathway is shown in Figure 55-5 . In this example, stimulation of a G protein-coupled beta-adrenergic receptor in the plasma membrane by beta-adrenergic agonists such as norepinephrine results in the activation of the enzyme adenylyl cyclase and in the increased production of cyclic adenosine monophosphate (cAMP) in the cytoplasm.[39] This increase in cAMP in turn activates the protein serine kinase, protein kinase A, which migrates to the nucleus where it phosphorylates the transcription factor CREB on a single serine residue (Ser133).[40]

Figure 55-5 Schematic illustration of a beta-adrenergic signaling pathway. Binding of a beta-adrenergic agonist to the transmembrane beta-adrenergic receptor (betaAR) results in the release of the active G protein, $G_{S.}$ G_S activates adenylate cyclase, which causes increased production of cyclic adenosine monophosphate (cAMP). cAMP in turn activates protein kinase A (PKA), which migrates to the nucleus where it phosphorylates the CREB transcription factor on serine 133. The phosphorylated transcription factor CREB binds as a homodimer to a cAMP response element (CRE)-binding site (TGANNTCA) and activates transcription of a CREB-responsive gene. (See also Figures 14-15 to 14-17 .)

Phosphorylated CREB then binds to its specific recognition sequence (TGANNTCA), which is present in the promoters of a set of cAMP-responsive genes, and activates their transcription and expression.[41] Similar types of signaling pathways have evolved to regulate gene expression in response to hormones, cytokines, hypoxia, cell-cell signals, and mechanical stretch.[33] [34]

GENETIC BASES OF HUMAN CARDIOVASCULAR DISEASE

Mutations are alterations in the structures of individual genes that result in corresponding structural changes in the proteins they encode (see also Chap. 56). Because many individual proteins play critical roles in the development and function of the cardiovascular system, such mutations leading to quantitative and qualitative defects in protein function can result in a wide variety of human cardiovascular diseases. Indeed, the preponderance of evidence suggests that genetic mutations often in combination with environmental factors are responsible for the majority of human cardiovascular diseases, including both classical congenital disorders of the heart and vasculature as well as "acquired diseases" such as hypertension, cardiomyopathies, and atherosclerosis.

Different types of mutations affect their encoded proteins in very different ways (Fig. 55-6) . "Missense mutations" result from the substitution of one or more nucleotides in such a way as to change the primary sequence of the encoded protein (e.g., mutation of TTT to TTG causes a single amino acid change of phenylalanine to leucine). Such missense mutations do not typically alter the level of protein expressed but can alter the function of the protein by altering its structure. In contrast, "nonsense mutations" (e.g., TAT to TAA) introduce a premature stop codon into a gene, resulting in a truncated protein product that can display alterations in function or can be unstable. Insertions or deletions of nucleotides can add or subtract amino acids from the resulting proteins if they result in the addition or deletion of triplets of amino acids (i.e., if they occur in multiples of three) or alternatively can result in "frameshifts" in which the codons of the gene are read in the wrong reading frame. Such frameshift mutations typically cause abnormal protein structures that often terminate prematurely, owing to the introduction of out-of-frame termination codons. Mutations in both exons and introns can cause splicing errors that result in alterations in protein structure and/or frameshifts. Finally, mutations in the promoters or enhancers of genes can lead to alterations (either increases or decreases) in the levels of expression of a given protein or, alternatively, can change the temporal or spatial patterns of expression of that protein. In addition to single gene mutations, rearrangements of genes on the same or different chromosomes can also result in human disease. For example, the "in frame" fusion of two different genes by chromosomal rearrangement can result in a fusion protein

Figure 55-6 Different types of mutations alter the structure and expression of human genes. *A,* An example of a wild-type gene sequence is shown in the top panel. The bottom panel shows examples of different types of nucleotide mutations and the resulting alterations in the amino acid sequences of the corresponding protein. Mutations are underlined; deletions are noted by a dot. Polymorphism is a nucleotide substitution that does not alter the primary amino acid structure of the resulting protein. *B,* Splice mutations: an example of a mutation in the 3 splice acceptor sequence that disrupts splicing, resulting in read-through into the intron and premature termination of the protein.

with a novel and sometimes deleterious function. Similarly, fusion of the promoter of one gene to the coding sequence of a second can lead to an abnormal spatial and

temporal pattern of expression of the second gene and protein.

These different types of mutations also lead to different types of diseases (see also Chap. 56). For example, the functional inactivation, deletion, or premature termination of a single gene often results in a "loss of function" of its encoded protein that is manifest as an autosomal recessive trait. That is, only homozygous patients who inherit two copies of the mutated gene (and therefore have a severe deficiency in the amount of protein expressed) manifest the disease. In contrast, heterozygous "carriers" express 50 percent of the normal level of the protein and therefore are usually (but not always) asymptomatic. In contrast, some mutations result in the production of a dominant negative protein that inhibits the function of the normal protein expressed by the other copy of the gene in the patient's cells. Such mutations are often inherited in a dominant fashion; that is, one mutant copy of the gene (allele) is sufficient to produce disease. Similarly, some mutations can result in a gain of function, that is, in constitutive activation or superactivation of the function of the encoded protein. Once again, such mutations are often inherited in an autosomal dominant fashion. Finally, mutations of genes on the X chromosome are often inherited in an X-linked fashion. That is, the disease is only manifest in boys (who have a single X chromosome and therefore are functionally homozygous for the mutation) and is usually inherited from an unaffected mother.

Examples of Genetically Determined Cardiovascular Diseases

Familial Hypertrophic Cardiomyopathy: Genetic Diseases of the Sarcomere (See also Chap. 48)

Familial hypertrophic cardiomyopathy (FHC) is an autosomal dominant inherited disorder with a prevalence of approximately 1 per 500 live births that is characterized by progressive left ventricular hypertrophy, diastolic dysfunction, arrhythmias, and often heart failure and premature death.[42] This disease unfortunately often presents as sudden death in young adults. FHC is genetically heterogeneous; that is, linkage studies in humans demonstrated that the disease maps to a number of different chromosomal loci in different families.[43]

A major breakthrough in cardiovascular genetics occurred when Christine and Jon Seidman and their coworkers identified mutations in the beta-myosin heavy chain (beta-MHC) in some families with FHC.[44] The majority of these were missense mutations, that is, they produced a full-length protein with single amino acid substitutions (e.g., in one common beta-MHC mutation, the arginine 403 was mutated to a glutamine). In these cases it is likely that the mutant protein serves as a dominant negative inhibitor of sarcomere function--that is, the mutant protein oligomerizes with the normal protein expressed from the wild-type allele and in some way impairs the normal protein's contractile function. This overall impairment in function then stimulates a hypertrophic response (through unknown signaling pathways) that leads to increased diastolic pressures and ultimately to congestive heart failure and arrhythmias.[43] This type of dominant negative phenotype explains how one mutant copy of the gene produces the human disease and is consistent with the dominant pattern of inheritance seen in this disorder.

Subsequently, several groups have identified mutations in other sarcomeric protein genes as the cause of FHC in other families. These include the troponin T gene,[45] the alpha-tropomyosin gene,[45] and the myosin-binding protein C gene.[46] Thus, a picture is now emerging in which many different disruptions of the sarcomeric proteins can lead to cardiac hypertrophy and heart failure.[43] [47] It will be of great interest to understand the molecular pathways by which the cardiomyocyte senses defects in contractile function in patients with FHC and then initiates the hypertrophic program because similar pathways may underlie pathological hypertrophy in patients with acquired hypertrophic cardiomyopathies such as those associated with hypertension and valvular heart disease.

One of the most interesting stories to emerge from the genetic analyses of FHC patients was the notion that one could begin to predict clinical outcomes based on the nature of the mutation causing the disease. Thus, for example, patients with the arginine 403 to glutamine mutation tended to display markedly increased mortality rates, whereas patients with a valine 606 to methionine mutation had normal life expectancies.[48] [48A] This type of genetic prognostication will likely play an increasingly important role in risk stratification in patients with inherited cardiovascular disorders (see Fig. 48-11 (Figure Not Available)). By use of genetic engineering, mutant myosins can be expressed in vivo, permitting functional analysis of the isolated mutant proteins by biophysical techniques in vitro.[48B]

Congenital Long QT Syndrome: A Disease of Cardiomyocyte Ion Channels (See also Chap. 25)

The congenital long QT syndromes are autosomal dominant inherited disorders characterized by repolarization abnormalities (manifest by prolonged QT intervals on an electrocardiogram) and torsades de pointes.[49] Like patients with FHC, long QT syndrome patients often present with syncope and sudden death. Our understanding of both the genetic and pathophysiological bases of this disease were significantly enhanced by Keating and coworkers, who first demonstrated linkage of the disease to three chromosomal loci (LQT1, LQT2, and LQT3) and then cloned the genes responsible at each locus.[50] [51] [52] [53] Interestingly, in each case the defective gene encoded a cardiac ion channel: LQT1 is caused by mutations in the *KVLQT1* cardiac K channel gene,[53] LQT2 by mutations in the *HERG* (Human Ether a-go-go Related gene) K channel gene,[51] and LQT3 by mutations in the *SCN5A* sodium channel gene on chromosome 3p21-24.[52] In the case of the *SCN5A* gene, in-frame intragenic deletions were shown to disrupt the inactivation of the channel, resulting in enhanced activity during repolarization. Thus, this was essentially a gain of function mutation also consistent with its dominant pattern of inheritance.[54] As in FHC, it appears that mutations in multiple genes involved in regulating the cardiac action potential can give rise to the long QT syndrome.

In addition to inherited long QT syndrome there are a number of environmental long QT syndromes, such as those associated with cardiac ischemia, hypokalemia, type I antiarrhythmic drugs, and certain drug interactions. It is tempting to speculate that polymorphisms (silent mutations or variations) in the same ion channel genes that cause congenital long QT syndrome might confer susceptibility or resistance to these environmental insults. In this regard it will be of interest to sequence these ion channel genes in patients who are very sensitive (or resistant) to hypokalemia or drug-induced QT prolongation.

BASIC TECHNIQUES OF MOLECULAR BIOLOGY

Cloning and Recombinant DNA

Because every human cell contains 3×10^9 base pairs or 80,000 to 150,000 human genes, it is difficult if not impossible to study the structure and function of a single human gene in the context of an intact human cell. To circumvent this problem, molecular biologists have developed simple and elegant techniques for isolating, sequencing, and mutating single genes and copying them millions of times either in simple organisms like bacteria or in the test tube in vitro.[55] Indeed, such gene cloning techniques in many ways represent the foundation of modern molecular biology. As described earlier, the power of gene cloning derives from the fact that bacterial, yeast, and mammalian cells use common mechanisms for copying and expressing DNA. Thus, human genes can be inserted into bacteria, yeast, fruit flies, or mice, where in most cases they are faithfully replicated and expressed into their cognate proteins.

RESTRICTION ENDONUCLEASES.

Restriction endonucleases are bacterial proteins that recognize and cleave or cut specific palindromic sequences in DNA.[56] For example, the EcoRI restriction endonuclease from the bacteria *Escherichia coli* recognizes the sequence GAATTC, which occurs approximately every 3000 to 4000 base pairs in human DNA. After recognition of its cognate sequence EcoRI cleaves the two strands of the double helix asymmetrically after the GA to produce overhanging single-stranded sticky ends of ATTC (Fig. 55-7) . Three properties of such restriction endonucleases make them extremely useful tools for molecular biologists. First, because the sequence of any gene is unique and generally identical among all members of the species, such endonucleases can be used to reproducibly cleave a given gene at a specific location, thereby resulting in predictably sized cleavage products containing that gene. Second, because there are hundreds of distinct restriction endonucleases each with its own unique recognition sequence, any gene can be reproducibly cut into pieces of almost any size (and the sizes of these fragments

Figure 55-7 Recombinant DNA technology can be used to amplify a human gene. Shown is ligation of a human DNA fragment digested with the restriction endonuclease HindIII into a HindIII-digested bacterial plasmid vector. Hybridization of complementary sticky ends on the two HindIII-digested DNAs allows precise ligation of the two fragments. Ab^R =an antibiotic resistance gene used to select bacteria transformed with the recombinant plasmid. The recombinant plasmid is used to transform bacteria. Bacteria containing the plasmid are selected by growth in antibiotic, resulting in the exponential amplification of the recombinant DNA molecule.

can be predicted in advance from the known sequence of the DNA). Finally, the existence of complementary sticky ends on fragments cut by a single restriction endonuclease allows molecular biologists to join together or "ligate" any two fragments of DNA that have been cleaved by that endonuclease. Thus, for example, a human gene fragment digested with EcoRI can be easily ligated to a bacterial gene cut by the same endonuclease. Similarly, a human gene can be ligated into an adenovirus vector after cleavage of both pieces of DNA with a single restriction endonuclease.

GENE CLONING.

Plasmids are small circular pieces of DNA that replicate autonomously to high copy number in bacteria.[57] Such plasmids often contain genes encoding antibiotic resistance in bacteria, allowing the selection of bacteria containing them by growth in antibiotic-containing medium. This type of drug resistance plasmid can be cleaved once with a restriction enzyme and a single human gene cut with that same enzyme ligated into the plasmid DNA to produce a plasmid copy of the human gene (see Fig. 55-7) . The resulting plasmid can then be introduced into bacteria. Growth of such genetically modified bacteria in the presence of the appropriate antibiotic yields an essentially pure culture of bacteria, each of which contains between 10 and 500 copies of the single cloned human gene. Because the doubling time of bacteria is on the order of 20 minutes, inoculation of a 1-liter culture of bacterial broth with a single bacterial cell containing 500 copies of a human gene at 6 P.M. results in a culture containing 10^{11} copies of that same gene the next morning. The bacterium serves as a logarithmic gene-duplicating machine with a short replication time--the ideal tool for copying genes.

RECOMBINANT PROTEINS.

In addition to their ability to copy genes rapidly and accurately, bacteria can also be used to express the human proteins encoded by cloned genes. By pasting the cloned human gene into a bacterial plasmid containing bacterial transcriptional regulatory sequences, the bacteria can be programmed to make large amounts of the human protein.[58] As long as the protein folds correctly and does not need to be posttranslationally modified by human enzymes (e.g., by adding sugar moieties or phosphate residues), such recombinant proteins made in bacteria will function normally both in vitro and after infusion into patients. In other cases, yeast or mammalian cells can be programmed to synthesize large amounts of recombinant proteins for human therapy.[59] [60]

Example of a Genetically Engineered Protein Used in Therapy: Production of Tissue Plasminogen Activator Using Recombinant DNA Technology

The use of thrombolytic agents has revolutionized the care of patients with acute myocardial infarction (see Chap. 35).[61] [62] Thrombolytic proteins are produced naturally by a wide range of organisms from bacteria to humans. One of the most potent agents, t-PA, was first isolated and purified in substantial amounts from human melanoma cells. However, such cells did not produce sufficient quantities of the active protein for widespread human therapy. Accordingly, there was great interest in using recombinant DNA technologies to engineer the production of large quantities of biologically active and pure t-PA. Although some human proteins such as growth hormone can be produced in their active form from bacteria like *E. coli,* bacteria often cannot properly fold or modify complex human proteins. This proved to be the case with t-PA. After cloning of the gene from melanoma cells[63] (using synthetic oligonucleotides based on the sequence of the purified protein as probes to pick the proper clones), the t-PA complementary DNA (cDNA) was cloned into a restriction endonuclease-digested plasmid containing a drug resistance gene *DHFR),* and a eukaryotic promoter.[64] After amplification in bacteria this plasmid was transfected into Chinese hamster ovary cells, and clones expressing t-PA were selected by growth in HAT media, which only allowed the survival of cells with large numbers of copies of the *DHFR*-bearing plasmid. These clones of transfected cells were then grown in large numbers in cell fermentors, and the recombinant t-PA that was secreted from the cells was collected and purified from the tissue culture medium.

Nucleic Acid Hybridization

Because the two strands of the DNA helix are complementary to each other, they tend to specifically find and anneal to each other if mixed together under appropriate temperature and salt conditions. Such annealing is stabilized by hydrogen bonding between the complementary base pairs present on each strand of the helix. The annealing of complementary DNA strands is called hybridization and is the basis of many of the techniques used to identify specific genes in large mixtures of genetic material (see blotting techniques and array technologies, later). Hybridization is also employed to specifically join together two pieces of DNA containing complementary single-stranded ends such as occurs after cleavage with a single restriction enzyme and to anneal synthetic single-stranded oligonucleotides to genes during amplification by the polymerase chain reaction (PCR).

The Polymerase Chain Reaction

As described earlier, bacterial cloning represents an elegant biological solution to the problem of the clonal amplification of genes. An even more rapid technique has been described that allows the clonal amplification of any specific fragment of DNA in less than 2 to 3 hours in a test tube[65] [66] [67] [68] [69] (Fig. 55-8) . In the PCR a mixture of double-stranded DNA from as little as a single cell is mixed with synthetic oligo

Figure 55-8 Gene amplification by the polymerase chain reaction (PCR). Synthetic oligonucleotide primers corresponding to the 5 and 3 ends of the DNA sequence to be amplified are chemically synthesized. The double-stranded DNA is melted by heating to 92%C, and primers are annealed by cooling the DNA solution to 72%C. A thermostable DNA polymerase then amplifies each strand of the target sequence, producing two copies of the gene segment. This process is repeated to produce an exponential amplification of the target sequence.

---

nucleotide primers (small pieces of DNA that are complementary to the ends of the sequence to be amplified). The mixture is heated to melt apart or separate the two strands of human DNA and then cooled to allow the complementary oligonucleotide primers to hybridize or specifically anneal to their complementary sequences, flanking the gene of interest on the single-stranded human DNA. A purified DNA polymerase is then used to synthesize a complementary copy of the fragment of interest. The mixture is again heated to melt apart the complementary strands of human DNA, and the process is repeated. The special heat-stable DNA polymerase used for PCR amplification derives from a bacterium adapted to live in hot water (*Thermus aquaticus,* hence "Taq" polymerase). Each such cycle of PCR, which takes only 3 minutes or so, produces a doubling of the quantity of the gene fragment of interest. Thus, beginning with the DNA from a single cell, in 30 cycles one can produce 2[30] copies of any gene, more than enough to clone, sequence, or manipulate in vitro. The entire amplification is carried out in a sealed test tube or well in a specially designed machine that can be programmed to automatically heat and cool the sample. This ingenious and simple technology has revolutionized our ability to copy, sequence, mutate, and clone genes beginning with only tiny amounts of a DNA sample.

DNA Sequencing and the Human Genome Project

The human genome contains all of the information necessary for the development and function of the organism. Of equal importance, variations and mutations in the human genome are important determinants of disease susceptibility. Thus, obtaining the sequence of the human genome has been one of the major goals of molecular biology and medicine during the past 20 years. During the 1970s several groups described techniques for sequencing short stretches (several hundred base pairs) of cloned human DNA.[69] [70] The problem was then how to scale up this technology to accomplish the sequencing of the 3×10^9 base pairs contained in each human cell. This scale up has been accomplished in a remarkably short time, particularly considering that a single sequencing reaction still typically generates less than 1000 base pairs of readable DNA sequence. During the past several years the complete sequences of bacteria, yeast, worms, and flies have been determined.[71] [72] [73] [74] The sequencing of the entire human genome was completed in 2000. Now that this sequence is in hand, the challenge will become how to organize, search, and manage this vast amount of new information and how to begin to understand the variabilities in sequence between human populations and individuals and how such genetic variability translates into phenotypic variation.

Monoclonal Antibodies

Antibodies recognize and bind to epitopes, specific shapes of molecules such as those assumed by a particular sequence of amino acids or sugars. A single plasma cell produces one antibody with a unique recognition site for a single protein or sugar epitope. However, in a typical immune response after vaccination with a foreign protein, the mammalian organism produces thousands of different plasma cells that secrete thousands of distinct antibodies into the serum. Although such polyclonal antisera are useful, it would clearly be desirable to identify a renewable cell source that could be used to produce a single homogeneous (monoclonal) antibody that is specific for a single epitope on a functionally important human protein. Unfortunately, it is not possible to clone and grow normal plasma cells in tissue culture for long periods of time.

The problem of monoclonal antibody production was solved by Kohler and Milstein,[75] who discovered that they could fuse a normal antibody-producing plasma cell to an immortalized myeloma cell to produce a continuously growing fusion cell that would in many cases continue to produce and secrete large amounts of the plasma

cell's antibody. This technique has subsequently been used by many investigators to produce immortalized plasma cells that produce antibodies to proteins of the cardiovascular system. Such monoclonal antibodies are useful for identifying and purifying individual proteins, for diagnostic tests designed to identify and quantify those proteins in cells, tissues, and serum, and in some cases as therapeutic reagents.[17] [76] [77] [78]

Example of a Monoclonal Antibody Use in Therapy: Monoclonal Antibody Directed Against the Platelet Glycoprotein IIb/IIIa in the Treatment of Thrombotic Coronary Syndromes (See also Chaps. 35 , 36 , 38 , and 62)

Platelet adhesion, aggregation, and secretion play an important role in the etiology of myocardial infarctions and strokes. Thus, there has been a great deal of interest in developing novel therapeutic reagents that can be used to inhibit platelet function in patients with these disorders. The platelet-specific glycoprotein (GP) IIb/IIIa is a cell surface molecule composed of a 136-kDa A chain and a 100-kDa B chain.[79] GP IIb/IIIa is a member of the integrin family of cellular adhesion receptors. Binding of GPIIb/IIIa to ArgGlyAsp (or RGD) peptide sequences in fibrinogen results in platelet cross-linking, adhesion, spreading, and secretion, and subsequent thrombus propagation.[79]

The importance of the GP IIb/IIIa molecule was demonstrated using RGD (or KGD) containing peptide inhibitors and monoclonal antibodies specific for the fibrinogen binding site of GPIIb/IIIa, both of which were shown to potently inhibit platelet aggregation and function in vitro.[80] These findings led directly to the idea of using such monoclonal antibodies as antiplatelet reagents in patients suffering from unstable coronary syndromes and those undergoing percutaneous revascularization. To avoid immune responses, a high-affinity murine monoclonal antibody directed against the human GP IIb/IIIa molecule (that also recognized the $alpha_V$ $beta_3$ vitronectin receptor) was "humanized" using recombinant DNA techniques to render the murine monoclonal antibody less immunogenic and to produce it in large quantities in the supernatants of cultured myeloma cells.

The resulting purified monoclonal antibody abciximab (or ReoPro) was then tested for efficacy in clinical trials in patients undergoing percutaneous coronary revascularization by either balloon angioplasty or stenting.[81] [82] [83] [84] These studies have shown a consistent 50 to 60 percent reduction in acute ischemic complications (death, myocardial infarction, and emergency revascularization) in the treated patients. Abciximab appears to be even more efficacious in patients with unstable coronary syndromes undergoing percutaneous revascularization.[85] Small molecule or peptidic GP IIb/IIIa antagonists have similar effects (see also Chaps. 38 and 62). The success of these clinical trials not only has provided us with important new therapeutic reagents for patients undergoing percutaneous revascularization but also has raised the level of enthusiasm concerning the development of additional monoclonal antibody drugs for patients with cardiovascular diseases.

Blotting Techniques

A typical human cell contains thousands of genes, mRNAs and proteins. Blotting techniques allow the identification of single genes, RNAs, or proteins based on their size and sequence without the need to purify individual molecules. Southern blotting begins with the cleavage of human genomic DNA with one or more restriction enzymes, thereby producing a mixture of thousands of DNA fragments of all sizes.[86] These DNA fragments are subsequently separated by size using electrophoresis in an agarose gel. In such a gel the smallest fragments migrate most quickly to the bottom of the gel whereas the larger fragments migrate more slowly and remain near the top of the gel. The fragments are then denatured (separated into single strands) and transferred to a sheet of filter paper to produce a replica of the gel. This filter is then exposed to a radioactive DNA probe (a radiolabeled single-stranded DNA fragment) that is complementary to the gene of interest. Such a probe hybridizes specifically to its complementary gene fragment on the filter and sticks to the filter during washing to remove unbound radioactivity. Because a given gene will only be contained in one or at most a few fragments whose size is based on the occurrence of restriction enzyme sites in and around the gene, the probe will only anneal to a few bands on the filter. Autoradiography of the hybridized and washed filter will

allow visualization of these bands and determination of their sizes.

Northern blotting is used to detect specific mRNAs and is based on principles similar to Southern blotting[55] (Fig. 55-9) . The mRNA corresponding to each gene displays a characteristic size or sizes. Therefore, a mixture of cellular RNAs of different sizes is separated by electrophoresis on agarose-containing gels, transferred to a filter, and hybridized to a radiolabeled DNA probe complementary to the mRNA of interest. After hybridization the radiolabeled bands are visualized by autoradiography.

Western blotting is an electrophoretic technique used to identify specific proteins. Once again it is based on the principle that different proteins display characteristic sizes and can be recognized specifically by antibodies. A mixture of proteins is separated by size by electrophoresis through a polyacrylamide gel and transferred to a filter. This filter is then incubated with an antibody that is specific for the protein of interest coupled to a radioactive isotope or an enzymatic marker. Specific bands corresponding to the protein of interest are then visualized by autoradiography or colorimetric or photometric reactions.[55]

In addition to allowing the identification of genes, RNAs, and proteins, these blotting techniques allow quantitation of the levels of specific biomolecules in different cell types, in cells from patients with disease, and in response to different developmental or environmental stimuli.

Gene Array Technologies

Blotting techniques allow quantitation and comparison of the levels of expression of a single gene between various cell samples. However, in many cases it would be desirable to compare the expression profiles of hundreds or even thousands of genes in two cell types or tissue samples. For example, it would be fascinating to understand the patterns of expression of all of the genes in the human genome in cardiomyocytes from failing as compared with normal hearts or in vascular smooth muscle cells immediately before and after mechanical injury such as balloon inflation. This type of gene profiling study has become increasingly powerful as the number of sequenced human genes increased over the past several years. Gene array technologies developed during the past 5 years allow the highly accurate and simultaneous quantitation of levels of mRNA expression from thousands of genes.[87] [88] [89] [90] [91] Although these technologies differ in their experimental details, they are all based on arraying cDNAs or oligonucleotides corresponding to known gene sequences on a grid of some sort (from a piece of filter paper to a glass slide or a silicon chip) and then hybridizing radiolabled or fluorescent cDNAs (DNA copies of RNA) from different cell samples to the grid. Computer software is then used to analyze the intensity of hybridization to the individual spots on the grid, and statistical analysis can be used to estimate the likelihood of significant changes in the levels of gene expression between the samples.

GENETICALLY MODIFIED MICE AS A MODEL SYSTEM OF HUMAN CARDIOVASCULAR DISEASE

One of the most surprising findings to emerge from molecular genetic studies of the cardiovascular system is the remarkable evolutionary conservation of the molecular pathways that control cardiovascular development and function. It is now clear that similar genes and signaling pathways regulate the development of the heart and vasculature in mice and humans.[2] In some cases these same pathways

Figure 55-9 Northern blot analysis. Cellular mRNAs of different sizes are separated by agarose gel electrophoresis and transferred to a filter membrane. The membrane is incubated in a solution containing a single-stranded radiolabeled DNA probe complementary to the mRNA of interest. This radiolabeled probe hybridizes only to the single band containing the complementary mRNA. Nonspecific binding of the probe is removed by washing the filter, and the band is visualized by exposure of the filter to x-ray film. As shown in the figure, the intensities of the resulting autoradiographic bands correspond to the abundances of the mRNA in the original samples. Hence, the technique can be used to quantitate the levels of gene expression in two different tissue samples.

have even been conserved in reptiles and insects. Thus, we can gain important insights into human cardiovascular biology and disease by studying these processes at the molecular level in lower organisms. In many ways, mice represent an ideal model system for studies of human cardiovascular biology and disease. The mouse is a small animal with a short gestation period (21 days). A great deal is known about murine embryology and genetics. The mouse genome is being sequenced as a part of the genome initiative. Therefore, it will soon be possible to compare the structures of all of the mouse and human genes. Perhaps most importantly, elegant techniques for gene insertion, inactivation, and modification have been devised that allow genetic manipulation of the mouse almost ad libitum.

Transgenic Mice

Overexpression of a wild-type or mutant gene in a mouse represents a powerful tool for understanding both the function of that gene in normal mouse development and, in some cases, its role in specific disease states. The production of a transgenic mouse involves (1) the cloning of the gene of interest, (2) fusion of that gene to

transcriptional regulatory sequences that program its expression either in all tissues of the mouse or in specific tissues, (3) injection of the purified transgene into the male pronucleus of a fertilized one-cell mouse embryo, and (4) reimplantation of the injected embryo into a foster mother[35] [92] [93] (Fig. 55-10) . In many cases the injected transgene is randomly integrated into a chromosome of the fertilized embryo, resulting in a founder mouse that not only will express the injected transgene but also will pass that transgene on to 50 percent of its progeny. By comparing the phenotype of the transgenic animals with that of their nontransgenic (but otherwise genetically identical) siblings, one can draw firm conclusions about the effects of transgene overexpression on development and function at the cellular, tissue, and organismal levels. Although the production of transgenic animals was originally a technically difficult procedure that could only be carried out in a few specialized research laboratories,[94] it is now possible to produce routinely multiple transgenic founders in less than a month after a single day of embryo injections with the appropriate transgene DNA construct. Thus, the production of transgenic mice has become a standard procedure carried out in many laboratories throughout the world. Moreover, similar techniques have recently been used to produce transgenic rats, rabbits, and pigs.

Promoters have recently been characterized that program transgene expression exclusively in cardiomyocytes, endothelial cells, and vascular smooth muscle cells.[35] [95] Thus, it is now possible to restrict transgene expression to specific cell types in the cardiovascular system. In addition to producing gain-of-function animals by overexpression of the wild-type or even a superactivated mutant gene, it is also possible to use transgenic techniques to eliminate the function of a single gene by overexpressing a dominant negative mutant of that gene whose encoded protein interferes with the function of the wild-type protein.[96] [97] Recently, it has also become possible to produce transgenic mice in which expression of the transgene is turned on or off by administration

Figure 55-10 Production of transgenic mice. The transgene of interest is coupled by recombinant DNA technology to a transcriptional regulatory sequence that directs its expression either in all cells or in specific tissue types of the mouse. This transgene construct is microinjected into the pronucleus of a fertilized mouse egg, which is then implanted into the uterus of a foster mother. Twenty-one days later, this mother gives birth to a litter containing one or more transgenic founder mice that have integrated the transgene cassette into their genomic DNA. Breeding of these founders to wild-type mice results in transmission of the transgene to 50 percent of the resulting offspring. Transgenic mice are shown in black. Nontransgenic mice are shown in white.

of a simple drug like tetracycline.[98] Such mice allow precisely timed transgene expression as well as a comparison in the same animal of the phenotypes of transgene-positive and transgene-negative states.

Example of the Use of Genetically Altered Mice to Investigate Cardiovascular Pathophysiology: Transgenic Mice Reveal the Role of Beta-adrenergic Receptor Downregulation in Congestive Heart Failure (See also Chap. 16)

Chronic overstimulation of beta-adrenergic receptors as is seen in patients with congestive heart failure leads to the downregulation of beta-adrenergic receptor (betaAR) signaling in cardiomyocytes.[99] Recent studies have demonstrated that this downregulation results from phosphorylation of the betaAR by beta-adrenergic receptor kinase (betaARK) and subsequent receptor internalization and uncoupling.[100] Receptor uncoupling, in turn, leads to decreased contractility and an exacerbation of heart failure. Thus, prevention of receptor phosphorylation and internalization might be beneficial in patients with congestive heart failure.[101] [101A]

During the past 5 years, several mouse models of dilated cardiomyopathy and heart failure have been described.[97] [102] [103] [104] [105] To ask if the prevention of betaAR uncoupling could ameliorate the progression of congestive heart failure in these models, Lefkowitz and colleagues produced transgenic mice that overexpressed a truncated form of betaARK (called betaARKct).[101] betaARKct was known to function as a dominant negative inhibitor of betaARK, that is, it prevented betaARK from phosphorylating the betaAR and therefore prevented betaAR internalization. To be certain that the effects of the betaARKct transgene were due to its activity in cardiomyocytes, Lefkowitz and colleagues linked the betaARKct transgene to the cardiomyocyte-specific alpha-myosin heavy chain (alpha-MHC) promoter using standard recombinant DNA techniques. After injection of the betaARKct transgene into fertilized mouse embryos, Lefkowitz and colleagues produced several lines of transgenic mice that expressed high levels of betaARKct only in cardiomyocytes. These betaARKct transgenic mice demonstrated increased basal heart rates and contractility as well as enhanced responses to betaAR stimulation.[101] To test the effects of betaARK inhibition on the progression of heart failure, the betaARKct transgenic mice were bred with MLP knockout (KO) mice[102] that develop dilated cardiomyopathy and heart failure. Remarkably, the betaARKct transgene prevented the development of congestive heart failure in the MLP KO mice, demonstrating directly that betaAR downregulation plays a key role in both the development and progression of heart failure in the MLP KO mice.[106] This exciting genetic experiment confirmed the important role of betaARK in this model of heart failure and suggested that drugs that inhibit betaARK activity may be useful new therapeutic reagents in patients with congestive heart failure.

Targeted Gene Inactivation ("Knockout") Technologies

Gene knockouts represent a complementary approach to transgenesis for studying the role of a specific gene in mouse development and physiology[107] [108] [109] [110] [111] [112] [113] [114] (Fig. 55-11) . Unlike transgenic experiments that typically result in overexpression of the transgene product (and hence produce a gain-of-function mouse), gene knockouts eliminate the expression of one or more genes to produce a loss-of-function mutant animal. The classical knockout approach involves transfection of a pluripotent mouse embryonic stem (ES) cell with a targeting construct or copy of the gene of interest containing a deletion or nonsense mutation.[108] Homologous recombination between the targeting construct and one copy of the endogenous gene produces an ES cell with a heterozygous deletion of the gene of interest. This mutant ES cell is then injected into a fertilized mouse blastocyst, which in turn is implanted into a foster mother. The resulting mouse is a chimera in which all tissues (including the gonads) are derived in part from the mutant ES cells and in part from the wild type cells of the injected blastocysts. This chimeric animal is then bred to a wild-type animal. Fertilization of a wild-type egg with a mutant sperm from the chimera produces a heterozygous KO animal in which one copy of the gene of interest in all cells is mutant and the other copy is wild type. Such heterozygous animals can be bred to produce homozygous knockouts that lack active copies of the gene of interest in all cells. The phenotype of such gene KO animals reveals the essential function(s) of that gene in both normal development and physiology. Unlike transgenesis, gene knockouts are difficult, time consuming, and expensive to produce. It typically takes a skilled investigator 6 to 12 months to produce a single KO mouse strain.

Example of Targeted Gene Deletion to Produce a Disease Model: Apolipoprotein E-Deficient Mice: A Murine Model of Atherosclerosis

Unlike humans, mice are remarkably resistant to atherosclerosis, even when maintained on a high-cholesterol diet.[115] This fact has limited our ability to use mouse models to study the pathogenesis and treatment of atherosclerotic vascular disease. It has been hypothesized that the resistance of mice to atherosclerosis may be due in part to the fact that most of the cholesterol in mouse serum is present in the high-density lipoprotein ([HDL], as opposed to the low-density lipoprotein [LDL]) fraction.[115] [116] To alter the lipoprotein pattern in mice and directly test the function of apolipoprotein E (apoE) in cholesterol metabolism, two groups independently used gene targeting to inactivate the apoE gene in mice.[117] [118] Due to delayed clearance of very low density lipoprotein (VLDL) particles lacking apoE, the mutant mice displayed marked elevations in VLDL-like particles and reciprocal decreases in HDL cholesterol (see also Chap. 31). Interestingly, these disorders in lipid metabolism were associated with the development of extensive atherosclerosis when these mice were maintained on a diet similar to those consumed in westernized countries.

These results not only proved the important role of apoE in determining sensitivity to atherosclerosis, but also provided a new animal model of the disease, which could be used to study both pathogenesis and treatment. For example, recent studies have demonstrated that the development of late atherosclerotic lesions in the apoE-deficient mice can be significantly reduced by breeding them to mice deficient in CD154 (or CD40 ligand)[119] or by administration of antibodies against CD154,[120] [120A] a proinflammatory receptor present on T cells, macrophages, vascular smooth muscle cells, and endothelial cells. These findings directly implicated the CD40/CD40L interaction in the progression of atherosclerosis in this model and suggested that strategies to block this pathway may represent novel approaches for the treatment of atherosclerosis.

Newer Gene-Targeting Approaches

Because many genes are required for the early development of multiple cell types and tissues, classical gene knockout approaches can often result in early embryonic lethal phenotypes that are difficult to analyze and understand. Thus, it would be desirable to be able to delete genes in a tissue-specific fashion and/or to inactivate them at different times in development. Moreover, in some cases it is of interest to produce specific mutations of genes rather than to eliminate their expression completely. Recently developed technologies have begun to address these issues.[110] [111] [112] [113] [114]

The same types of homologous recombination methods that are used to knockout genes by deletion can be used to introduce specific mutations into wild-type genes. The only major difference in technique is that such "knock-ins" use a targeting construct containing a mutant gene rather than a gene deletion. Moreover, it is possible using homologous recombination to introduce a distinct or unrelated gene into a foreign genetic locus and to thereby regulate the new gene under the control of the promoter of the targeted locus.

Gene deletion can also be carried out in a tissue-specific manner by using an elegant bacterial phage recombination system called Cre-lox.[112] [121] The P1 bacteriophage encodes an enzyme called Cre that catalyzes recombination of DNA between two specific sequences (called loxP sites) that signal recombination.[121]

This system can be used in mice by

Figure 55-11 Gene targeting in mice. *A,* A schematic illustration of a wild-type prototypical eukaryotic gene with three exons *(top),* a targeting construct in which exon 2 has been replaced with a neomycin resistance gene (neo^R) under the control of the phosphoglycerate kinase (PGK) promoter *(middle),* and a targeted allele in which the wild-type gene has been replaced with the targeting construct by homologous recombination *(bottom). B,* Production of gene-targeted mice. The targeting construct produced in *A* is introduced into murine embryonic stem (ES) cells by electroporation. Cells containing the targeted allele produced by homologous recombination are identified by Southern blot analysis and injected into a fertilized mouse blastocyst. Injected blastocysts are implanted into a foster mother, that gives birth 21 days later to chimeric mice in which all of the tissues are derived in part from the targeted ES cells and in part from wild-type cells within the blastocysts. Breeding of the chimeric mouse to a wild-type mouse results in germline transmission of the targeted allele, producing heterozygous mice that contain one targeted and one wild-type allele. Interbreeding of two heterozygous mice produces a litter composed of one-fourth wild-type (+/+) mice, one-fourth homozygous targeted (-/-) mice, and one-half heterozygous (+/-) mice. *C,* Southern blot analysis of a cross between two heterozygous gene-targeted mice. The wild-type (WT) and targeted (T) alleles can be distinguished by their different sizes on Southern blot. The genotypes of resulting mice can be deduced from the patterns of the wild-type and targeted alleles. Wild-type (+/+) mice contain two copies of the wild-type allele. Heterozygous (+/-) mice contain a single copy of the wild-type allele and a single copy of the targeted allele. Homozygous deficient mice (-/-) contain two copies of the targeted allele.

producing a targeting construct in which the gene of interest is flanked by loxP sites (a so-called floxed allele).[112] [121] Mice homozygous for the floxed allele can then be bred with transgenic mice that express the Cre recombinase in a tissue-specific manner. Such mice will then delete the gene of interest only in the tissue expressing the Cre recombinase. By placing the Cre transgene under the control of a tetracycline-responsive promoter it is also possible to program gene deletion only after tetracycline feeding.

By using combinations of transgenesis, gene knockout, and new gene targeting approaches it is now possible to produce gain-of-function and loss-of-function mice in a temporally and spatially regulated fashion. In addition to identifying the function of individual genes at the organismal level, such studies often produce new animal models of human cardiovascular disease that are useful for studies of molecular pathogenesis and therapy. For example, such approaches have already produced mouse models of hypertrophic[122] [123] and dilated cardiomyopathy,[96] [97] [102] [103] [104] [105] familial hypercholesterolemia,[124] and congenital cardiac disorders. The completion of the human genome project, announced in June of 2000,[124A] [124B] will lead to the identification of large numbers of variations in gene sequence (polymorphisms), some of which will be associated with specific human diseases. Homologous recombination-mediated knock-ins of these mutations into mice will become an important tool for validating the role of these polymorphisms in the etiology of these diseases.

Advances in Mouse Physiology

To harness the full power of mouse genetics, it is important to be able to perform accurate physiological studies of the cardiovascular system in genetically modified animals. Until recently, the ability to analyze the mouse cardiovascular system was severely limited by both the small size of the heart and vessels in the mouse and by the resting murine heart rate of greater than 500 beats/min. During the last several years, a number of groups have solved this problem by developing miniaturized instrumentation and microsurgical techniques.[3] [96] [125] Using these approaches it is now possible to obtain a wide variety of physiological measurements in anesthetized and intubated closed-chested animals. Such parameters include aortic blood pressures, real-time left ventricular pressure tracings, dP/dt_{max} and dP/dt_{min} , and arterial blood gases and pH both at baseline and after the infusion of pressors such as dobutamine or isoproterenol. In addition, by using high-frequency transducers and customized software it is possible to obtain high-resolution M mode and two-dimensional echocardiograms from mice. These images can be used to determine end-systolic and end-diastolic left ventricular dimensions, left ventricular wall thickness and mass, shortening fraction, and wall stress rate-corrected velocity of fiber shortening (Vefc) relationships. It is also possible to produce myocardial infarctions by coronary artery ligation with or without reperfusion injury and to induce left ventricular hypertrophy by aortic banding or chronic infusion of angiotensin II. Finally, it is now possible to obtain 24-hour electrocardiographic recordings on conscious mice using implanted transducers and to perform limited electrophysiological studies to detect inducible cardiac arrhythmias in these animals.[126] Taken together, these advances make it possible to use the mouse as an accurate and convenient model system for studies of cardiovascular physiology and pathology and, when combined with the genetic manipulations described earlier, suggest that the mouse will become an increasingly useful system for studies of the genetic bases of human cardiovascular disease.

GENE- AND CELL-BASED THERAPIES FOR HUMAN CARDIOVASCULAR DISEASE

Somatic Gene Therapy for Cardiovascular Disease

Somatic gene therapy can be defined as the ability to introduce genetic material into non-germline cells to produce a therapeutic effect at the level of the intact organism. The recent rapid increase in the number of cloned and characterized human genes when coupled with an improved understanding of the genetic pathways involved in normal and pathological cell function has increased the potential usefulness of somatic gene therapy approaches for the treatment of a wide variety of human cardiovascular diseases.[127] [128] [129] [130] Indeed, human gene therapy trials have recently been initiated for the treatment of patients with chronic myocardial ischemia[131] and vein graft stenoses.[132]

Gene therapy strategies can be divided into two categories based on the location of cell transduction. Ex vivo approaches are those in which cells or tissues are removed from an animal or patient, transduced with the therapeutic gene in vitro, and then retransplanted into the recipient host. In contrast, in vivo gene therapies involve the transduction of the appropriate cell type in vivo without the need for cell isolation or transplantation. During the past 5 years there has been a paradigm shift in our thinking about gene therapy approaches for human disease. Initial studies focused on the correction of inherited genetic disorders such as familial hypercholesterolemia or muscular dystrophy and often employed ex vivo methods. More recently, it has become clear that gene therapies may also be quite useful for the treatment of acquired disorders such as cardiac ischemia or restenosis and that particularly in the cardiovascular system it is often preferable to develop and employ in vivo gene transduction strategies.[127] [128] [129] [130]

Like any successful therapeutic strategy, gene therapies must be tailored to the patient and the patient's disease. Relevant considerations in this design process include an understanding of the cell type that must be transduced and the efficiency of transduction that is needed to correct or prevent the disease. Different disorders require different stabilities of transgene expression. Thus, for example the treatment of an inherited metabolic disorder such as familial hypercholesterolemia requires long-term stable transgene expression (or alternatively the ability to readminister the transgene on a regular basis), whereas the treatment of restenosis likely only requires transient expression of an appropriate transgene. Moreover, some gene therapies such as those designed to treat diabetes mellitus with transgene-encoded insulin clearly require regulated transgene expression whereas others such as the treatment of hemophilia with transgenes encoding coagulation factors XIII or IX simply require constitutive transgene expression. Finally, as with any new therapy it is important to carefully consider the potential risks of any gene therapy, including the effects of overexpression or ectopic transgene expression, the possibility of germline transmission of the transgene, risks associated with the vector used to introduce transgenes into cells (this is particularly true of viral vectors), the chance of mutagenesis of the host genome, and the potential for stimulating host inflammatory and immune responses to the vector or the transgene itself.

Most cardiovascular gene therapy approaches require at least three separate but related components: (1) an appropriate therapeutic transgene, (2) a vector for introducing that transgene into the relevant cell type such as a cardiomyocyte or a vascular smooth muscle cell, and (3) a device (e.g., a catheter or stent) for efficient delivery of the vector to the appropriate location in the cardiovascular system (e.g., to a localized segment of the vasculature or myocardium).

Vectors for Cardiovascular Gene Therapy

To date, five different vector systems have been tested or show promise for cardiovascular gene therapy (Fig. 55-12) : (1) "naked" plasmid DNA,[133] (2) synthetic oligonucleotides,[134] (3) replication defective adenoviruses,[135] [136] [137] (4) replication defective adeno-associated viruses,[138] and (5) retroviruses/lentiviruses. [135] [136] [137] Each of these vectors displays unique advantages and disadvantages, which define their usefulness for the treatment of different cardiovascular diseases (Table 55-1) .

"NAKED" DNA.

Naked plasmid DNA vectors (i.e., purified plasmids containing only a transgene and an appropriate transcriptional regulatory element) (see Fig. 55-12) are taken up and expressed by small numbers of cardiomyocytes after direct intramyocardial injection.[133] [139] The advantages of such vectors include the simplicity of their production and administration, the stability of their expression (at least 19 months in rodents),[140] and their inability to transduce most other cell types in vivo after

intramyocardial injection. However, these advantages are offset by the extremely low efficiency of cardiomyocyte transduction (less than 0.01 percent of the cells in the area of injection),[133] [139] [140] the requirement for direct injection into the myocardium, and their inability to appreciably transduce endothelial cells and smooth muscle cells in the vasculature. Thus, such vectors will likely only be useful for gene therapy strategies that require local expression of transgenes in very small numbers of cardiomyocytes after direct intramyocardial injection. An example of such an approach

Figure 55-12 Commonly used gene therapy vectors. The structures of retroviral, adenoviral, adeno-associated viral (AAV), and plasmid gene therapy vectors are shown. Viral and bacterial sequences are crosshatched. Transgene, promoter/enhancer, and selectable marker sequences are shown as unshaded boxes. LTR=long terminal repeat from the retroviral genome; Pr/E=an eukaryotic promoter/enhancer; ITR=inverted terminal repeat from either the adenoviral or AAV genomes; Ab^R =an antibiotic resistance gene for selection of plasmid-containing bacteria. Arrows show the direction of transcription of transgenes and selectable markers.

in which plasmid vectors are currently being tested in humans is the localized expression of vascular endothelial growth factor (VEGF) to induce angiogenesis after direct injection into regions of ischemic myocardium.[131]

OLIGONUCLEOTIDES.

Synthetic oligonucleotides are short (10 to 50 base pair) pieces of chemically synthesized single- or double-stranded DNA that can be used to inhibit the expression of one or more genes after their introduction into cells. The mechanism of action of these oligonucleotides is complex and not fully understood. However, in some cases the single-stranded antisense oligonucleotides (i.e., oligonucleotides whose sequence is complementary to the coding sequence of an mRNA molecule) appear to base pair through hybridization with their complementary mRNAs and thereby to promote their degradation.[74] Double-stranded oligonucleotides corresponding in sequence to the recognition site of a specific transcription factor can serve as decoys that bind and sequester their cognate transcription factor, thereby inhibiting its ability to activate its normal set of target genes.[141] The advantages of such oligonucleotides for gene therapy include their ease of production and their relative safety. Disadvantages include significant batch-to-batch variability in activity, the fact that they are generally limited to turning target genes off as opposed to augmenting the expression of therapeutic transgenes, their nonspecific activities in cells, and their short half-lives (on the order of hours to days) in vivo. In addition, the ability of oligonucleotides to transduce cells in vivo is quite limited, necessitating the use of lipid-viral conjugates to enhance transduction.[142] Thus, such oligonucleotide-mediated approaches of gene therapy will likely be useful only for transiently turning off the expression of specific genes in localized areas of the cardiovascular system. Indeed, such approaches have been successful in inhibiting vascular smooth muscle cell proliferation and intimal thickening in animal models of balloon angioplasty.[134] [142] [143]

ADENOVIRUS.

Adenoviruses are double-stranded DNA viruses that can be used to efficiently transduce a wide variety of tissues and cell types in vivo.[144] These viruses can be genetically engineered to render them replication-defective (i.e., to render them capable of infecting a normal human cell once but incapable of generating infectious progeny and spreading the infection beyond the initial site of administration) and to allow them to program high-level transgene expression in vivo (see Fig. 55-12). The advantages of adenovirus vectors include their very high efficiency of transduction of resting cells (including cardiomyocytes, vascular smooth muscle cells, endothelial cells, and hepatocytes) in vivo, the relative ease of producing large amounts of virus, the ability to deliver the vectors through a catheter, and their relative safety.[145] These vectors have not been associated with persistent infection or malignancy, and they generally do not integrate into the host genome, minimizing the risk of insertional mutagenesis. Unfortunately, these advantages are offset by the fact that adenovirus vectors generally produce potent inflammatory and immune responses both to themselves and to the transgenes that they express.[146] [147] [148] [149] These responses produce local tissue damage and usually eliminate virus-transduced cells, thereby limiting the duration of transgene expression to 2 to 3 weeks.[135] [146] [147] [148] [149] Moreover, adenovirus vectors generate neutralizing antibodies that prevent readministration of the virus,[148] and in some cases these vectors can break tolerance to self proteins that are related to the transgene protein, thereby producing autoimmunity and/or precluding future gene therapies involving the same transgene.[149] Thus, in their present form these vectors will likely only be useful for gene therapy approaches requiring high-level and efficient but transient transgene expression in vivo. Examples include their use in gene therapy strategies designed to inhibit restenosis and to program myocardial angiogenesis after injection into the myocardium.

Despite the apparent limitations on the use of current-generation adenovirus vectors, recent studies have suggested that in some cases it may be possible to obtain long-term transgene expression in vivo with first-generation adenoviruses (e.g., in the case of expression of a self transgene after injection into skeletal muscle and in the case of adenovirus perfusion of the donor heart before transplantation).[138] [149] Moreover, newer versions of adenovirus vectors in which all of the viral genes have been deleted (so-called helper dependent or gutted adenoviruses) also appear to yield stable transgene expression in vivo.[150] [151] [152] Thus, future developments may result in adenovirus vectors that are useful for a wider range of cardiovascular gene therapies.

ADENO-ASSOCIATED VIRUS.

Adeno-associated viruses (AAVs) are single-stranded DNA viruses that are nonpathogenic in humans.[153] By replacing all of the viral genes in these vectors with a transgene and promoter cassette it is possible to produce replication-defective AAV vectors that are quite useful for cardiovascular gene therapy[153] (see Fig. 55-12). Like adenoviruses, AAV vectors efficiently infect many resting cell types in vivo, including cardiomyocytes and hepatocytes.[138] [154] Their efficiency of transduction of vascular endothelial and smooth muscle cells remains less clear.[155] [156] Unlike adenoviruses, AAV vectors do not cause significant inflammatory or immune responses. Thus, these vectors can be used to program transgene expression in vivo that is stable for at least 1 year.[157] [158] Cardiomyocytes can be efficiently transduced after either intramyocardial injection or coronary artery perfusion.[138] Moreover, these

TABLE 55-1 -- COMPARISON OF DIFFERENT CARDIOVASCULAR GENE THERAPY VECTORS

VECTOR/TRANSGENE	ADVANTAGES	DISADVANTAGES
Retroviruses	Stably integrate into host genome	Low titers
	Easily manipulated viral genome	Capacity for insertional mutagenesis
	No viral gene products; relatively nonimmunogenic	In vivo instability
		Transcriptional shut off in vivo
Adenoviruses	Highly efficient transduction of many cell types	Require cell proliferation for infection
	Maintained as an episome	Evoke potent host inflammatory and immune responses that eliminate transgene expression and preclude repeated administration
	Highly efficient transduction of replicating and nonreplicating cells	
	Stable in vivo in absence of immune response	
		Difficult to target to specific cell types

Adeno-associated virus	High-level transgene expression in vivo	Relatively difficult to manipulate viral genome
	Relatively nonpathogenic	
	High titers	
	Infects replicating and nonreplicating cells	Can accept only small transgenes
	Potential for site-specific integration	Difficult to produce in large quantities
	Relatively nonimmunogenic	Does not appear to stably transduce all cell types in vivo
Plasmid DNA	High titers	
	Nonpathogenic in humans	Potential for insertional mutagenesis
	Easy to manipulate and produce in large quantities	Very low transduction efficiency
	Nonpathogenic	
	Relatively nonimmunogenic	
	Does not require an infectious vector	
	Maintained as an episome	
	Can program long-term gene expression in postmitotic cells in vivo	
Synthetic oligonucleotides	Easy to synthesize in large quantities	Can only reduce or ablate gene expression
	Relatively high transduction efficiencies if delivered with viral liposomes	
		Large number of nonspecific and nonreproducible biological effects
		Cannot target specific cell types
		Relatively short half-life in vivo
Ribozymes	Can specifically and effectively target mRNAs	Can only reduce or ablate gene expression
		Difficult to deliver to cells in vivo
		Stability in vivo unclear

vectors appear to be quite safe, because they do not produce human disease even in their wild-type form.[153] Limitations of AAV vectors include the difficulty to date in producing large amounts of high-titer vector, the limitation on the size of the transgene that they can accommodate (less than 4.5 kb), and their potential for integration into the host genome.[153] These vectors will quite likely be very useful for gene therapy approaches that require efficient and stable transgene expression in the heart, including the treatment of myocardial ischemia, heart failure, and cardiac arrhythmias.

OTHER VIRAL VECTORS.

Retroviruses and lentiviruses are single-stranded RNA viruses that integrate into the host genome after infection[159] [160] [161] [162] (see Fig. 55-12). Retroviruses are unlikely to be useful for most cardiovascular gene therapies because they require cell proliferation for efficient infection.[162] Most cardiovascular cell types do not proliferate in vivo. In contrast, lentiviruses based on human or animal immunodeficiency viruses are capable of efficiently transducing many nonproliferating cell types in vivo.[160] [161] [162] [163] Like AAV vectors, lentiviral vectors can have most of their viral genes removed and do not appear to trigger inflammatory and immune responses.[163] These vectors can program stable transgene expression in neurons in vivo.[160] Their usefulness in the heart and vasculature has not yet been fully evaluated. Potential disadvantages of these vectors include difficulties producing high-titered virus stocks and the risk of recombination with human immunodeficiency virus or endogenous retroviruses to produce replication-competent pathogenic viruses.

Recent Advances in Vector Development

During the past several years a number of advances have been made that have improved both vector efficacy and safety. These include the use of cell-type specific transcriptional regulatory sequences to produce vectors that express their transgenes in a tissue-specific manner[164] (e.g., smooth muscle cell-specific vectors) and structural modifications of vector coat proteins that enhance their infection of specific cell types.[165] In addition, several systems have been described that allow the regulation of transgene expression in response to exogenously administered drugs.[166] [167] Finally, there has been a great deal of interest in developing systems that will allow the repair of mutant genes in cells in vivo or in vitro. One such system has recently been described that uses chemically synthesized RNA/DNA oligonucleotides called chimeroplasts to direct the cell-mediated repair of single base mutations.[168] The usefulness of this and related gene repair systems for the treatment of inherited cardiovascular diseases will require additional investigation.

Devices for Gene Delivery

The development of devices that can be used for gene delivery has not advanced as quickly as vector development. The design specifications for such gene delivery devices include the ability to efficiently deliver a gene therapy vector to a localized area of the cardiovascular system with minimal invasiveness and no adverse effects on vector viability or efficiency.[169] A variety of catheters have been

tested for local vascular gene delivery. These include double-balloon catheters,[128] hydrogel catheters, [170] and porous and microporous balloon catheters.[171] [172] Each of these catheters has been plagued with specific problems, including inefficient or nonuniform transgene delivery, leak of vector into the systemic circulation, and vascular injury due to balloon inflation and/or jetting of vector solution. Similarly, catheters have been described for direct intramyocardial injection. However, to date such devices produce local tissue damage and can result in significant leak of vector into the left ventricular cavity. Importantly, many of these devices have not yet been carefully tested for compatibility with the different vector systems described earlier. Indeed, recent studies have suggested that many of these catheters efficiently and rapidly inactivate adenovirus vectors.[172A] Areas that require more investigation include the use of gene- or vector-coated stents for gene delivery to the

vasculature, production of delivery systems that will facilitate intracoronary perfusion with gene therapy vectors, and iontophoresis to enhance the efficiency of localized gene delivery to the heart and vasculature.

Cell-Based Therapies

A variety of cardiovascular cell types including vascular endothelial cells, vascular smooth muscle cells, and embryonic cardiomyocytes can be cultured in the laboratory in vitro. This finding has suggested the possibility of using either wild-type or genetically modified cardiovascular cell transplantation to treat a variety of cardiovascular disorders. Cultured endothelial cells have been used to seed synthetic grafts in an attempt to reduce graft thrombosis.[173] [174] Similarly, endothelial cells genetically modified to produce tissue plasminogen activator have been suggested as a therapy to reduce the thrombotic potential of grafts and native injured coronary arteries.[175]

Cardiomyocytes are terminally differentiated cells that do not retain the capacity to proliferate. Therefore, the heart lacks the capacity for regeneration after ischemic, toxic, or infectious injury. Accordingly, there has been a great deal of recent interest in developing gene- or cell-based therapies for myocardial repair and regeneration.[176] Potential gene-based approaches to this problem include the use of transgenes to stimulate cardiomyocyte proliferation or to program the differentiation of cardiac fibroblasts into cardiomyoctyes. Unfortunately, genes with these activities have not yet been discovered. Alternative cell-based approaches would include the injection of either cultured cardiomyocytes or skeletal myocytes into the damaged myocardium. Recent studies have demonstrated that skeletal myocytes injected into the myocardium form a stable graft that may improve global hemodynamics after myocardial injury in rodents.[177] [178] [179] However, to date there is no evidence that such grafts form the electrical or functional junctions with the endogenous myocardium that would be required to initiate synchronous contraction of the graft. In contrast, studies from a number of groups have demonstrated stable engraftment of embryonic cardiomyocytes injected into the myocardium with formation of intercalated discs and gap junction between the injected cells and the endogenous cardiomyocytes.[180] [181] [182] These findings suggest that such engrafted cells might be capable of forming beating grafts. However, the efficiency of engraftment of such embryonic cardiomyocytes has been low (less than 0.1 percent). Moreover, it will be important to identify a nonembryonic renewable source of such transplantable cardiomyocytes. In this regard it is of interest that recent studies have suggested that such cells can be derived from embryonic stem cells in vitro as well as from adult bone marrow.[181] [182] [183] Indeed, adult bone marrow appears to contain pluripotent mesenchymal stem cells with the capacity to differentiate into a variety of cell types, including skeletal and cardiac muscle, hematopoietic cells, cartilage, and fat.[184] Such cells have been reported to repopulate damaged skeletal muscle after intravenous injection.[185] It will be of interest to determine if these cells can similarly repopulate the damaged myocardium after systemic administration.

Example of the Use of Gene Therapy for Cardiovascular Disease: Gene Therapy Approaches for Vascular Proliferative Disorders

Vascular smooth muscle cell (VSMC) migration, proliferation, and extracellular matrix deposition are thought to play important roles in vascular proliferative syndromes such as restenosis after balloon angioplasty or stenting.[186] [187] Despite numerous clinical trials with new drugs and devices, restenosis rates of 20 to 40 percent are still seen with most, if not all, percutaneous coronary revascularization procedures.[188] Thus, there has been interest in developing gene therapy approaches that could be used to treat the vascular proliferative syndromes. Such approaches would require (1) a vector that could efficiently transduce VSMCs at the site of revascularization after delivery through a catheter, (2) an appropriate cytotoxic or cytostatic gene that could either kill or inhibit the proliferation of VSMCs after vessel injury, and (3) a device that could be used to deliver this vector to a localized area of the vasculature.

During the past several years a number of successful gene therapy approaches to this problem have been developed. Nabel and coworkers demonstrated that adenovirus-mediated gene transfer of the herpes simplex virus thymidine kinase (HSV-tk) gene followed by systemic ganciclovir therapy killed proliferating VSMCs and inhibited restenosis by more than 50 percent in a pig model of iliofemoral balloon injury.[130] [189] Using a cytostatic approach, Leiden and coworkers demonstrated that adenovirus-mediated gene transfer of a constitutively active retinoblastoma (Rb) transgene (that inhibits the G1-S transition) or the cyclin-dependent kinase (CDK) inhibitor p21 that prevents Rb phosphorylation prevents smooth muscle cell proliferation and inhibits intimal thickening by 40 to 60 percent in both the rat carotid and porcine iliofemoral models of balloon injury.[189] [190]

Dzau and coworkers demonstrated that double-stranded decoy oligonucleotides containing an E2F binding site (E2F is a transcription factor that is released and activated upon Rb phosphorylation and is needed to drive cells through the G1-S transition) also inhibit restenosis in the rat carotid artery model of balloon injury by more than 70 percent.[143] These investigators have recently gone on to use these same decoy oligonucleotides in a phase I clinical trial of peripheral vein grafting and have reported a statistically significant reduction in graft occlusion after treatment with the E2F decoys.[132] Taken together, these studies suggest that both viral and oligonucleotide-mediated gene therapies may be useful adjuncts to percutaneous and surgical revascularization approaches in patients with atherosclerotic vascular disease.

FUTURE DIRECTIONS OF MOLECULAR CARDIOVASCULAR MEDICINE

Advances in molecular and cellular cardiology have already had a profound impact on cardiovascular biology and medicine. These advances, however, represent only the beginning of a set of revolutionary discoveries that will fundamentally change our understanding of normal cardiovascular function and thereby enhance our ability to diagnose and treat cardiovascular disease. It is impossible to predict the future of this scientific revolution. However, several implications are clear.

The determination of the sequence of all of the genes in the human genome along with the characterization of the role of specific genetic variations in cardiovascular diseases will provide a powerful new set of genetic diagnostic tools. Within 10 years, genetic analyses of a simple blood sample from a child will allow the accurate prediction of the susceptibility of that child to a wide variety of diseases from hypertension, atherosclerosis, and diabetes to cancer and neuropsychiatric disorders. This type of genetic susceptibility testing will fundamentally change the practice of medicine. Rather than treating patients only after they develop symptoms of cardiovascular disease it will be possible to identify those patients at high risk in childhood and intervene to reduce risk factors before disease develops. In addition, it will be possible to predict accurately the response of an individual patient to different drugs. Thus, susceptibility

testing will allow the development of a new genetically based preventive medicine.

From the standpoint of basic investigation, the cloned genes and their encoded proteins can be structurally analyzed by nuclear magnetic resonance and crystallographic techniques. The resultant structures will produce important clues about the function of these proteins and will also provide that basis for the rational development of drugs designed to augment or inhibit those functions. Biochemical technologies to unravel protein-protein interactions (for example, one known as the yeast two-hybrid system) will be used to place the newly cloned genes (and proteins) into their intracellular pathways. Such approaches will help to define critical domains in molecules that should help to identify new targets for the development of drug- and gene-based therapies. Finally, newly cloned genes emerging from the genome project will be used in transgenic, knockout, and knock-in strategies in mice to determine, more precisely, their functions, to discover the effects of mutations, and to produce new animal models of human diseases for studies of pathogenesis and new therapies ("functional genomics").

From a therapeutic standpoint, the newly cloned genes will be used to design new in vitro or cell-based strategies that can be used by pharmaceutical companies to screen large libraries of compounds for new drugs. Of equal importance, these genes will form the basis for the development of novel genetic therapies for cardiovascular disease.

Like any powerful new technology, molecular genetics will also raise important ethical questions. Which genetic traits are appropriate for modification? What is the role of germ-line gene therapies that modify the genome in a genetically transmissible fashion? How is the confidentiality of genetic susceptibility data about individual patients guaranteed? And how do we handle information about susceptibility to a disease for which we lack an effective treatment? These questions and many others will be actively debated by physicians, patients, ethicists, and politicians for years to come. Despite these thorny problems, the potential for benefit from molecular genetics significantly outweighs the potential for harm. It is safe to predict that the era of molecular medicine will revolutionize the ability to diagnose and treat patients with cardiovascular diseases.

Chapter 56 - Genetics and Cardiovascular Disease

REED E. PYERITZ

GENETIC FACTORS IN DISEASE

Genes contribute to both the cause and the pathogenesis of virtually any abnormality of human physiology and behavior, including, of course, disorders of the heart and vascular system (see Chap. 55) . This statement carries two messages in addition to the obvious one. First, the pathology associated with even the most "environmental" of causes, such as trauma, malnutrition, and drug abuse, can be defined only in terms of the human body's response to the insult. How the stress of the initial insult is expressed (the *phenotype*) and how the patient suffers and perhaps recovers depend, to various and yet often poorly defined degrees, on the patient's *genotype.* This idea seems self-evident and verges on the trite, but it is frequently neglected. Some environmental insults, such as massive trauma or poisoning, are lethal to all, regardless of genotype. Nonetheless, as developments in fields such as *pharmacogenetics* and *ecogenetics* are defining genetic susceptibilities to human disease better and more simply, physicians must become increasingly attuned to the importance of the genotype.[1]

Second, the introductory statement emphasizes that genetic factors have roles in *both* cause and process; etiology and pathogenesis, although related, are conceptually distinct.[2] For example, the cause of sickle cell anemia is clearly a single mutant gene, whereas whether a patient homozygous for this mutation expresses all, some, or none of the manifestations of the disease depends on many other genetic and nongenetic factors. Conversely, the cause of pneumococcal pneumonia is equally evident, but the severity and resolution of the disease depend on the patient's immune competence (which in turn depends on genetic and nongenetic factors) as much as on treatment with an antibiotic.

The genotype, therefore, can be detrimental in at least two distinct ways. First, mutant genes can so upset embryology or physiology that a clinical abnormality occurs. Whereas the phenotype of any particular mutation depends on a host of factors, including which homeostatic systems are available to modulate the action of the defect, the genotype has the principal role in causing the disease. It is this class of mutations that are usually referred to as genetic diseases. Second, a mutation can facilitate the action of an extrinsic cause in producing disease. Inherited susceptibilities are part of the pathogenesis of disease and are one reason for taking a patient's family history. Until recently, clinicians could do little to pursue tantalizing facts, such as several relatives' suffering myocardial infarction before age 50. The long-touted prospect of detecting a patient's inherited susceptibilities and intervening before irreversible clinical sequelae occur is becoming reality.

Disorders Due to Microscopic Alterations in Chromosomes

Estimates of the total number of human genes range between 50,000 and 100,000. Two copies (termed *alleles*) of each gene are arrayed along 23 pairs of *chromosomes.* Twenty-two of the chromosomes are called *autosomes* (numbered 1 through 22), and the 23rd pair are the *sex chromosomes,* X and Y. Females have two X chromosomes and males have an X and a Y chromosome. Both autosomal alleles are potentially active in specifying RNA copies of their DNA sequences; whether a gene is active depends on the cell type, the developmental stage of the organism, and the regulatory molecules that interact with promoter and enhancer nucleotide sequences that control transcription of the gene. In cells with two X chromosomes (i.e., in all females, in Klinefelter syndrome in which two Xs and one Y occur, and in other rare conditions), only one X is entirely active after early embryogenesis.

Human chromosomes can be examined by culturing cells capable of mitosis; T lymphocytes obtained from venous blood are the usual source, but fibroblasts, cells from chorionic villi, amniocytes, and leukocyte precursors present in bone marrow are also used clinically. Chromosomes are distinguished from one another by their size,

shape (determined by the position of a constriction called the *centromere,* which functions as the attachment of the mitotic apparatus), and characteristic banding pattern as revealed by any of several staining techniques. The chromosomes are photographed, cut out, and arranged in pairs, from 1 through 22 and the sex chromosomes, in a display called the *karyotype.* This display and its interpretation are the end results of a clinical study of a patient's chromosomes. The chromosome constitution of a cell is designated by first specifying the number of chromosomes present (46 being normal in diploid cells), then specifying the sex chromosomes, and finally describing any abnormalities. For example, a normal male is designated 46,XY, and a female with an extra chromosome 21 is designated 46,XX,+21.

ANEUPLOIDY.

Chromosome aberrations, especially too many or too few chromosomes (*aneuploidy*), are extremely common in human embryos; more than one-half of all conceptuses are spontaneously aborted in early pregnancy, and at least one-half of them are aneuploid. Among live-born infants, about 0.5 percent have a chromosome aberration.

Gain or loss of chromosomes generally happens by nondisjunction, or the failure of a homologous pair of chromosomes to separate. Absence of one chromosome is termed *monosomy;* all autosomal monosomies are embryonic lethals, as is presence of only a Y sex chromosome. Presence of three chromosomes is *trisomy,* and presence of an entire extra set of chromosomes (for a total of 69) is *triploidy.* The most common autosomal aneuploidy, trisomy 21 associated with Down syndrome, and aneuploidy for sex chromosomes all are compatible with survival into adulthood.

CHROMOSOME REARRANGEMENTS.

A chromosome can break and rejoin within itself, potentially giving rise to an *inversion* of genetic material. Often no apparent phenotypic effect is seen in people with an inversion, but because inversions may disrupt chromosome pairing during meiosis, their offspring may have more profound aberrations.

DELETIONS AND DUPLICATIONS.

Just as their names imply, these aberrations are losses or gains of chromosomal material. Many clinical syndromes have been associated with aberrations of specific chromosome regions.[3] [4] The smallest deletion detectable by light microscopy is associated with loss of considerable DNA, on the order of one million base pairs, so

more than one gene is potentially disrupted or lost.

A number of conditions, each initially thought to be due to a mutation in a single locus, are associated with small interstitial chromosome aberrations affecting a cluster of genes (Table 56-1) . So rather than pleiotropic manifestations of one mutation, these conditions are likely to be due to the effects of several, and perhaps many, mutations and are therefore called *contiguous gene syndromes.* [5] Such defects are potentially heritable, and the occurrence of the disorder in a family behaves as a mendelian dominant.

Disorders Due to Changes in Single Nuclear Genes (See also Chap. 55)

Mutations of genes located on the 22 pairs of autosomes and the two sex chromosomes produce phenotypes inherited according to the two principal tenets of Mendel: alleles segregate and nonalleles assort. The first statement refers to gametes receiving only one of the two alleles at a given locus as a result of meiosis. The second statement describes the results of recombination, the meiotic process of rearranging DNA between the two chromosomes of the pair (*homologous chromosomes*); if two loci are widely spaced along a chromosome, their chances of being separated by recombination are 50-50, and they are said to be *unlinked.*

The Human Genome Project, begun in 1990, has set goals to map all expressed genes, to create a physical map of overlapping pieces of DNA composing the entire genome, and, finally, to sequence all 3 to 3.5 billion nucleotides in the haploid complement of human DNA.[6] The project is well ahead of schedule, and a "rough draft" of the entire sequence became available in 2000. The beginnings and ends of more than 100,000 expressed sequences, most representing genes, have been identified out of a total of perhaps 125,000 genes. More than 10,000 individual loci have been identified on the basis of the phenotype that mutations in single genes produce. The presumption of single-gene defects is based in most instances on the pattern of inheritance in families; segregation of the phenotype according to mendelian principles is the central piece of evidence. For an increasing number of loci, however, molecular genetic techniques have mapped the phenotype to a narrow chromosome region, to a single gene, or even revealed the actual alteration in nucleotide sequence (see also Chap. 55) [7] (Table 56-2) . The range of known mendelian variation in humans and information about gene mapping and molecular defects are routinely catalogued and available on-line.[8]

Of the more than 10,000 loci that have been clearly identified on the basis of either an abnormal phenotype or a normal product, 9.1 percent involve the heart.[8] Many others involve other parts of the cardiovascular system. Thousands of loci have been mapped to a restricted region of the genome. Many of these loci cause specific mendelian disorders, and the genetic map of these loci represents the "morbid anatomy of the human genome." Many of the cardiovascular and hemostatic disorders that were mapped by the end of 1999 are shown in Figure 56-1 .

DOMINANCE AND RECESSIVENESS.

These related concepts are characteristics of the phenotype, *not of the gene.* A phenotype is dominant when the patient is *heterozygous* for a mutation, i.e., when one copy of the mutant allele and one copy of the normal allele are present; this holds for genes on both autosomes and the X chromosome. A phenotype is recessive when the patient has two mutant alleles at the locus causing the condition. If the mutant alleles are identical, the patient is *homozygous* at that locus, a situation usually present either when the allele is identical by descent through both parents (i.e., the parents had a common ancestor and are *consanguineous*) or

TABLE 56-1 -- CONTIGUOUS GENE SYNDROMES

	REGION	LOCUS	CARDIOVASCULAR ABNORMALITIES
Syndromes with Cardiovascular Involvement			
Arteriohepatic dysplasia	AHD	del 20p11.23-p12.2	Peripheral pulmonic stenosis/hypoplasia
Cat-eye syndrome	CES	dup22q11	Total anomalous pulmonary venous return
DiGeorge sequence	DGS	del 22q11	Truncus arteriosus, right aortic arch, TOF, PDA
Miller-Dieker syndrome	MDS	del 17p13	PDA ± complex anomalies
Prader-Willi syndrome	PWS/AS	del 15q12	Cor pulmonale (secondary to obesity and central apnea)
WAGR syndrome		del 11p13	Hypertension (secondary to Wilms tumor)
Syndromes Without Frequent Cardiovascular Involvement			
Angelman syndrome		del 15q12*	
Smith-Magenis syndrome		del 17p11.2	

TOF=tetralogy of Fallot; PDA=patent ductus arteriosus; WAGR=Wilms tumor, aniridia, genitourinary, and retardation.

*The deletion is often indistinguishable at the cytogenetic level from that of the Prader-Willi syndrome; genetic imprinting of locus *UBE3A* is thought to account in part for the phenotypic differences. In Prader-Willi Syndrome, the deleted chromosome is always the chromosome 15 inherited from the father, whereas in Angelman syndrome, the deletion affects the maternal chromosome 15.

TABLE 56-2 -- MENDELIAN CONDITIONS THAT INVOLVE THE CARDIOVASCULAR SYSTEM WITH KNOWN GENETIC DEFECTS OR GENE MAPPING OF THE PHENOTYPE

Disorders may have been mapped by the phenotype, by the gene, or both; (?) after a disorder indicates the mapping data are still in limbo. The annotations p and q refer to band patterns in chromosomes detected cytochemically that mark specific regions.

AV=atrioventricular; FDC=familial dilated cardiomyopathy; FHC=familial hypertrophic cardiomyopathy; LV=left ventricle; RV=right ventricle.

*Refers to the entry for the locus in http://www.ncbi.nlm.nih.gov/htbin-post/Omim.

when the mutant allele is common in the population (e.g., the most prevalent mutation for cystic fibrosis and the mutation for sickle cell anemia). Biochemical and molecular genetic assessment of mutant alleles has shown that the majority of recessive phenotypes are due to two distinct mutant alleles, a situation termed a *genetic compound,* indicative of the widespread heterogeneity in mutations at each locus. Males have but one X chromosome, and each locus is therefore *hemizygous;* a mutant locus is always expressed in the phenotype of a male. Dominance and recessiveness for X-linked traits refer to expression in heterozygous and homozygous women, respectively.

Whether a disorder is called dominant or recessive depends on how carefully the phenotype is assessed and how it is defined. For example, familial hypercholesterolemia is a relatively common hereditary disorder due to defects in the receptor for low-density lipoprotein (see LDL, see also Chap. 31) . The vast majority of patients are heterozygous for a mutant allele at the *LDLR* locus on chromosome 19, and the disease is inherited as a mendelian dominant trait. However, if a man and a woman, each heterozygous for an *LDLR* mutation, produce a child, that child has a 25 percent risk of inheriting both of the mutant alleles and thereby is either homozygous or a genetic compound for *LDLR.* Such a child has a much more severe form of familial hypercholesterolemia that is inherited as a mendelian recessive trait. Similarly, homozygosity for the sickle hemoglobin mutation at the beta-globin locus on chromosome 11 produces the familiar autosomal recessive

disease sickle cell anemia. However, heterozygosity for the same mutation rarely produces disease but produces sickling of erythrocytes if they are examined under conditions of low oxygen tension; this phenotype is transmitted as a dominant trait.

AUTOSOMAL RECESSIVE INHERITANCE.

Nearly all deficiencies of enzymatic activity--the classic inborn errors of metabolism first defined by Archibald Garrod in 1903--cause recessive phenotypes. Most homeostatic systems, which include all metabolic pathways, have sufficient flexibility to function well if one of the enzymatic steps functions at half-normal efficiency, as would occur in heterozygosity for a mutant allele at a structural gene for an enzyme. However, homeostasis cannot cope if two mutant alleles cause a reduction in enzymatic activity to a few percent or less of normal activity. The characteristics of autosomal recessive inheritance, features common to such phenotypes, and a typical pedigree are shown in Figure 56-2 .

AUTOSOMAL DOMINANT INHERITANCE.

Only a few enzyme deficiencies, but many disorders of development and structure, are inherited as dominant traits. The reasons for this are several. One possibility is that developmental homeostasis has a limited repertoire of responses to stress, and when a structural or regulatory macromolecule is reduced to only one-half normal amount, the system cannot cope. Another possibility, illustrated by mutations in procollagen molecules, pertains to gene products that must interact before becoming functional; an aberrant protein combined with a normal one would be a defective multimer, and the effect of being heterozygous for a mutation would be magnified--a *dominant-negative effect*[2] [9] The characteristics of autosomal dominant inheritance, features common to many such phenotypes, and a typical pedigree are shown in Figure 56-3 .

Most human dominant traits are *incomplete,* in that the heterozygote is less severely affected than the homozygote. Defects of *LDLR* are illustrative, in which the heterozygote has classic type IIa hyperlipidemia whereas the homozygote has a quantitatively worse form of the same disease. It may well be that homozygosity for most alleles that cause dominant disorders is incompatible with life.

X-LINKED INHERITANCE.

The characteristics of X-linked inheritance, features common to such phenotypes, and a typical pedigree are shown in Figure 56-4 . Whereas virtually all diseases due to mutations on the X chromosome are more severe in hemizygous males, women heterozygous for the same mutations often show some manifestations, albeit less severe and of later age of onset. For example, most women carriers of alpha-galactosidase A deficiency (Fabry disease) eventually develop cerebrovascular disease or renal failure due to accumulation of sphingolipid.

MITOCHONDRIAL INHERITANCE.

Energy generation through oxidative phosphorylation occurs in mitochondria in the cytoplasm of most cell types. Numerous mitochondria, each containing a single chromosome, exist in each cell. Some of the enzymes of oxidative phosphorylation are encoded by genes on the nuclear chromosomes and the proteins transported into the mitochondrion; the rest of the proteins are encoded by genes on the mitochondrial chromosome. Thus, genetic defects of oxidative phosphorylation can be due to mutations of genes on the autosomes or the X chromosome, and the resulting diseases behave as mendelian recessive traits, or mutations of genes on the mitochondrial chromosome, in which case the resulting diseases do not behave as mendelian traits.[10] [11] The differences are explicable by the events of conception. The spermatocyte contributes virtually no mitochondria to the zygote, and the entire complement of mitochondria that will ever be present in the fetus is derived from the mitochondria already present in the cytoplasm of the oocyte. Thus, phenotypes due to mutations of the mitochondrial chromosome show *maternal inheritance,* the characteristics of which are shown in Figure 56-5 .

Principles of Clinical Genetics

PLEIOTROPY.

Most mutant alleles have effects on more than one organ system, and a mendelian phenotype frequently displays numerous, often diverse manifestations. For example, Marfan syndrome (see p. 2000) is defined by abnormalities in the eye, skeleton, skin, heart, and aorta, and until the recognition of a defect in extracellular microfibrils, the findings could not be linked either etiologically or pathogenetically.[12]

VARIABILITY.

The effects of the same mutant allele on phenotype can be different among people heterozygous (for dominant traits), homozygous (for autosomal recessive traits), or hemizygous (for X-linked traits) for the allele. Variability can be described in terms of the frequency of a particular pleiotropic manifestation among patients with the mutation; the severity of the phenotype; and the age of onset of manifestations. If a person has the mutant allele(s) but shows no phenotypic effect, the trait is called *nonpenetrant.* To an important degree, whether or not a clinical phenotype is called nonpenetrant depends on the sensitivity of the techniques used for detection. For example, two decades ago, based on bedside examination, cardiovascular abnormalities were thought to affect about half of people with Marfan syndrome; echocardiography now reveals aortic dilatation in more than 90 percent. The term *incomplete penetrance* should not be used with reference to individuals but to mean a prevalence of the phenotype is less than 100 percent of people known to carry the mutation(s). The Holt-Oram syndrome (see Chap. 43) is an instructive example. In this autosomal dominant syndrome of reduction anomalies of the upper limb and congenital heart defect, patients in the same family can have only arm anomalies, only a heart defect, or both. Moreover, the severity of the reduction defect varies widely, from a proximally

Figure 56-1 Chromosomal location of human genes associated with some disorders of the cardiovascular system. These genes affect the structure, function, and metabolism of the heart and blood vessels and hemostasis and have been identified by the deleterious effects of mutations. Numerous additional genes that encode structural proteins important to the cardiovascular system have been identified but not yet associated with disease. In the figure, brackets next to the chromosome show the regional localization of the gene causing a particular disorder. Brackets next to two or more disorders indicate that all of the genes causing the disorders map to the same region. Disorders surrounded by boxes are caused by different mutations at the same gene.

placed thumb to near total absence of the arm. The cardiac feature is incompletely penetrant because only about 50 percent of patients have it, but in any individual with the Holt-Oram allele, the heart is either structurally normal or not.

Numerous genetic and environmental factors can affect expression of a gene (Table 56-3) , and it is often impossible to determine which of these factors are most important in a specific patient or particular disease. However, the pervasiveness of variable expression emphasizes that phenotypes determined by single genes are to some extent really "multifactorial."

GENETIC HETEROGENEITY.

Similar or even identical phenotypes can be due to fundamentally distinct mutations, a phenomenon termed *genetic heterogeneity.* For example, Marfan syndrome and homocystinuria were long thought to be the same disorder, despite what now appear in retrospect to be obvious differences in inheritance pattern and intelligence.[13] As in the case of these two disorders, the causes may lie in two different genes whose products are

Figure 56-2 *Characteristics of autosomal recessive inheritance:* A single generation is affected.
Both sexes are affected equally frequently.
Each parent is heterozygous (a carrier).
Each offspring of two carriers has a 25 percent chance of being affected, a 50 percent chance of being a carrier, and a 25 percent chance of inheriting neither mutant allele.
Two-thirds of clinically normal offspring are carriers.
The rarer the phenotype, the greater is the likelihood of consanguinity.
Characteristics of autosomal recessive phenotypes:
Often due to enzyme deficiencies.
Often more severe than dominant disorders.
Often early age of onset.

functionally distinct. Osteogenesis imperfecta exemplifies a disorder in which mutations in two genes, alpha1(I) and alpha2(I) procollagen, can each produce the same phenotype because the two proteins interact to form type I collagen.[14] Genetic heterogeneity is pervasive at the intragenic level of analysis; except for sickle cell anemia, hemochromatosis, and achondroplasia, virtually all single-gene disorders are due to a wide variety of mutations at a given locus.

Nonpathological Variation in the Cardiovascular System

CARDIAC STRUCTURE AND PHYSIOLOGY.

All aspects of the ontogeny of the cardiovascular system are dictated by the genome. If, as seems most credible, few genes have a large effect and many have small contributions, any specific aspect of "normal" cardiovascular phenotype--size, shape, function--exhibits multifactorial inheritance. In other words, to the extent that any given phenotype can be quantified,

Figure 56-3 *Characteristics of autosomal dominant inheritance:* Several generations are affected.
Both sexes are affected equally frequently.
In familial cases, only one parent need be affected.
Male-to-male transmission occurs.
Offspring of an affected parent has a 50 percent chance of being affected.
The frequency of sporadic cases is higher, the more severe the condition.
Paternal age has an effect in sporadic cases.
Characteristics of autosomal dominant phenotypes:
Often associated with malformations.
Often pleiotropic.
Usually variable.
Often age dependent.

Figure 56-4 *Characteristics of X-linked inheritance:* No male-to-male transmission.
All daughters of affected males are carriers.
Sons of a carrier mother have a 50 percent chance of being affected; daughters have a 50 percent chance of being carriers.
Some mothers of an affected male are not heterozygotes in all cells of their body, but they may have more affected sons if germinal mosaicism is present.
Characteristics of X-linked phenotypes:
More severe in males.
Heterozygous females may be unaffected.
Variable, especially in females.

Figure 56-5 *Characteristics of disorders due to a mutation of the mitochondrial chromosome:* Both sexes are equally frequently and severely affected.
Transmission is only through women; offspring of affected men are unaffected.
All offspring of an affected woman may be affected.
Variability of expression can be extreme in a family, including apparent nonpenetrance.
Phenotypes may be age dependent.

it shows a normal distribution within the population, and near-relatives are more similar to each other than they are to distant relatives and the rest of the population. The twin method should demonstrate a higher concordance of the trait in monozygotic than dizygotic twins. However, surprisingly few phenotypes have been examined.

Preliminary data on left ventricular dimensions measured echocardiographically showed higher correlations between parent and child than between matched controls, suggesting a genetic contribution[15] ; however, as in many such studies, the effect of shared environment was not estimated. In an attempt to minimize environmental contributions, left ventricular sizes of twins who were not exercise trained were compared; the mean intrapair differences in echocardiographic dimensions were less in the monozygotic than in the dizygotic twins and nontwin sibs.[16] The caliber and branch geometry of coronary arteries show familial resemblance, and both parameters are much more similar in monozygotic twins than in other relatives.[17] Further support for the importance of genetic factors in normal development derives from studies that demonstrate ethnic differences in structure. For example, the thickness of the intima and the media of coronary arteries of children who died of noncardiovascular causes varied significantly with the ethnicity of the child.[18]

Measures of cardiac electrophysiology show familial resemblance. Studies of both nuclear families[19] [19A] and twins[20] [21] suggest a genetic contribution to resting heart rate, conduction times, and repolarization time. Genetic control of normal cardiovascular function has been especially difficult to study because of the multitude of environmental (training, diet), stochastic (age), and clinical (subtle, unrecognized pathology) issues that confound comparisons of relatives and controls. Thus far, no strong genetic contribution to an individual's response to physical conditioning has emerged.[16]

VASCULAR SYSTEM.

All members of certain inbred animal strains show little variation in arterial anatomy, especially branch angles, and considerable variation with other strains of the same species. Except for the studies of coronary arterial anatomy already noted,[17] similar studies of humans have not been reported.

One intriguing question of clinical importance is whether certain individuals are predisposed to arterial spasm and whether this susceptibility has a genetic basis. An examination of hereditary pathological and polymorphic variation in factors elaborated by endothelial cells, platelets, and leukocytes to maintain patency of blood vessels, such as prostacyclin, endothelium-derived relaxing factor (nitric oxide), or endothelin-1, may prove enlightening.[22] [23] [24] [25] Similarly, is there genetic contribution to arterial stiffness or its variation with age and conditioning?

CARDIOVASCULAR DISORDERS ASSOCIATED WITH CHROMOSOME ABERRATIONS

Chromosome aberrations occur in 0.5 percent of the population at birth and are common findings in tumors.[26] Visible alterations of the amount of chromosomal material cause primarily structural defects of the cardiovascular system that are evident in the newborn. The frequency of chromosome aberrations among live-born children with congenital heart defects has been found to range from 5 to 13 percent.[27] [28] Upward of 40 percent of all fetuses with heart defects detected by ultrasonography at 18 to 20 weeks' gestation have chromosome aberrations; most are spontaneously aborted. Most forms of aneuploidy and most duplications and deletions of more than a chromosome band are associated with defects of the cardiovascular system[29] (see Tables 56-1 and 56-3) . Exceptions are 47,XXX, 47,XYY, and 47,XXY (Klinefelter syndrome), in which the incidence of congenital heart disease is probably not elevated over the population baseline.

ANEUPLOIDY.

How the abnormal phenotypes caused by autosomal aneuploidy develop remains controversial. One view holds that disturbance of the dosage of the genes present on the specific aneuploid chromosome segments is the central issue. The other view is that any aneuploid state disturbs developmental homeostasis in a nonspecific manner. The former theory predicts some distinctiveness of phenotype among the trisomy syndromes that occur in live-born children, whereas the latter predicts shared manifestations. At a coarse level, the clinical pictures are similar, with grave problems of the craniofacies, central nervous system, genitalia, distal limbs, and heart usually present. But when a more refined examination of the phenotypes is obtained, considerable distinctiveness emerges.

The three most common autosomal trisomies--13, 18, and 21--can be readily distinguished at the bedside. In all three, membranous ventricular and atrial septal defects are common. However, the detailed accounting of cardiovascular lesions among large numbers of patients with these trisomies reveals important differences that suggest aneuploidy exerts more than a global effect on development. In this and most other analyses of congenital heart defects, the system of classification based on the presumed pathogenetic mechanisms proves most instructive and is a useful approach to comparing different causative factors (Table 56-4) .

About one-quarter of the defects in trisomies 13 and 18 are due to cell migration abnormalities, and two-thirds are flow lesions; when combined, these two mechanisms account for considerably more of these classes of defects than in the general population with congenital heart disease. By contrast, in trisomy 21, left-sided flow lesions are much less common, whereas abnormal closure of endocardial cushions is strikingly frequent. Indeed, in contrast to endocardial cushion defects without a chromosome 21 anomaly, left-sided flow lesions are rarely seen in patients with Down syndrome and endocardial cushion defects.[27] [30] Furthermore, the high incidence of endocardial cushion defects and low incidence of conotruncal and distal aortic anomalies have suggested a distinct pathogenetic mechanism in trisomy 21, potentially involving cell adhesiveness and the extracellular matrix.

TRISOMY 21--DOWN SYNDROME.

This most common phenotype due to a human chromosome aberration occurs about once in every 600 births.[31] Most patients have trisomy 21, and the risk of this aberration is exponentially related to maternal age; the risk is lowest for young women and rises steeply after age 35, reaching 4 percent for women older than 45. A small minority (3 percent) of Down syndrome results from an extra copy of all or part of the long arm of chromosome 21 translocated to another chromosome. This situation is relatively more common in mothers younger than 30 years. The phenotypes of the two forms of Down syndrome do not differ. The phenotype tends to be less severe if the trisomy is mosaic (3 percent of Down syndrome) as a result of a mitotic nondisjunctional error in the embryo.

The most common causes of morbidity and mortality in patients with Down syndrome are congenital heart defects (present in 40 to 50 percent of cases),[32] hematological malignant disease, and duodenal atresia. If patients either escape or survive these problems, survival into the fifth decade and beyond is likely but is complicated by progressive dementia of the Alzheimer type. Premature aging may also affect the vasculature, although definitive studies are lacking.

The most characteristic cardiac anomaly in Down syndrome is a defect of closure of the endocardial cushions (see Chap. 43) . Complicating the clinical problems in such patients and those with simple septal defects is a seeming predisposition to pulmonary hypertension in the presence of elevated pulmonary blood flow.[33] About one-third of congenital heart defects are complex, and affected individuals tend not surprisingly to be the most ill patients. Mitral valve prolapse (MVP) is found with a frequency exceeding that in age- and gender-matched controls.[34] The aortic and pulmonary valve cusps seem predisposed to fenestrations in adulthood.

Through the study of individuals trisomic for only a portion of the long arm of chromosome 21, the region crucial to the development of heart defects has been narrowed to 1.5 to 2.0 megabases (mb) of DNA in bands 21q22.2-q22.3 out of about 35 mb DNA on the entire long arm of chromosome 21.[35]

Medical treatment of patients with Down syndrome has undergone evolution to more aggressive measures in recent years. Objections and hesitations on medical, societal, and ethical grounds to operative repair of heart defects in Down syndrome have been mollified substantially.[31] [36] More follow-up data are becoming available, and early and late postoperative survival in patients with Down syndrome appears to be comparable to that in other patients with similar defects.[36]

TRISOMY 18.

Edwards syndrome is the second most common autosomal trisomy. Most cases are due to meiotic disjunction, and there is a strong relationship to maternal age. Routine prenatal diagnostic testing of women older than 34 years would detect all aneuploid fetuses in them, but this would represent only one-third of all autosomal

TABLE 56-4 -- CARDIOVASCULAR MANIFESTATIONS ASSOCIATED WITH CHROMOSOME ABERRATIONS

CHROMOSOME ABERRATION	EPONYM	CARDIOVASCULAR MANIFESTATIONS
Triploidy		

69,XXX (or XXY or XYY)		>50% have CHD: ASD and VSD
Aneuploidy		
+13	Patau	~80% have CHD; 75% of CHD is complex: PDA, VSD, ASD, PS, AS, dextrocardia, CoA
+18	Edwards	~90% have CHD: most CHD is complex: VSD, PDA, ASD, bicuspid PV and AV, CoA
+21	Down	~40% have CHD: ECD, TOF: MVP in ~20%; AR
+8 mosaicism		~25% have CHD, most of little clinical consequence: VSD, PDA, CoA, PS
+9 mosaicism		~70% have CHD, usually complex: VSD, PDA, PLSVC
45,X	Turner	~10% have clinically important CHD: 50% of these have CoA; mild CoA is likely much more common; also AS, ARD, VSD, ASD, dextrocardia
47,XXX		CHD not increased
47,XXY	Klinefelter	CHD possibly slightly increased; ? mild conduction changes; venous thromboembolic disease
47,XYY		CHD not increased; ? mild conduction changes
Deletions		
4p-	Wolf-Hirschhorn	~50% have CHD, usually complex: VSD, ASD, PDA, PS
5p-	Cri du chat	~20% have CHD, usually single: VSD, PDA, ASD, PS
7q-		~20% have CHD, various, often complex
13q-		CHD common, often severe, but depend on region deleted
18p-		CHD uncommon
18q-		~25% have CHD, usually single, of little consequence: VSD, PDA, ASD, PS
ring 18		~20% have CHD: CoA, PA hypoplasia, HLH, PLSVC
Duplications		
4p trisomy		~10% have CHD, usually single: no defect predominates
9p trisomy		<10% have CHD: VSD, ASD, AS, PS
10 p trisomy		~30% have CHD, usually single: no defect predominates
10q24-qter trisomy		~50% have CHD, usually complex: ECD, VSD, TOF
22pter-q11 trisomy or tetrasomy	Cat eye	~50% have CHD, usually complex: TAPVR, VSD, TOF
Other Aberrations		
Marker Xq27.3	Fragile X syndrome	~50% have aortic root dilatation, MVP, or both

CHD=congenital heart defect(s); ASD=atrial septal defect; VSD=ventricular septal defect; PDA=patent ductus arteriosus; PS=valvular pulmonic stenosis; AS=aortic stenosis; CoA=coarctation of aorta; PV=pulmonic valve; AV=aortic valve; ECD=endocardial cushion defect; TOF=tetralogy of Fallot; MVP=mitral valve prolapse; AR=aortic regurgitation; PLSVC=persistence of left superior vena cava; ARD=aortic root dilatation; PA=pulmonary artery; HLH=hypoplastic left heart; TAPVR=total anomalous pulmonary venous return.

trisomies; in the United States, less than one-half of all women of this advanced age undergo definitive testing. Prenatal detection of trisomies followed by termination of pregnancy is currently having a small but measurable impact on decreasing the incidence of *Down, Edwards,* and *Patau* syndromes.

Although the severity of the phenotype rarely enables survival beyond a few months, 10 percent of patients live to 1 year, and a few survive to adulthood, perhaps because of undetected mosaicism for a chromosomally normal cell line. However, central nervous system function is far less than that in Down syndrome and leads to complex medical management and supportive care for long-term survivors.[37]

Cardiovascular defects occur in at least 90 percent of cases and contribute to death. Complex lesions, usually involving septal defects, dysplastic valves that are rarely hemodynamically important, patent ductus arteriosus (PDA), and persistence of the left superior vena cava are common.[38] [39] Right ventricular enlargement is common and may indicate not only shunting from left to right but pulmonary hypertension due to anomalies of the pulmonary vasculature.[38] As in Down syndrome, transposition of the great arteries is virtually unknown in trisomy 18.[39] Rarely should invasive diagnostic procedures or aggressive supportive measures be undertaken in Edwards syndrome.

TRISOMY 13.

Patau syndrome occurs in about 0.01 percent of live births and in progressively higher frequencies in stillbirths and spontaneous abortions. The external phenotype is usually severe but occasionally not as characteristic as other trisomies; survival beyond a few weeks is rare, and the causes of death involve several organ systems, especially the heart. Cardiovascular anomalies are a bit less frequent than in trisomy 18 and have a slightly different spectrum.[31] [38] Septal defects are the most common isolated lesions; dextrocardia and bicuspid semilunar valves occur in association with other anomalies.

Patients who survive beyond 1 month often are mosaic for a chromosomally normal cell line; thus, prognosis is fraught with uncertainty until detailed analysis is completed. Whether invasive cardiological studies are performed or aggressive management is undertaken can be determined by the severity of involvement of other organ systems, especially the brain, pending cytogenetic investigation.

TURNER SYNDROME.

About one in every 2500 females lacks an X chromosome and has a 45,X karyotype, which is by far the most common cause of Turner syndrome. The frequency of a nonmosaic 45,X karyotype is much higher in spontaneous abortuses than in live-borns, and probably less than 2 percent of such conceptuses come to term. The clinical phenotype is variable and often mild; the diagnosis is often not suspected until a child's short stature is evaluated or a woman complains of amenorrhea. Many cases are mosaic for cell lines with 46,XX or 46,XY constitutions. Various structural aberrations involving the X chromosome can cause partial or complete Turner's syndrome.

Among patients with the 45,X karyotype, reported frequencies of congenital cardiovascular defects vary from 20 to 50 percent, depending on how patients were ascertained.[40] Fifty to 70 percent of those with cardiovascular defects have clinically important aortic coarctation, usually of the postductal form.[41] As noninvasive imaging studies of asymptomatic patients became routine, the frequency of coarctation may increase. Various other cardiac malformations may occur, either singly or combined with coarctation. However, there is strong support for left-sided flow abnormalities as a major pathogenetic mechanism. Bicuspid aortic valve and dilatation of the ascending aorta (with a risk of dissection and histopathology showing elastic fiber disruption) occur even in the absence of coarctation,[42] and hypoplastic left heart has been reported.[43] Partial anomalous pulmonary venous drainage without an atrial septal defect is fairly common and should be suspected when right ventricular overload is detected on echocardiography.[44]

Postmortem examination of midtrimester abortuses with 45,X showed a higher incidence of left-sided flow lesions than found at

birth, suggesting an association between the pathogenesis of the cardiovascular anomalies and the uniform presence of lymphatic obstruction at the base of the heart.[41]

Blood pressure elevation is common, even without coarctation or after its repair; a high frequency of renal anomalies is one likely cause but not the sole explanation for

the prevalence of hypertension.

In about two-thirds of cases, the retained X chromosome derives from the oocyte (maternal X). Because entire chromosomes or regions of a chromosome may be differentially regulated (imprinted)[45] by passage through oogenesis versus spermatogenesis, could some of the variability in phenotype among patients with Turner syndrome be due to the origin of the retained X or the origin of the lost X? In a study of 63 patients, 10 had severe cardiovascular features, and 9 of them had retained the maternal X.[46] This is an idea worthy of further investigation. Women with mosaic karyotypes are less likely to have cardiovascular defects. Some studies also suggest a "critical region" of the X chromosome, which, when deleted, results in most of the features of Turner's syndrome.[47]

CONGENITAL HEART DISEASE (See Chaps. 43 and 44)

In the past few decades, the reported incidence of structural heart defects in newborns has increased from 5 to 7 per 1000 live births, probably as the result of increased diagnostic sensitivity (especially cross-sectional and Doppler echocardiography and magnetic resonance imaging).[48] [49] [50] [51] [52] Supporting this explanation is the lack of change over the same period in the incidence of critical defects diagnosed neonatally at 3.1 to 3.5 per 1000.[48] [53] This enhanced resolving power of noninvasive methods should prove particularly useful in the study of familial structural defects, because apparently unaffected relatives can be evaluated for subclinical evidence of anomalies. Few investigations to date have capitalized on this approach.[54] [55]

As is evident from the previous section, gross aberrations of chromosomes produce an extensive and varied array of structural heart disease, an observation as true for spontaneous abortuses as for live-born children.[56] Unfortunately, cytogenetic aberrations have provided few clues about etiology and pathogenesis of congenital malformations.[57] [58] Better understanding comes from investigating the other two mechanisms by which genes cause congenital heart defects--multifactorial processes and mutations of single genes. In addition to the mendelian syndromes discussed later, evidence for the involvement of genes of large effect derives from studies of incidence of congenital heart disease in populations with a high rate of inbreeding. The increased occurrence of defects in offspring of consanguineous matings suggests that mutations in one or more genes, when homozygous, strongly predispose to abnormal cardiovascular development.[59]

MULTIFACTORIAL PROCESSES.

The empirical risks of recurrence of congenital heart defects have increased in recent years,[60] [61] in keeping with the overall higher incidence noted earlier. However, this conclusion has been criticized because the studies focused on the offspring of women probands, in whom the recurrence risk appears higher than in men with congenital heart defects.[62] In addition to this unexplained maternal influence, other factors may be at work. For example, improved detection of subtle lesions, more faithful reporting of patients, and the assiduousness of epidemiologists may have shown a systematic variation. More patients with cardiovascular problems now survive[61] [62] [63] [64] to bear children because of improved medical and surgical care; their offspring might be at increased risk because of the severity of the parents' problems, but some evidence refutes this idea.[65]

The familial aggregation of congenital heart defects supports many of the predictions of the threshold liability model of multifactorial inheritance.[53] [66] [67] In most studies, whether focused on populations or families, defects were classified by their pathology; for example, all ventricular septal defects were considered as one group. There has been bias in reporting families in which one type of defect aggregates, which has led to many reports of "familial atrial septal defect," "familial cardiomyopathy," and so on, without regard to the fact that not all septal defects or cardiopathies have the same structure on careful scrutiny, let alone the same cause.[68] [69]

A major advance has been the movement to examine familial aggregation of defects based on presumed pathogenesis.[52] [70] The scheme developed by Clark[71] and since modified and expanded[72] (Table 56-5) , has become widely used. Under this approach, some anatomically distinct lesions are related by common pathogenesis; if the pathogenetic mechanism has substantial genetic control, then the occurrence of distinct defects in the same family would still be consistent with a genetic model. Alternatively, defects unrelated by pathogenesis would require a different interpretation. This model rationalizes examination of apparently unaffected relatives, which increases the chances of detecting subtle manifestations of defective development of cardiovascular structures.

ERRORS IN MESENCHYMAL TISSUE MIGRATION.

Included in this category are a wide range of anomalies of the outflow tract, some due to failure of fusion and others due to failure of septation. Relatives of probands with interruption of the aortic arch type B or truncus arteriosus, both uncommon conotruncal malformations, had 2.5 percent and 6.6 percent incidences, respectively, of congenital heart defects.[73] Both recurrence rates were higher than expected. The frequency of congenital malformations was much lower in relatives of patients with other forms of interrupted aortic arch. Moreover, relatives of probands with truncus arteriosus and other defects had a recurrence rate of 13 percent, the majority in the spectrum of conotruncal lesions. Here is an instance in which refined empirical risk data should improve the accuracy of genetic counseling.

Categorizing anatomical defects by presumed pathogenesis emphasizes that all ventricular septal defects are not alike. However, even within an embryologically circumscribed category, the situation is complex. Many perimembranous ventricular septal defects can be considered errors in mesenchymal tissue migration. Evidence exists for the effects of major genes (e.g., as yet unidentified ones in the 22q11 region[74] and *Jagged1,* the gene that when mutated also causes Alagille syndrome[75] and for multifactorial effects.[76]

Conotruncal Development.

Considerable progress has been made during the past few years in identifying a region of chromosome 22 that has a major role in development of the conotruncus, the branchial arches, and the face. Interest was first stimulated by detection of small deletions involving 22q11 in patients with *DiGeorge sequence.*[77] This condition includes developmental anomalies of the fourth branchial arch and derivatives of the third and fourth pharyngeal pouches. Hypoplasia of the thymus and parathyroids causes immune deficiency and hypocalcemia. The cardiac defects range from tetralogy of Fallot to ventricular septal defect, truncus arteriosus, interrupted aorta type B, and right aortic arch and are often lethal. Deletion of 22q11 accounts for about 90 percent of instances of DiGeorge sequence.

TABLE 56-5 -- CLASSIFICATION OF CONGENITAL HEART DEFECTS BASED ON PATHOGENETIC MECHANISMS

PATHOGENETIC MECHANISM	EXAMPLES OF DEFECTS
Embryonic blood flow defects	
Left-sided lesions	HLH; bicuspid aortic valve; IAA type A; CoA; PDA
Right-sided lesions	Secundum ASD; PS
Mesenchymal tissue migration defects	TOF; D -TGA
Extracellular matrix defects	ECD
Abnormal cellular death	Ebstein anomaly; muscular VSD
Defects of looping and situs	l -TGA
Abnormalities of targeted growth	TAPVR

HLH=hypoplastic left heart; IAA=interrupted aortic arch; CoA=coarctation of aorta; PDA=patent ductus arteriosus; ASD=atrial septal defect; PS=valvular pulmonic stenosis; TOF=tetralogy of Fallot; TGA=transposition of great arteries; ECD=endocardial cushion defect; VSD=ventricular septal defect; TAPVR=total anomalous pulmonary venous return.

Subsequently, patients with *velocardiofacial syndrome* (VCF, also called Shprintzen syndrome) and what has been called in Japan the *conotruncal anomaly face syndrome* were found to have deletions in the same region, albeit generally smaller ones than in DiGeorge syndrome.[78] Because the deletion is often too small to be detected by routine cytogenetics, fluorescent in situ hybridization (FISH) with a DNA probe for the region is the assay of choice. The VCF syndrome is unlike DiGeorge syndrome and includes an abnormal but characteristic facies, cleft palate, pharyngeal insufficiency, and conotruncal cardiac defects.

This same region of chromosome 22 has been examined in patients with familial occurrence of various congenital cardiac defects and in patients with nonfamilial occurrence, nonsyndromic conotruncal defects, and an important fraction of patients in both categories have submicroscopic deletions of 22q11.[74] [79] Thus, a gene or genes in this region account for much of the recurrence risk of defects due to mesenchymal tissue migration abnormalities. Further, accurate counseling about recurrence risks for this broad range of defects necessitates FISH or molecular analysis for the presence of a deletion in the proband and, if present, in both parents.

Deletion of 22q11 occurs in about 13 per 100,000 live births and is, after trisomy 21, the second most common genetic cause of congenital heart disease.[80]

Investigation of a strain of Keeshond dogs prone to conotruncal defects has shown that a single gene can be responsible for pathogenetically related defects of widely varying severity.[81]

FLOW DEFECTS.

Left-sided flow lesions comprise a spectrum that includes hypoplastic left heart, congenital aortic stenosis, bicuspid aortic valve, interrupted aortic arch type A, and aortic coarctation. Various components of this spectrum can be present in the same patient. Data from the Baltimore-Washington Infant Study,[52] a population-based case-control study of congenital cardiovascular malformations, were used to show that in first-degree relatives of probands with isolated hypoplastic left heart, the incidence of bicuspid aortic valve was 12 percent; most of the cases were asymptomatic and unrecognized before they were detected by echocardiography as part of this investigation.[59] In an exceptional family, four instances of aortic coarctation occurred in four generations.[82]

The association of coarctation of the aorta, bicuspid aortic valve, and dilatation of the ascending aorta, which may occur as part of *Turner syndrome,* is well known in the general population.[83] Several intriguing questions about the genetics and pathogenesis of this association need to be addressed. To what extent is the ascending aorta intrinsically abnormal and hence predisposed to dilate, and to what extent is the dilatation simply a result of abnormal turbulence created by a bicuspid aortic valve? The fact that some patients with this association also have subtle evidence of a systemic connective tissue abnormality, reminiscent of Marfan syndrome, supports the former hypothesis. It will be of interest to extend the study of left-sided flow lesions to include probands with coarctation or congenital aortic stenosis and to evaluate close relatives with techniques capable of detecting the entire range of flow defects.

EXTRACELLULAR MATRIX ABNORMALITIES.

Enough is known about the biochemistry and cell biology of cardiac embryology to state with some confidence that the extracellular matrix ("connective tissue") has an important role. The endocardial cushions have received the most attention as an area where defects in the extracellular matrix might produce malformations.[71] The high frequency of endocardial cushion defects and atrioventricular septal defects in Down syndrome has been noted (see p. 1986). Of interest is the finding of increased adhesiveness of fibroblasts from patients with trisomy 21, a phenomenon that could reflect interaction with the extracellular matrix.[84] The distinctiveness of endocardial cushion defects in patients with normal chromosomes and in those with trisomy 21 has been suggested because of differences in associated cardiovascular malformations.[68] However, of six families in which the proband had an endocardial cushion defect, three had recurrence of the same type of defect in a relative, including two with trisomy 21.[85]

SITUS AND LOOPING DEFECTS.

This is an area fraught with difficulties of nomenclature, diagnosis, and heterogeneity of both etiology and pathogenesis. In analysis of clinical data, the most informative approach, but clearly arduous because of the large amount of data required, would be to categorize probands and their relatives by the type of situs (solitus, inversus, dextroversion, and levoversion: see Chap. 43) and each of those by presence or absence of other cardiac and visceral defects. This has not been done on epidemiological cohorts, and in family studies relatives have rarely been subjected to evaluations sufficient to characterize their phenotypes in detail. These variable phenotypes are grouped in a category, *heterotaxy,* that accounts for 3 to 4 percent of all congenital heart defects.

Several mendelian phenotypes point to single genes that have a major effect on determining laterality. In the autosomal recessive *Kartagener syndrome,* a randomization of lateralization of the heart (situs solitus and situs inversus are equally likely in homozygotes)[86] coexists with a defect in ciliary motility, which leads to sinusitis, bronchiectasis, and sperm immotility.[87]

Heterotaxy with splenic and other cardiac defects, particularly of the position of the great vessels, can be inherited as an autosomal recessive, as an autosomal dominant,[88] and as an X-linked recessive.[89] Some of the families with these apparently single-gene disorders have concordance of phenotype, but many do not, suggesting that in some cases various types of situs defects, polysplenia, and asplenia are different manifestations of the same mutation.[90] [91]

In recent years, investigation of molecular embryology has shed increasing light on cardiovascular development and maldevelopment.[92] The determination of laterality and defects involving heterotaxy have been especially revealing, in both mice and humans.[93] [94] In mice, the *inv* locus has long been associated with left/right asymmetry, and the gene was recently cloned.[95] In humans, mutations of two genes thus far, one encoding the activin receptor type IIB[96] and one encoding the connexin43 gap junction protein,[97] both have been associated with defects of laterality.

Few data define the recurrence risks of defects in the *cell death* (e.g., Ebstein anomaly) and *abnormal targeted growth* (e.g., anomalous pulmonary venous return) categories. Data from the Baltimore-Washington Infant Study do not show an increased risk of any cardiovascular defect in the relatives of a proband with a defect in either of these categories.[52]

DISORDERS OF UNCLEAR CAUSE.

A number of disorders include an important likelihood of malformation of the cardiovascular system but are of unclear cause (Table 56-6) . Familial recurrence is low enough to be *incompatible* with multifactorial inheritance. Several of these disorders deserve comment.

Certain congenital cardiac defects and other malformations occur together more frequently than expected by chance; this *association* of defects suggests a common cause, pathogenesis, or both, but the following disorders and those in Table 56-7 remain enigmatic on most of these counts. Designation as a *sequence* implies that some evidence exists for a common developmental problem to account for the features.

CHARGE Association

(see Table 56-6) . Patients with this condition by definition have congenital heart defects.[98] [99] The spectrum of cardiovascular malformations suggests not so much a common pathogenetic scheme as a common time of abnormal development. During gestational days 32 to 45, cardiac septation, fusion of the endocardial cushions and membranous ventricular septum, and formation of the outflow tracts and valves occur. An environmental insult or a breakdown in developmental homeostasis during this period could result in the malformation spectrum of this disorder. The defects in other systems could also arise during this embryological window and would be consistent with either environmental or intrinsic factors.

VACTERL Association

(see Table 56-6) . This condition has expanded over the years to include *v*ertebral, *v*entricular septal, *a*nal, *c*ardiac *t*racheo*e*sophageal, *r*enal, and *l*imb defects. Omitted from the mnemonic is the single umbilical artery often present.[100] Cardiac defects are present in about one-half of patients with more than two components of this association but usually are not life threatening. VACTERL association occasionally occurs in relatives.[101] Although infants with this condition often fall to thrive initially, the long-term prognosis for health and mental function is good, so aggressive management of the multiple malformations is warranted. It is important to separate as soon as possible those patients who have the features of trisomy 18 or 13q chromosome aberrations, as prognosis in these cases is distinctly unfavorable.

Mendelian Disorders

Some congenital cardiovascular defects segregate in occasional families as predicted of a mendelian phenotype. Strong bias favors reporting such occurrences, and equally strong is a temptation to conclude that, at least in some cases, the defect is caused by mutation in a single gene. However, rarely and by chance alone, a multifactorial trait recurs in a family in a pattern mimicking mendelian segregation. This potential confusion and the resultant uncertainty in counseling patients and families pertains equally well to disturbances of conduction and rhythm, to various cardiomyopathies, to vascular anomalies, and to hypertension, all discussed subsequently. The true cause of the cardiovascular diseases in such families may not become clarified until each is investigated in detail, in concert with efforts to map and sequence the entire human genome.

The subject of this section can therefore be parsed into three broad classes of conditions: congenital cardiac defects that occasionally seem to be inherited as mendelian traits (Table 56-7) , pleiotropic mendelian syndromes that always or frequently affect the structure of the cardiovascular system (Table 56-8) , and mendelian syndromes that occasionally affect the cardiovascular system (Table 56-9) .

PATENT DUCTUS ARTERIOSUS.

Most instances of PDA are sporadic occurrences, and a strong association with prematurity

TABLE 56-6 -- DISORDERS OF UNCERTAIN CAUSE AND INHERITANCE THAT ARE ASSOCIATED WITH A HIGH INCIDENCE OF CARDIOVASCULAR ABNORMALITIES

DISORDER AND PHENOTYPE	OMIM NO.*	CARDIOVASCULAR ABNORMALITIES
Aase syndrome (congenital anemia, triphalangeal thumbs)	205600	VSD
Bilateral left-sidedness sequence (polysplenia syndrome)	208530	ASD
Bilateral right-sidedness sequence (asplenia syndrome; Ivemark syndrome)	208530	Situs inversus, ECD, VSD
CHARGE association (*c*oloboma, *h*eart anomaly, choanal *a*tresia, *r*etardation, *g*enital, and *e*ar anomalies)	214800	TOF, PDA, ECD, VSD
Cornelia de Lange syndrome(short stature, retardation, synophrys, hypertrichosis, micromelia, genital anomalies)	122470	~20% have CHD: VSD, PDA, ASD, PLSVC, TOF
DiGeorge sequence (abnormalities of derivatives of 3rd and 4th pharyngeal pouches and 4th branchial arch: hypoplastic thymus with cellular immune deficiency, hyoplastic parathyroids with hypocalcemia)	188400	CHD in ~100%: aortic arch anomalies (especially IAA type B and right-sided aortic arch); PDA, TOF
Goldenhar syndrome (abnormalities of derivatives of 1st and 2nd branchial arch: hemifacial microsomia, microtia, vertebral anomalies)	141400,164210,257700	~50% have CHD: VSD, TOF, PDA, CoA, right-sided aortic arch, PLSVC
Klippel-Feil sequence (short neck, limited rotation of the head, cervical anomalies)	118100, 148900,214300	Variable estimates (5-70%) of CHD: VSD, dextrocardia
"Kabuki make-up" syndrome (dwarfism, peculiar facies, scoliosis, mental retardation)	147920	30% have CHD: ASD, VSD, TOF, CoA, PDA
Pallister-Hall syndrome (hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, postaxial polydactyly)	146510	ECD
Poland sequence (unilateral absence of sternocostal pectoralis major, ipsilateral synbrachydactyly)	173800	~10% have dextrocardia or dextroversion
Rubinstein-Taybi syndrome (short stature, retardation, microcephaly, characteristic facies, broad thumbs)	268600	~20% have CHD: ECD, ASD, TOF, PDA, VSD
VATER association (*v*ertebral defects, *a*nal atresia, *t*racheo-*e*sophageal fistula, *r*adial dysplasia, *r*enal anomaly)	192350	VSD

VSD=ventricular septal defect; ASD=atrial septal defect; TOF=tetralogy of Fallot; PDA=patent ductus arteriosus; ECD=endocardial cushion defect; CHD=congenital heart defect(s); PLSVC=persistence of left superior vena cava; IAA=interrupted aortic arch; CoA=coarctation of aorta; VSD=ventricular septal defect.

*None of these disorders is evidently due to a mutation in a single gene; however, most are listed in Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim)[8] and the OMIM no. is provided as a ready source to the literature.

Cardiovascular defects listed in approximate order of decreasing frequency.

90% of cases associated with del(22q11); likely a contiguous gene deletion defect.

TABLE 56-7 -- CONGENITAL HEART DEFECTS OCCASIONALLY SHOWING FAMILIAL AGGREGATION CONSISTENT WITH MENDELIAN INHERITANCE

DEFECT	OMIM NO.*	DEFECT	OMIM NO.
Aneurysm, intracranial berry	105800	Hypoplastic left heart	140500, 241550
Aneurysm, abdominal aortic	100070	Hypoplastic right heart	277200
Angioma	106050, 106070, 206570	Lymphedema, congenital	153000, 153100, 153400, 214900, 247440
ASD, ostium primum	209400		
ASD, ostium secundum	108800, 108900, 178650	Mitral valve prolapse	157700
Bicuspid aortic valve	109730	Patent ductus arteriosus	169100
		Pulmonary venous return, anomalous	106700

TABLE 56-8 -- MENDELIAN DISORDERS WITH CONGENITAL DEFECTS OF CARDIOVASCULAR STRUCTURE AS FREQUENT MANIFESTATIONS

DESCRIPTIVE NAME	EPONYM	OMIM NO.*	CARDIOVASCULAR ABNORMALITIES
Adult polycystic kidney disease		173900	MVP, dilated aortic root, intracranial berry aneurysm
Arteriohepatic dysplasia	Alagille syndrome	118450	PPS
Cataract and cardiomyopathy		212350	HCM
Chondroectodermal dysplasia	Ellis-van Creveld syndrome	225500	ASD (ostium primum), common atrium
Deafness, mitral regurgitation, and short stature	Forney syndrome	157800	MR

Familial collagenoma syndrome		115250	DCM
Heart-hand syndrome	Holt-Oram syndrome	142900	ASD (ostium secundum), VSD, MVP, HLH
Keratosis palmoplantaris	Mal de Meleda	248300	DCM, dysrhythmia
Malignant hyperthermia and skeletal defects	King syndrome	145600	Malignant hyperthermia cardiac arrest
	Noonan syndrome	163950	PS, HCM
Pulmonic stenosis and deafness		178651	PS
	Smith-Lemli-Opitz syndrome	270400	PDA, ASD, VSD, TOF, ECD, CoA
Velocardiofacial syndrome	Shprintzen syndrome	192430	TOF, tortuous retinal vasculature

MVP=mitral valve prolapse; PPS=peripheral pulmonic stenosis; HCM=hypertrophic cardiomyopathy; ASD=atrial septal defect; MR=mitral regurgitation; DCM=dilated cardiomyopathy; VSD=ventricular septal defect; HLH=hypoplastic left heart; PS=valvular pulmonic stenosis; PDA=patent ductus arteriosus; TOF=tetralogy of Fallot; ECD=endocardial cushion defect; CoA=coarctation of aorta.

Data from Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

and all of its antecedents is noted. However, in a number of families that have been described, PDA occurs as an autosomal dominant trait.[102] In some pedigrees, mild facial dysmorphism segregates with PDA; because the facial features differ among families, the number of syndromes remains unclear.[103] [104]

FAMILIAL ATRIAL SEPTAL DEFECT.

Two mendelian forms of atrial septal defect exist as autosomal dominant traits. One has no associated problems and has been described in few pedigrees.[105]

The second, more common condition is associated with atrioventricular conduction delay.[106] [107] The defect is of the secundum type, and relatives do not seem to be at increased risk of other cardiac malformations. The severity of heart block rarely progresses to third degree. The electrocardiographic abnormality in a patient with apparently sporadic atrial septal defect should prompt a detailed family history and evaluation of close relatives. Attention should be directed to the upper limbs, particularly the thumbs, to rule out the Holt-Oram syndrome; radiographic examination of the upper limbs of the proband is helpful on this account.

In patients with atrial septal defect due to aneuploidy (a syndrome with extracardiac features), when one of the autosomal dominant forms is excluded, the recurrence risk of secundum atrial septal defect is about 3 percent, a value that conforms closely to the multifactorial threshold model. Several pleiotropic mendelian conditions have defects of the atrial septum as frequent manifestations.

HOLT-ORAM SYNDROME.

This autosomal dominant condition, first elaborated in 1960, shows marked variability within a pedigree.[108] The cardinal manifestations are dysplasia of the upper limbs and atrial septal defect. In heterozygotes for the mutation, arm deformity ranges from undetectable through distally placed thumbs and hypoplastic thenar eminences, triphalangeal thumbs, anomalies of the carpus, and radial aplasia, to phocomelia and hypoplasia of the clavicles and shoulders. Upper-extremity deformity is usually bilateral but may be asymmetrical in severity, with the left side more affected. Similarly, the atrial involvement ranges from none to a large secundum defect with early, severe hemodynamic compromise. Other cardiac malformations have been reported, with ventricular septal defects and PDA the most frequent.[109] The skeletal and cardiac manifestations are not correlated in individuals, and how a parent is affected is not a reliable predictor of effects on offspring.[110] Prenatal diagnosis by ultrasonography was reported in a fetus with severe limb abnormalities; a large septal defect could presumably be detected as well. Other manifestations include dermatoglyphic abnormalities, pectus excavatum, hypoplastic peripheral arteries, and cardiac conduction disturbance, the last usually involving the atrioventricular node and present in patients with septal defects. Although the Holt-Oram syndrome bears some resemblance

TABLE 56-9 -- MENDELIAN DISORDERS WITH CARDIOVASCULAR ABNORMALITIES AS OCCASIONAL MANIFESTATIONS

SYNDROME	EPONYM	OMIM NO.*	CARDIOVASCULAR ABNORMALITIES
Acrocephalosyndactyly type I	Apert syndrome	101200	PS, PPS, VSD, EFE
Acrocephalopolysyndactyly type II	Carpenter syndrome	201000	PDA, VSD, PS, TGA
Hereditary angioedema		106100	Coronary arteritis
Imperforate anus with hand, foot, and ear anomalies	Townes-Brocks syndrome	107480	Sporadic cases have CHD: VSD, ASD
Mandibulofacial dysostosis	Treacher Collins syndrome	154500, 248390	10% have CHD: variable
Neuronal ceroid lipofuscinosis	Batten disease	204200	HCM
Orofacial digital syndrome type II	Mohr syndrome	252100	Variable
Short rib-polydactyly syndrome	Saldino-Noonan syndrome	263530	TGA, ECD, hypoplastic right heart
Thrombocytopenia--absent radius syndrome		274000	TOF

Data from Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

to the VACTERL association, the clear mendelian nature and lack of more extensive organ system involvement of the former indicate that the two conditions do not represent a pathogenetic spectrum.

The diagnosis of Holt-Oram syndrome is most likely to be missed in a patient with an unknown or unremarkable family history, a secundum septal defect, and minimal or no thumb anomaly. In any "sporadic" case of an atrial septal defect, the patient and the parents should be carefully examined for limb malformations and the family history studied in detail. Detection of a subtle limb defect alters the recurrence risk in offspring of the proband from the empirical risk of an isolated septal defect of 3 percent to the 50 percent of an autosomal dominant trait.

Mutations in the *TBX5* gene, which is a transcriptional regulator, cause one form of Holt-Oram syndrome.[111] Different mutations have more or less effect on limb and cardiac development, which accounts for much of the interfamilial variability. Not all families with Holt-Oram syndrome are linked to this locus at 12q2, so at least one additional gene can cause this spectrum of defects.[112] [113]

ELLIS-VAN CREVELD SYNDROME

(Fig. 56-6) . This rare autosomal recessive chondrodysplasia is found among the old order Amish because of a founder effect and consanguinity. Short stature, metaphyseal dysplasia, dysplastic nails and teeth, and postaxial polydactyly are the pleiotropic manifestations in addition to congenital heart disease.[114] The last is present in more than one-half of homozygotes, and most of the defects affect the atrial septum. The majority are defects of endocardial cushion closure, including ostium primum defects of widely varying size up to a single atrium. This disorder has long been thought to be due to a yet unknown defect in the extracellular matrix, which would fit with the high frequency of endocardial cushion lesions. However, defects thought due to abnormal embryonic flow (coarctation, hypoplastic left heart, and patent ductus arteriosus) occur in about 20 percent of cases. The gene maps to 4p16 in patients of all ethnic derivations.[115] A gene of unknown function within this locus has been called *EVC*, with the finding of pathological mutations in a number of patients.[115A] Ellis-van Creveld syndrome can be diagnosed prenatally by detection

of polydactyly by ultrasonography.

FAMILIAL ATRIOVENTRICULAR CANAL DEFECTS.

This spectrum of defects occasionally occurs in an autosomal dominant pattern in families and is unassociated with features in other systems. Because the cardiac defect is suggestive of that in Down syndrome, linkage to chromosome 21 markers was pursued, to no avail. In a large kindred that showed variable expression of nonsyndromic atrioventricular canal defects, analysis of shared markers among those clearly affected identified a region on chromosome 1 (1p31-p21) that must harbor a gene that effects susceptibility to failure of closure of the endocardial cushions.[116]

VENTRICULAR SEPTAL DEFECT.

This malformation does not seem to be inherited as an isolated mendelian malformation, and no syndromes include it as a common, isolated manifestation.

SUPRAVALVULAR AORTIC STENOSIS.

This congenital lesion, which may be asymptomatic and detected long after birth because of an ejection murmur, occurs in at least three settings. It can be a sporadic anomaly, a component of Williams syndrome, or an autosomal dominant trait associated with peripheral pulmonic stenoses and a diffuse arteriopathy.

Williams syndrome is usually sporadic but, in more instances than previously recognized, is a highly variable autosomal dominant condition. The full spectrum includes infantile hypercalcemia, abnormal (elfin) facies (see Fig. 43-35) , mental deficiency, short stature, numerous peripheral pulmonic stenoses, and supravalvular aortic stenosis.[117] [118] [119] Although patients usually survive the problems of infancy and show catch-up growth, progressive problems of joint contractures, genitourinary and gastrointestinal dysfunction, hypertension, and psychosocial adjustment define the long-term prognosis.[120] [121] [122]

Supravalvular aortic stenosis (SVAS) is due to heterozygosity for a mutation in tropoelastin (discussed later). Because elastic fibers are

Figure 56-6 Ellis-van Creveld syndrome in a young woman. *A,* Note short stature, joint contractures at the elbows, and marked genu valgum. *B,* The fingers are short and the nails dysplastic. Note the protuberances along the ulnar edges of the hands where sixth digits were amputated.

intrinsic to the media of elastic and muscular arteries, a diffuse, progressive arteriopathy develops, with thickening of the wall and reduction of the lumen. The natural history of the arterial disease is just emerging as patients with Williams syndrome live longer and are monitored prospectively.[123] A predisposition to cerebrovascular disease seems certain.[124] [125]

Virtually all patients with Williams syndrome who have been tested have a deletion of the long arm of chromosome 7.[126] [127] Those with SVAS have a deletion that involves the tropoelastin locus. The crucial gene(s) involved in the rest of the Williams phenotype lie telomeric to the tropoelastin locus; considerable effort is currently being directed at identifying these gene(s) that have a role in development of the face, in calcium metabolism, and in development of personality and cognitive capability.

Autosomal dominant SVAS is an entity distinct from Williams syndrome,[128] [129] [130] although some patients have subtle defects in personality and intelligence. Peripheral pulmonary artery stenoses may be present but rarely cause hemodynamic problems. The aortic lesion requires surgery in less than half of patients.

MITRAL VALVE PROLAPSE.

(see Chap. 46) . This trait is of heterogeneous cause and pathogenesis; although it has been called the most common abnormality of human heart valves.[131] MVP is equally clearly not always an abnormality.[132] [133] Here only the heritable forms of MVP are discussed. These can be classified into three groups. The first is a familial form with minimal extracardiac involvement. The second is an autosomal dominant condition that is clinically variable and at one end of its spectrum merges with Marfan syndrome; it could just as well be discussed as a heritable disorder of connective tissue. The third category is composed of the various mendelian syndromes that include MVP as a pleiotropic manifestation. In all of these categories, prolapse of the tricuspid valve is a frequent accompaniment.

The first category, which some have called MVP syndrome or familial MVP,[134] includes a condition that is centered on the mitral valve. The development of actual prolapse shows the age- and gender-dependent behavior characteristic of the idiopathic form.[134] [135] Formal genetic studies in most families confirm *autosomal dominance with variable expression.* This category has been partitioned into those patients with billowing of the mitral leaflets and those with excessive systolic mitral annular expansion; because this phenotype breeds relatively true, two distinct autosomal dominant forms may exist.[136] The cause(s) of these entities is unknown. Moreover, when and how the phenotype of this condition can be distinguished from the sporadic cases of MVP and the cases with obvious evidence of a systemic disorder of connective tissue are unclear. The only consistent extracardiac manifestations are excessive arm span in women and relatively low body weight and systolic pressure.[137] [138] Susceptibility to myxomatous degeneration of all cardiac valves can be inherited as an X-linked trait that maps to Xq28.[139]

Many clinical geneticists and cardiologists have referred patients with a suspicion of Marfan syndrome (see p. 1983) or Ehlers-Danlos syndrome (see p. 1986). Some of these patients do not meet minimal diagnostic criteria for a recognized connective tissue disorder[140] [141] but clearly have extracardiac features consistent with a defect of the extracellular matrix described later. MVP is commonly but not always present; when it is and when evidence of a systemic abnormality of connective tissue is lacking, the patient should be considered to have the condition described in the preceding paragraph, what some call primary MVP.[142] The clinical spectrum of the patients with syndromic MVP includes abnormal striae atrophicae, excessive arm span and leg length, joint hypermobility, pectus excavatum, scoliosis, reduction in thoracic kyphosis ("straight back"), myopia, and mild aortic root dilatation.[143] Aortic dilatation beyond 3 SD above the mean for body surface area, aortic dissection, ectopia lentis, or a family history of any of these three features *removes* a patient from this category. For the remainder of patients, the acronym MASS phenotype, for *m*itral *v*alve, *a*orta, *s*kin, and *s*keletal, describes what certainly is a heterogeneous grouping of patients and families. The aorta is mentioned specifically because of the appropriate concern that progressive dilatation and dissection will occur; in fact, neither has been the case, although prospective evaluation has been unsystematic. Many of the associations between MVP and deformity of the thoracic cage and spontaneous pneumothorax are explained by the MASS phenotype.[144]

Finally, as described later, MVP frequently accompanies Marfan syndrome, several of the Ehlers-Danlos syndromes, and cutis laxa and occurs more often than expected in osteogenesis imperfecta, Larsen syndrome, pseudoxanthoma elasticum, and other mendelian syndromes (Table 56-10) . In addition, occasional families with otherwise unclassified heritable disorders of connective tissue have prominent involvement of the mitral apparatus, with myxomatous deterioration, calcification, or both.[145]

NOONAN SYNDROME.

Among the pleiotropic mendelian syndromes that have frequent cardiovascular involvement, Noonan syndrome is important because of its relatively high prevalence and clinical variability. This autosomal dominant condition has been called the male Turner syndrome in the past because of the short stature, cubitus valgus, neck webbing, congenital lymphedema, and congenital heart defects that coexist in the 45,X Turner syndrome. However, Noonan syndrome is distinct, not simply because both men and women are affected. Patients with Noonan syndrome often have an unusual deformity of the sternum, mental dullness, hypertelorism, ptosis, and cryptorchidism.[146] The cardiovascular defects, although widely varied, do not include an increased incidence of coarctation of the aorta. Because of the dysmorphism of the facies and the cardiac involvement, Noonan syndrome is often classified, along with William, leopard, King, and Watson syndromes, as a cardiofacial syndrome.

The entire phenotype of Noonan syndrome is highly variable, and affected persons can escape clinical problems (or accurate diagnosis) even if they have obvious manifestations.[147] Similarly, a wide range of cardiovascular involvement can occur. *Valvular pulmonic stenosis* was the first defect identified, and Noonan syndrome should always be considered in a patient with this lesion.[148] The valve cusps are thickened and dysplastic, even in the absence of hemodynamic compromise. Obstruction to right-sided flow can also occur in patients with Noonan syndrome because of pulmonary artery hypoplasia or infundibular subvalvular changes. The latter finding reflects a generalized predisposition to hypertrophic cardiomyopathy, often asymmetrical, that can affect either ventricle.[149] *Atrial septal defect* occurs in about one-third of patients, usually in association with pulmonic stenosis.

TABLE 56-10 -- CARDIOVASCULAR DEFECTS ASSOCIATED WITH PRENATAL EXPOSURE TO TERATOGENS

TERATOGEN	CARDIOVASCULAR ABNORMALITIES*
Ethanol	~50% have CHD: VSD (~50% close spontaneously), TOF, ASD, ECD, absence of a pulmonary artery
Hydantoin	~10% have CHD: VSD, ASD, PS
Lithium	<3% have Ebstein anomaly
Phenylalanine	~20% have CHD: TOF
Retinoic acid	>50% have CHD: TGA, TOF, VSD, IAA
Rubella	>50% have CHD: PDA with or without ASD, VSD, PPS, IAA
Trimethadione	~50% have CHD: complex combinations most frequent (involving VSD, ASD, PDA, AS, PS), VSD, TOF
Valproic acid	>50% have CHD: left- and right-sided flow lesions: CoA, HLH, ASD, VSD, pulmonary atresia
Vitamin D	Supravalvular aortic stenosis is the cardinal manifestation; PPS
Warfarin	~10% have CHD: PDA, PS; rarely, intracranial hemorrhage.

CHD=congenital heart defect(s); VSD=ventricular septal defect; TOF=tetralogy of Fallot; ASD=atrial septal defect; ECD=endocardial cushion defect; PS=valvular pulmonic stenosis; TGA=transposition of great arteries; IAA=interrupted aortic arch; PPS=peripheral pulmonic stenosis; PDA=patent ductus arteriosus; AS=aortic stenosis; CoA=coarctation of aorta; HLH=hypoplastic left heart.

*Among patients with the full clinical spectrum associated with each teratogen; cardiovascular defects listed in decreasing order of prevalence.

Ventricular septal defects and patent ductus arteriosus each occur in about 10 percent. Congenital anomalies of coronary arteries are occasionally and unexpectedly found during evaluation of more obvious defects. The electrocardiogram often shows left anterior hemiblock and a deep precordial S wave, a pattern not common in pulmonic stenosis of other causes.

Lymphatic dysplasia, especially of the lower limbs, is common but causes clinical difficulties in less than 20 percent.[146] Although evidence of lymphedema often disappears during childhood, chylothorax and a protein-losing enteropathy represent the severe end of the spectrum.[150]

Noonan syndrome shares features with other cardiofacial syndromes, and in sporadic cases (which account for 50 percent of Noonan syndrome) diagnosis can be difficult. All are *autosomal dominant,* so genetic counseling is somewhat easier. Affected males have reduced reproductive capabilities because of testicular abnormalities. Susceptibility to malignant hyperthermia can be detected by family history, elevated skeletal muscle creatine kinase levels, or muscle biopsy. Despite the relatively high frequency of Noonan syndrome, estimated to be as great as 1 per 1000, neither its cause nor its pathogenesis is clear. One gene has been mapped to 12q24.2-q 24.31, but interlocus genetic heterogeneity is likely.[151] [152] Intriguing issues that may shed light on these uncertainties are the overlap in phenotype with type I neurofibromatosis[153] [154] (the gene for which is on chromosome 17), and the frequent coexistence of Noonan syndrome and deficiency of coagulation factor XI.[155]

Teratogenic Effects

A teratogen is any agent that adversely affects embryonic or fetal development, such as infectious vectors, radiation, drugs, and other chemicals (see Table 56-10) .[156] Teratogenic effects on the cardiovascular system are considered in this chapter for several reasons: First, the phenotypes are often reminiscent of those due to chromosomal aberrations and single-gene mutations. Second, clinical geneticists and dysmorphologists are involved in diagnosing, managing, and investigating both teratogenic and genetic syndromes. Finally, how the organism responds to an encounter with a potential teratogen is largely determined by its genome. The entire field of ecogenetics and part of pharmacogenetics are concerned with these issues.

The abilities to resist disruption of normal human embryogenesis and development involve systems quite distinct from physiological homeostasis and related only in part with developmental homeostasis. Genetic susceptibilities to teratogens can be illustrated by diverse mechanisms: reduced or inaccurate repair of radiation-induced DNA damage; enhanced receptiveness to viral entry or replication; immune deficiencies that prevent inactivation of infectious vectors or maintenance of immunity; slow inactivation of a compound that exerts a direct deleterious effect; or rapid conversion of an inoffensive drug to a teratogenic metabolite. These types of hereditary variation may be determined by single genes, with susceptibility inherited as a mendelian trait, or by many genes, each of small effect. Either situation can account for the well-known fact that only a fraction of pregnancies exposed to a given agent are affected adversely. Variation in dose and timing of exposure also confound interpretation of epidemiological and family data. It is not surprising, then, that the actual appearance of the abnormal phenotype is not amenable to traditional pedigree analysis. Rather, examination of the biochemical susceptibilities have proved, and will continue to prove, more enlightening.

Some teratogens, such as *warfarin,* have a clear action that explains how the pleiotropic manifestations emerge. The action of other teratogens, such as alcohol, is obscure. Finally, in some teratogenic syndromes, such as that in offspring of women with diabetes mellitus, the actual offensive agent is unclear, and numerous pathogenetic mechanisms seems to pertain.[157] [158] Regardless of cause and pathogenetic mechanism, the phenotypes of many teratogens often share manifestations, especially prenatal growth retardation, abnormalities of the craniofacies, and mental retardation.[159] The following syndromes have prominent consequences on the cardiovascular system.

FETAL ALCOHOL SYNDROME.

Ethanol is the most common teratogen to which the human embryo and fetus are exposed. The period of greatest vulnerability is the first trimester, and the risks are clearly related to the amount of alcohol consumed; the risk of the fetal alcohol syndrome's occurring in an offspring of a chronic alcoholic woman is 30 to 50 percent. The features are highly variable and include growth retardation, mild to moderate mental retardation, hyperactivity, short palpebral fissures, a smooth philtrum with a thin upper lip, and small distal phalanges.[160] [161] Congenital heart defects occur in more than one-half of children with the full spectrum of the phenotype; ventricular septal defects are most common and often insignificant, but atrial septal defects, tetralogy of Fallot, and aortic coarctation can occur.

FETAL HYDANTOIN SYNDROME.

Virtually all antiseizure medications can affect the fetus. Hydantoin was the first to be identified as a teratogen. The risk to the fetus depends in part on the genotype of the fetus; defects in arene oxidase predispose to the full syndrome.[162] [163] The features include prenatal and postnatal growth retardation, mild mental retardation, a broad face with a short nose, short distal phalanges with small nails, and hip dislocation. Cardiovascular defects, which are an inconstant part of the syndrome, include septal defects, right- and left-sided flow defects, and a single umbilical artery.

RETINOIC ACID EMBRYOPATHY.

Isotretinoin was not recognized as a teratogen until after it was licensed for the treatment of acne. The vulnerable period extends from the first week through the fourth month of gestation. Isotretinoin increases the risks of miscarriage and stillbirth. The phenotype includes anomalies of the craniofacies and gross neuroanatomical disruption. Cardiovascular defects are common and emphasize various conotruncal malformations.[164] Live-born infants often succumb to the cardiac and brain anomalies. Although the mechanism of action is not certain, vitamin A derivatives such as retinoic acid function as *morphogens* during embryogenesis, serving as signals for cell migration. The fact that the cardiovascular defects are primarily those of rotation and folding suggests disruption of a normal developmental homeostatic system.

WARFARIN EMBRYOPATHY.

Coumarin-related vitamin K antagonists are usually prescribed for various cardiovascular problems to women of childbearing age and can cause diverse cardiovascular and other organ damage to the fetus. Coumarin interferes with embryogenesis directly when administered during gestational weeks 6 through 9. The most pronounced effects are on cartilage because of inhibition of enzymes of extracellular matrix metabolism. Congenital cardiac defects are perhaps increased in frequency but fit no specific pathogenetic mechanism.[165] The second pattern of coumarin effects involves exposure during the second and third trimesters and includes spontaneous

abortion, stillbirth, and various central nervous system defects. The last are not due simply to intracranial hemorrhage as was once assumed.[165]

What predisposes to the adverse fetal effects of coumarin remains to be discovered. First, more than 75 percent of women who take coumarin derivatives throughout pregnancy have normal offspring; reassuring most women while identifying those at risk for adverse effects has obvious advantages. Second, placing all pregnant women on a regimen of heparin is not an acceptable solution, because heparin can cause stillbirth or premature fetal loss in about 20 percent of exposures, is not as effective as coumarin in some indications for anticoagulation, and is more trouble to administer and regulate.

MATERNAL PHENYLKETONURIA.

The inborn error of metabolism phenylketonuria (PKU), produces severe mental retardation unless the phenylalanine content of the diet is markedly reduced soon after birth.[166] Deficiency of phenylalanine hydroxylase in the fetus produces no harm because fetal blood levels of phenylalanine are regulated by the heterozygous mother's enzyme. Because neonatal screening for this disease is now routine in all states, virtually all patients receive treatment and grow to adulthood with average intelligence. Many patients discontinue the rigorous dietary therapy during adolescence when the elevated phenylalanine levels have far less deleterious effects. The embryopathy occurs when a woman with homozygous deficiency for phenylalanine hydroxylase becomes pregnant and her fetus is exposed to high levels of the amino acid, which overwhelm its ability to metabolize. The result is highly predictable if the mother does not restart dietary restriction of phenylalanine for the entire gestation: moderate to severe mental retardation, prenatal and postnatal growth retardation, microcephaly, and various cardiovascular defects in 15 to 20 percent.[167] This condition can largely be prevented by effective counseling of female patients with PKU.

FETAL RUBELLA EFFECTS

(see Chapter 29) . About 50 percent of fetuses become infected with the rubella virus when the mother is infected during the first trimester. An infected fetus not only suffers varied and severe interference with development and organogenesis but acquires a chronic viral illness that can persist for years. The most common features of the embryopathy are mental deficiency, deafness, cataract, and cardiovascular defects. PDA is common, as are septal defects. Peripheral pulmonary stenosis and fibromuscular proliferation of medium and small arteries often improve postnatally.

CARDIOMYOPATHIES (See also Chap. 48)

Each of the three clinical categories of primary cardiomyopathy--hypertrophic, dilated, and restrictive--can be caused by mutations in single genes as judged by mendelian inheritance of a consistent phenotype in numerous families. Many other mendelian and mitochondrial disorders also cause cardiomyopathies as a secondary consequence of their basic metabolic disturbance.

Hypertrophic Cardiomyopathy

In the more than four decades since the recognition of hypertrophic cardiomyopathy as a clinical entity, many aspects of its natural history, pathology, and management have been substantially clarified.[168] [169] The phenotype is most clearly defined anatomically and histologically and consists of myocardial hypertrophy without secondary cause; cellular and myofiber disarray; myocardial fibrosis; and mediointimal proliferation of small coronary arteries. None of these features is pathognomonic; for example, myofiber disorganization is present in the normal human heart during embryogenesis and in congenital heart defects that place strain on the right-sided circulation.

About half of probands with idiopathic hypertrophic cardiomyopathy of any segment of the left ventricle have affected first-degree relatives, and in those families the phenotype is inherited as an autosomal dominant, familial hypertrophic cardiomyopathy (FHC). There is wide variability of expression within a family, in part because of age dependence of the trait.[168] Later generations of relatives in adolescence and childhood may not have developed echocardiographic evidence of hypertrophy. Hence, pedigree screening by phenotype for clinical, counseling, or investigative purposes should not be considered complete until the following criteria are satisfied: Two-dimensional echocardiography is used to ensure that segmental hypertrophy is detected; a person at risk has normal echocardiographic findings and no evidence of electrocardiographic abnormality or important dysrhythmia after about age 20; and a person of any age has left ventricular hypertrophy without any other explanation, such as hypertension or aortic stenosis.

FHC is a disease of the sarcomere, with primary defects of thick and thin filaments now defined. Mutations of at least six and perhaps more loci cause FHC (see Table 56-2) . The first gene identified was the cardiac beta-myosin heavy chain gene (*MYH7*). Depending on the population studied, about 50 percent of all FHC mutations occur in *MYH7,* and many mutations have been described.[169] [170] Patients with neither parent affected may also have *MYH7* mutations, suggesting that the genetic alteration occured in the egg or sperm of a parent.[171] The likelihood of germline mosaicism is strongly suggested by two sibs with FHC and the same mutation in *MHY7*, even though neither parent shows the mutation in leukocyte DNA[171A] Mutations that alter charge of the beta-myosin heavy chain generally carry a worse prognosis in terms of age of detection, electrocardiographic abnormalities, and sudden death.[172] [173] [174] Thus, defining the specific gene involved, followed by the specific mutation, has likely clinical importance.[175] However, because of the substantial technical challenges and expense of identifying the specific mutation in any given patient with FHC, genetic testing is not yet routine.[176] How the mutant protein interacts with other components of the sarcomere of both cardiac and skeletal muscle to produce the phenotype is another area of active research, as is the generation and characterization of animal models of FHC.[177]

Although intergenic and intragenic heterogeneity account for much of the interfamilial variability in the FHC phenotype, considerable variation remains among relatives who share the same mutation. Both environmental and genetic factors have impacts. A possible example of the latter is the angiotensin I-converting enzyme (ACE) genotype, with different polymorphic variants of ACE associated with more or less hypertrophy.[178]

The importance of presymptomatic and even prehypertrophy diagnosis through mutation analysis in families will become more important as improved methods of therapy evolve.[178A]

Dilated Cardiomyopathy

The prevalence of idiopathic dilated cardiomyopathy is about double that of the hypertrophic form, or about 2 to 8 per 100,000.[179] [180] [181] Although numerous occurrences of familial dilated cardiomyopathy (FDC) are reported, few investigations have been conducted of an unselected series of probands for clinical and subclinical evidence of cardiac disease.[182] Thus, it is unclear what fraction of patients with idiopathic dilated cardiomyopathy have a mendelian disease, how many have a new mutation for a mendelian disease, and how many have phenocopies of nongenetic causes. Estimates of a positive family history, which could suggest a mendelian condition or a shared environmental cause, range from 7 to 30 percent.[168] [169] [182]

Because of the risk of severe dysrhythmia in dilated cardiomyopathy, early detection of individuals with the disorder can be life saving. Two-dimensional echocardiography is a sensitive method for detecting affected relatives with subclinical disease. Individuals who have equivocal left ventricular enlargement or dysfunction can have ambulatory electrocardiographic monitoring and, if the diagnosis is still uncertain, can have serial examinations. Certainly every patient with idiopathic dilated cardiomyopathy should have a detailed family history; about 20 percent reveal an affected relative.[182] If any close relative has a history consistent with cardiomyopathy, dysrhythmia, or sudden death at a relatively young age, counseling about the risk of a familial disease and the potential benefits of pedigree screening should be offered.

The majority of instances of FDC fit autosomal dominant inheritance, but X-linked, autosomal recessive, and mitochondrial forms exist.[168] [183] [184] [185] Clinical variability characterizes virtually all pedigrees; variation in severity, clinical phenotype, and age of onset is typical.

In late 1999, the causes of most of the autosomal dominant forms of FDC were unknown. Mutation of the cardiac actin gene (*ACTC*) causes one uncommon form of FDC.[186] In some families with autosomal dominant disease, a mild proximal skeletal myopathy of type I fibers coexists with cardiac involvement.[187]

In one family, cardiomyopathy developed only in association with pregnancy.[188] Although peripartum cardiomyopathy is a well-recognized, usually sporadic disorder, its occurrence in five women in two generations suggests a hereditary predisposition.

Histological examination of myocardium generally shows nonspecific hypertrophy and fibrosis. By electron microscopy, however, mitochondria are distinctly abnormal, a finding not seen in congestive heart failure due to other causes.[189] Although various mutations of the mitochondrial chromosome can cause dilated cardiomyopathy, including of childhood onset, the inheritance pattern in most cases does not suggest maternal transmission.[185]

Some pedigrees show convincing evidence of X linkage of dilated cardiomyopathy. At least three loci have been identified. In *Barth syndrome,* cardiac involvement is associated with skeletal myopathy, proportionate short stature, and neutropenia. The cause is mutation of the (*TAZ*) gene at Xq28.[189] [190] Mutations of this gene can also cause isolated FDC and noncompaction of the left ventricle.[168] [191]

Many males with *Duchenne* and some with *Becker muscular dystrophy* develop myocardial dysfunction (see Chap. 71) .[192] In the Becker form, right ventricular involvement may be unassociated with left ventricular dysfunction.[193] Deletion of exon 49 of the dystrophin gene predisposes to cardiomyopathy. This pleiotropic feature in a disease that presents as a skeletal myopathy prompted evaluation of the dystrophin locus in pedigrees with apparently isolated cardiomyopathy. Mutations in the 5
end of the dystrophin gene have been found to account for some instances of X-linked dilated cardiomyopathy.[194] [195] Why some dystrophin mutations are selectively expressed in cardiac muscle (and other in brain) is unclear.

Emery-Dreifuss muscular dystrophy (see Chap. 71) is distinguishable clinically from the Duchenne and Becker forms by absence of pseudohypertrophy of skeletal muscle, early involvement of the arms with elbow contractures, and early onset of cardiac conduction abnormalities and atrial dysrhythmia.[192] [196] Autosomal dominant and X-linked recessive forms occur. In the latter, female heterozygotes are also commonly affected, albeit more mildly than males.[197] The disease was mapped to the distal region of Xq28, and a previously unknown gene, called emerin, was found to be mutated.[198] Hearts show replacement of myocardium, especially in the atria, with fat and fibrosis. Even though the conduction system is not primarily affected histologically, sudden death is common in both hemizygous men and heterozygous women; thus, carrier detection can be life saving.

The dominant form of Emery-Dreifuss muscular dystrophy is caused by mutations in the lamin A/C gene.[199] Both emerin and lamin A/C are expressed in the nuclear membrane of skeletal and heart muscle.

An autosomal recessive form of limb-girdle muscular dystrophy with dilated cardiomyopathy has been found to be due to mutations in the gene encoding beta sarcoglycan.[200] In a number of families with severe, adult-onset autosomal dominant skeletal myopathy, cardiac conduction defects, and cardiomyopathy have been due to mutations in the gene encoding the intermediate filament protein, desmin.[200A]

Restrictive Cardiomyopathy

The pathogenesis of the majority of cases of restrictive cardiomyopathy involves infiltration or replacement of the myocardium or both. The causes are varied and can be nongenetic or genetic; the latter are mostly metabolic diseases with secondary effects on the heart and are summarized in Table 56-9; some are reviewed subsequently. One form of restrictive cardiomyopathy that has primary genetic forms among many other causes is endocardial fibroelastosis. Other mutations produce restriction through pericardial constriction. Isolated pedigrees of primary myocardial fibrosis without secondary cause and leading to restrictive hemodynamics are not classifiable.[201] [202]

ENDOCARDIAL FIBROELASTOSIS

(see Chap. 48) . This abnormality is characterized by thickening of the endocardium, which leads to decreased compliance and impaired diastolic function. Primary forms, discussed here, are unassociated with other cardiac anomalies (see Table 56-9) . In infants there is often an indolent course of failure to thrive, tachypnea, and tachycardia, until a precipitant such as an upper respiratory infection leads to rapid cardiac decompensation. Treatment of children with primary endocardial fibroelastosis is ineffective; cardiac transplantation now offers some hope. Autopsy shows enlargement of the left ventricle and perhaps other chambers, no abnormality of lung vessels, and collapse of the left lower lobe. Histopathological study reveals extensive deposition of extracellular matrix, primarily collagen and elastic fibers, in the endocardium.

X-linked recessive inheritance is the most firmly established of the single-gene causes. Some pedigrees show mainly small, contracted cardiac chambers, whereas others have chamber dilatation; both are compatible with the functional pathophysiology described by the term "restrictive." Males are affected earlier and more severely by both forms, and death in infancy is not unusual.[203] The condition must be distinguished from X-linked dilated cardiomyopathy and Barth syndrome (see also earlier on this page).[189] Morphological abnormalities of mitochondria occur on ultrastructural studies of heart and leukocytes. Insufficient longitudinal experience is recorded to know whether females heterozygous for this mutation develop a dilated or restrictive cardiomyopathy later in life.

Several pedigrees suggestive of autosomal recessive inheritance of primary endocardial fibroelastosis were reported before the routine availability of laboratory methods to diagnose metabolic derangements, especially defects in fatty acid catabolism.[204] The occurrence of hydrocephalus, endocardial fibroelastosis, and neonatal cataracts may be due to a single gene mutation but could represent sequelae of a viral infection.[205] Endocardial fibroelastosis can be a prominent finding at autopsy in patients with autosomal dominant dilated cardiomyopathy[206] , whether the endocardial changes are primary, representing yet another mendelian form of this disorder, or whether they are secondary is unclear.

Restrictive cardiomyopathy often occurs with both hemodynamic evidence of impaired diastolic filling and wall thickening; any of the conditions causing pseudohypertrophy of the myocardium can eventually exhibit restrictive pathophysiology. Hemochromatosis and the amyloidoses, both hereditary and acquired forms, are especially likely to present in this manner. Connective tissue replaces myocytes or infiltrates the interstitium in a number of conditions. Fibrosis of the myocardium may cause pseudohypertrophy, but the clinical consequences are more those of restriction. Restrictive pathophysiology often accompanies fibrosis of the myocardium, at least in the early stages. Replacement of myocytes or infiltration of the interstitium by collagen and proteoglycan occurs in various conditions, such as muscular dystrophies and disorders that predispose to ischemia due to coronary artery occlusion, such as diabetes mellitus, hemoglobinopathies associated with sickling, Fabry disease, and the mucopolysaccharidoses. Severe fibrosis may produce considerable thickening of the myocardium, or pseudohypertrophy. Finally, a number of hereditary conditions are associated with endocardial fibroelastosis (Table 56-11) .

CONSTRICTIVE PERICARDITIS

(see also Chap. 50) . Two rare autosomal recessive disorders include fibrous thickening of the pericardium as a manifestation. In both, signs and symptoms of constrictive pericarditis develop insidiously, and treatment by pericardiotomy is life saving. One condition was first described in Finland and given the name *MULIBREY nanism,* a combination of a mnemonic for *muscle, liver, brain,* and *eye* and an archaic word for dwarfism (nanism). Growth failure from an early age is common, and growth does not improve once pericardial constriction is abated. Subsequently, more than a dozen patients, generally with consanguineous parents, have been reported from around the world.[207] The disease locus has been mapped to 17q.[208]

The *arthropathy-camptodactyly syndrome* previously had been reported because of the skeletal and rheumatological manifestations before pericardial effusion and fibrous thickening of the pericardium were recognized as manifestations.[209] The disease locus was mapped in consanguineous kindreds by homozygosity by descent to 1q25-q31, and mutations occur in the gene, *CACP,* that encodes a secreted proteoglycan.[210] [211]

TABLE 56-11 -- DISORDERS ASSOCIATED WITH RESTRICTIVE CARDIOMYOPATHY

	OMIM NO.*
Primary Endocardial Fibroelastosis	
Familial endocardial fibroelastosis	226000, 305300
Faciocardiorenal syndrome	227280
Secondary Endocardial Fibroelastosis	
As a Relatively Common Manifestation	
Maternal lupus erythematosus	
Pseudoxanthoma elasticum	177850, 264800

Systemic carnitine deficiency	212140
Trisomy 18

Cardiomyopathies Secondary to Other Causes

INBORN ERRORS OF METABOLISM.

These can affect the left ventricle by various mechanisms (Table 56-12) and produce diverse anatomical, histological, and functional disturbances. The most common anatomical result is an apparent hypertrophic cardiomyopathy, which is actually *pseudohypertrophic* because the thickened walls are not due to myocardial cell hypertrophy but to cellular or interstitial infiltration by metabolites. Abnormalities of both systolic and diastolic function result, outflow obstruction may occur, and in some cases the hemodynamic characteristics resemble a restrictive cardiomyopathy. The offending metabolite may be an incompletely degraded macromolecule such as glycogen (*glycogen storage disorder II* [Pompe disease] and *glycogen storage disorder III*), proteoglycan and glycosaminoglycan (*mucopolysaccharidoses I, III, IV, VI,* and *VII*), sphingolipid (*Fabry disease, Tay-Sachs disease, Farber disease, Refsum disease,* and *Gaucher disease*), glycoprotein (*fucosidosis* and *mannosidosis*), and amyloid (*familial amyloidoses I* and *III*) or a small molecule such as iron in *hemochromatosis.* Some of these disorders are discussed later. True myocardial hypertrophy occurs as a part of mendelian syndromes, such as *Noonan syndrome, von Recklinghausen neurofibromatosis*,[212] and *leopard syndrome*,[213] [214] and monogenic errors of metabolism, notably those producing *hyperthyroidism* and *pheochromocytoma.* Any of the mendelian disorders that cause hypertension may, over time, produce true myocardial hypertrophy.

Dilated cardiomyopathy often results from inborn errors of energy production, especially fatty acid metabolism. Various disorders associated with *carnitine deficiency, mitochondrial* and *peroxisomal dysfunction,* and *muscle dysfunction* can present with symptoms of congestive heart failure or dysrhythmia.

PRIMARY DISORDERS OF RHYTHM AND CONDUCTION

Virtually every dysrhythmia and conduction abnormality has been reported to occur in relatives.[215] [216] For example, *familial disturbance of conduction* occurs, without evident cause, at the sinus node,[217] [218] atrioventricular node,[219] [220] and bundle branches.[221] [222] However, understanding the genetics of cardiac electrophysiology has been hampered by several characteristics of this extensive literature: Most families have been small, so that mode of inheritance, or even whether the inheritance is mendelian, is uncertain; many of the families show a mixture of different defects, partly because the disease is progressive[223] [224] ; and some specific conduction defects are associated with hereditary myocardial diseases, such as familial cardiomyopathy,[168] [225] atrial cardiomyopathy,[226] and familial amyloidosis.[227] As noted earlier, there seems to be genetic control of normal electrical conduction, so it would not be surprising to find mutations in single genes that produced clinically important disturbance.

Several important causes of complete heart block, although not mendelian, nonetheless involve genetic factors. The association between rheumatic diseases and heart block was clearly established when the offspring of mothers with acquired disorders of connective tissue, especially lupus erythematosus, were found to have complete heart block.[228] [229] [230] Many examples of "autosomal recessive" congenital heart block represent this familial but nonmendelian etiology. The risk is not related to severity of the maternal disease but is highest in children of women with antibodies to ribonucleoprotein (anti-Ro[SS-A])[231] and at least one allele for HLA-DR3.[232] Thus, it may be the maternal genotype that determines susceptibility to inflammation of the fetal heart at vulnerable periods, such as gestational weeks 3 to 4, when the atrioventricular node is forming. Also, genetic susceptibility to inflammation of the atrioventricular node of patients themselves is suggested by the relatively high association of HLA-B27 in adults requiring permanent pacemakers[233] ; not all of these patients have overt evidence of HLA-B27-associated rheumatic diseases.

Familial dysrhythmia is also not uncommon.[215] Nodal rhythm,[234] ventricular irritability, [235] and tachydysrhythmia associated with accessory atrioventricular pathways[236] [237] have been reported in families. Familial atrial fibrillation has been genetically mapped to 10q22-q24.[238] In one family, three generations were affected by a syndrome of ventricular extrasystoles and tachydysrhythmias with recurrent syncope, hypoplasia of the distal toes, and hypoplasia of the mandible (Robin sequence).[239]

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA.

Hereditary cardiomyopathies are another cause of familial dysrhythmia, and a notable example is arrhythmogenic right ventricular dysplasia (ARVD), an autosomal dominant condition with variable expression[240] [241] (see also Chap. 25) . Although ARVD is uncommon, the familial form shows clusters of high incidence (0.4 percent) in some regions of Italy and is an underappreciated cause of life-threatening dysrhythmia.[242] The right ventricle is involved primarily in most cases, with thinning and replacement of myocardium by fat and fibrosis.[243] [243A] Dysrhythmia, usually ventricular but occasionally supraventricular, may precede signs of right ventricular dysfunction. About one-third of cases are familial, generally in an autosomal dominant pattern. At least six loci can cause ARVD (see Table 56-2) .[244] [244A] Whether the pathogenesis is homogeneous or not and whether true dysplasia, degeneration (due to a metabolic defect or muscular dystrophy), or inflammation has the leading role are unclear.

LONG QT SYNDROME

(see Chap. 26) . Familial syncope and sudden death have long been associated with ventricular dysrhythmia, but a distinct syndrome was not recognized until Ward[245] and Romano,[246] working independently three decades ago, reported the characteristic prolonged QT interval. Subsequent investigations of numerous families have clearly established that the defect in repolarization is inherited as an *autosomal dominant.* Although a long QT_c is consistently present, other abnormalities of conduction also occur, although they may not be evident on the resting electrocardiogram.[247] Long QT syndrome is generally unassociated with systemic abnormalities, but three patients with a negative family history for long QT had syndactyly of multiple fingers and toes.[248]

TABLE 56-12 -- MENDELIAN ERRORS OF METABOLISM WITH MANIFESTATIONS IN THE CARDIOVASCULAR SYSTEM

DISORDER	EPONYM OR COMMON NAME	OMIM NO.*	PATHOGENESIS	CARDIOVASCULAR INVOLVEMENT	BIOCHEMICAL DEFECT	GENE LOCUS	ANIMAL MODEL
Aminoacidopathies							

Alkaptonuria	Ochronosis	203500	Deposition of homogentisic acid in connective tissue	AS; atherosclerosis			
Cystinosis, nephropathic type		219800	Lysosomal storage	Hypertension from renal failure, vascular wall thickening	?	?	
Homocystinuria		236200	Unknown	Early CAD; venous thrombosis; pulmonary embolism	Cystathionine-beta-synthase	CBS	
Oxalosis I	Hyperoxaluria	259900	Vascular and tissue accumulation of oxalate	Conduction defect; vascular occlusions; Raynaud's phenomenon	Peroxisomal alanine: glyoxylate aminotransferase	AGT	
Defects in Fatty Acid Metabolism							
Carnitine transport defect	Primary carnitine deficiency	212140	Lipid myopathy; defective energy generation	DCM: ECF	?	?	Syrian hamster
MCAD deficiency		201450	Lipid myopathy; defective energy generation	DCM	Medium-chain acyl-CoA dehydrogenase	ACADM	
LCAD deficiency		201460	Lipid myopathy; defective energy generation	DCM	Long-chain acyl-CoA dehydrogenase	ACADL	
Glycogen Storage Disorders							
GSD I	Pompe	252300	Lysosomal storage	Pseudohypertrophic CM; short PR interval; ECF	alpha-1,4-glucosidase	GAA	Canine and bovine
GSD II	Adult acid maltase deficiency	232300	Lysosomal storage	Primarily skeletal muscle; respiratory insufficiency; cor pulmonale	alpha-1,4-glucosidase		
GSD III	Forbes; debrancher deficiency	232400	Intracellular glycogen accumulation fibrosis	Pseudohypertrophic CM	Amylo-1,6-glucosidase		
Phosphorylase kinase deficiency	GSD of the heart			DCM	Phosphorylase kinase		
Glycoproteinoses							
Fucosidosis, severe		230000	Lysosomal storage	Myocardial thickening	alpha-Fucosidase	FUCA1	
Fucosidosis, mild		230000	Lysosomal storage	Angiokeratoma	alpha-Fucosidase	FUCA1	
Mannosidosis		248500	Lysosomal storage	Myocardial thickening; valvular thickening; conduction disturbance	alpha-Mannosidase	MANB

Gene symbol; for chromosomal locus see Table 56-2 .

Naturally occurring mutants; does not include transgenic and knockout rodent models.

Long QT syndrome is genetically heterogeneous, and mutations of at least 5 loci can produce similar disorders (see Table 56-2) . Each gene identified encodes a protein involved with a cation channel.[249] Most mutations in individuals with an autosomal dominant form of long QT occur in potassium channel, rather than sodium channel gene.[250] Long QT syndrome should be suspected as a cause of sudden death, especially in young people without other evident cardiovascular risk factors, and especially when the death is associated with exercise or fright.[251] A positive family history of sudden death would obviously heighten the suspicion of long QT, but in many families penetrance is reduced.[252] Use of genotype to determine unequivocally who is heterozygous for the mutation has permitted assessment of both penetrance and the reliability of electrocardiographic criteria for diagnosis.[253] Not unexpectedly, the criterion of a corrected QT interval greater than 0.44 second is good, but it is less than 90 percent sensitive and specific. Treatment with beta-adrenergic blockade or an automatic implanted defibrillator is effective. Individuals heterozygous for the mutant gene should be identified through a detailed family history, clinical assessment, and, if necessary, DNA testing, and counseled appropriately. In some instances, the nature of the mutation has prognostic implications and can be used to guide the aggressiveness of therapy.[254] [255] However, given the extensive intergenic and intragenic heterogeneity, molecular testing, especially of a person with no family history, is not warranted, given the current technology.[176]

The association of familial syncope, sudden death, and congenital deafness was codified by Jervell and Lange-Nielsen in 1957,[256] although as with most eponymous syndromes, reports of affected individuals occurred previously. As would be expected for a rare autosomal recessive condition, the parents of affected children are more likely than average to be consanguineous. The frequency of a long QT_c among deaf children is about 1 per 100, so routine electrocardiographic screening of anyone with congenital deafness is warranted. Fright and rage clearly precipitate syncope and sudden death.

Patients with this disorder are homozygous or compound heterozygotes for mutations of several of the same cation-channel genes that cause dominant long QT syndrome.[257]

DISORDERS OF CONNECTIVE TISSUE

The two broad classes of disorders of connective tissue are those due to mutations in single genes that determine or somehow affect components of the extracellular matrix and those due to extrinsic factors affecting the extracellular matrix, such as rheumatoid arthritis and systemic lupus erythematosus. The former category includes many disorders that affect the cardiovascular system. Susceptibility to so-called acquired disorders of connective tissue is, in part, determined by genes, and this specific aspect is reviewed.

Mendelian Disorders of the Extracellular Matrix

Close to 200 distinct phenotypes now compose this category, which was first defined less than four decades ago with fewer than 10 disorders.[258] Several reviews and textbooks describe the phenotypes, genetics, and causes of many of the conditions (Table 56-13) .[14] [259] [260] [261] [262]

Marfan Syndrome

This *autosomal dominant* disorder is relatively frequent (
1 per 10,000), occurs in all races and ethnic groups, and is often not diagnosed during life.[262] In light of the classical

TABLE 56-13 -- CARDIOVASCULAR MANIFESTATIONS OF HERITABLE DISORDERS OF CONNECTIVE TISSUE

DISORDER	OMIM NO.*	CARDIOVASCULAR MANIFESTATIONS

*Data from Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

phenotype, failure to diagnose Marfan syndrome may seem surprising; however, marked clinical variability, age dependence of all of the manifestations, and a high (30 percent) rate of new mutation all conspire to make detection of mildly affected, young, sporadic patients challenging.[262A] Even with the discovery of the genetic and biochemical bases of the condition, the diagnosis of Marfan syndrome outside of families with the classical phenotype remains entirely clinical. Current criteria (Table 56-14) depend on the manifestations in the cardinal organ systems--the eye, the skeleton, the heart, and the aorta--and other systems, as well as the family history[141] [176] (Fig. 56-7) . The presence of manifestations more specific for Marfan syndrome, such as aortic dilatation, aortic dissection in a nonhypertensive young person, ectopia lentis, and dural ectasia, clearly is more important diagnostically than features common in other connective tissue disorders and in the general population, such as scoliosis, joint hypermobility, myopia, and MVP.

The most common cardiovascular features are MVP and dilatation of the sinuses of Valsalva.[263] [264] Associated clinical problems of mitral regurgitation, aortic regurgitation, and aortic dissection account, if untreated, for most of the early mortality that results in an average age of death in the fourth and fifth decades of life.[265] Children tend to be more severely affected by mitral valve disease,[266] [267] whereas aortic problems are progressive and more likely in adolescence and beyond.

MITRAL VALVE INVOLVEMENT.

MVP (see also Chap. 46) is age dependent and more common in women with Marfan syndrome. The incidence reaches 60 to 80 percent when patients are studied by two-dimensional echocardiography,[142] and the valve leaflets generally have an elongated and redundant appearance. Progression of severity, as judged by appearance or worsening of mitral regurgitation by clinical and echocardiographic criteria, occurs in at least one-quarter of patients,[268] a much higher rate than in MVP found in the general population.[133] The mitral annulus dilates

TABLE 56-14 -- DIAGNOSTIC CRITERIA FOR MARFAN SYNDROME PHENOTYPIC MANIFESTATIONS*

Skeleton

Joint hypermobility, tall stature, pectus excavatum, reduced thoracic kyphosis, scoliosis, arachnodactyly, dolichostenomelia, pectus carinatum, erosion of the lumbosacral vertebrae from dural ectasia

Eye

Myopia, retinal detachment, elongated globe, ectopia lentis

Cardiovascular

Mitral valve prolapse, endocarditis, dysrhythmia, dilated mitral annulus, mitral regurgitation, tricuspid valve prolapse, aortic regurgitation, aortic dissection , dilatation of the aortic root

Pulmonary

Apical blebs, spontaneous pneumothorax

Skin and Integument

Inguinal hernias, incisional hernias, striae atrophicae

Central Nervous System

Attention deficit disorder, hyperactivity, verbal-performance discrepancy, dural ectasia , anterior pelvic meningocele

If the family history is positive for a close relative clearly affected by Marfan syndrome, to make the diagnosis in the patient, a major criterion should be present as well as findings in one other system.

If the family history is negative or unknown, to make the diagnosis, the patient should have one major criterion and manifestations in two other systems.

*Manifestations are listed within each organ system in increasing specificity for Marfan syndrome, although none is completely specific; those indicated by are the most specific and constitute major criteria.[141]

and contributes to the regurgitation, as do stretching and occasional rupture of chordae. About 10 percent of patients with marked prolapse have calcification of the mitral annulus. Standard treatment for chronic mitral regurgitation is indicated, but coexistent aortic root dilatation usually requires that increasing inotropy be avoided. When mitral regurgitation becomes severe enough to warrant surgical intervention, two considerations must be added to the balance: (1) Repair of the mitral apparatus is often successful and durable in Marfan syndrome.[269] [270] Repair is less easily accomplished when the cusps are extremely redundant, there is marked chordal damage, or the annulus is heavily calcified. (2) The aorta may be enlarged enough to permit concomitant repair. In Marfan syndrome, as in virtually all of the heritable disorders of connective tissue, there is an increased susceptibility to dehiscence of prosthetic mitral valves, regardless of the care taken in placing them.

AORTIC ROOT INVOLVEMENT (See also Chap. 40) .

The sinuses of Valsalva are often dilated at birth, and the rate of progression varies widely among patients in general and also among relatives (Fig. 56-8) . Thus, predicting long-term risks of developing aortic regurgitation (which clearly is positively associated with aortic root diameter[271]), suffering aortic dissection (which is less clearly associated with diameter), or requiring aortic surgery is fraught with uncertainty. Transthoracic echocardiography is sufficient for detecting and monitoring changes in diameter, because in the absence of dissection, dilatation is limited to the proximal ascending aorta, and the rate of change is slow, measured in millimeters per year. Rare exceptions of principal dilatation of the thoracic aorta can be monitored with transesophageal echocardiography or magnetic resonance imaging. Patients with dilatation less than 1.5 times the mean diameter predicted for their body size[272] can be observed annually; as the diameter increases, more frequent evaluation is necessary. Aortic regurgitation often appears in adults at a diameter of 50 mm but may be absent at diameters of more than 60 mm.[271] [272] The risk of dissection increases with the size of the aorta and fortunately occurs infrequently below a diameter of 55 mm in the adult. Many physicians have adopted the criterion of a 50 to 55 mm maximal aortic root dimension for performing elective surgery in adult patients with Marfan syndrome, regardless of the severity of the aortic regurgitation,[270] although patients with a family history of aortic dissection should have surgery at the lower end of this range. The perioperative results of both elective and emergency repair of the aortic

root have been excellent and a marked improvement from the pre-composite graft era that ended in the mid 1970s. Long-term results of operation are limited by the problems of endocarditis and anticoagulation, common to all prosthetic valves, but in the absence of chronic aortic dissection appear favorable for patients with Marfan syndrome.[270] [273] [274] [275]

Several approaches to repairing the dilated or dissected aortic root while preserving the native aortic valve have been developed.[276] Both short- and now long-term follow-up of patients with Marfan syndrome who have undergone this repair have been quite favorable.[270] [276A] The operation must be performed before the root is widely dilated and the valve commisures and cusps markedly stretched. This approach is increasingly being taken in all patients when the maximal root dimension reaches 50 mm, and it is an especially suitable procedure for women of childbearing age who want to consider pregnancy, as well as for all others in whom anticoagulation is contraindicated.

THORACIC ABNORMALITIES.

Severe *pectus excavatum* may complicate cardiovascular surgery by hampering exposure of the heart by median sternotomy. For elective cardiovascular surgery, repair of the sternal deformity some months in advance permits sufficient healing of the costochondral junctions that a stable and functionally and cosmetically improved thoracic cage will facilitate further surgery and postoperative recovery.[277] Simultaneous repair of cardiac and sternal defects, although possible, is a long procedure, and intraoperative bleeding from bone can be considerable because of the anticoagulation associated with cardiopulmonary bypass.

AORTIC DISSECTION

(see also Chap. 40) . This complication usually begins just above the coronary ostia (type A in the Stanford scheme) and extends the entire length of the aorta (type I in DeBakey scheme). About 10 percent of dissections begin distal to the left subclavian (type B or III), but rarely is dissection limited to the abdominal aorta. Angiography, magnetic resonance imaging, and transesophageal echocardiography all have a role in the diagnosis of acute dissection in Marfan syndrome, with the capabilities and experience of the medical center and the stability of the patient important determinants of the approach. Because many acute dissections of the ascending aorta in Marfan syndrome have a stuttering course that culminates in death due to rupture or hemopericardium, rapid transfer to a facility prepared to perform immediate repair is essential.

Not all acute dissections in Marfan syndrome involve severe, tearing chest pain that radiates to the back; indeed, some extensive dissections have been occult. This experience reinforces the need for a high index of suspicion by physicians whenever a tall, nearsighted young person with a thoracic cage deformity arrives at an emergency department with vague complaints of lightheadedness, chest or abdominal discomfort, or a murmur of aortic regurgitation. Similarly, patients known to have Marfan syndrome and their close relatives need to be educated about the signs and symptoms of aortic dissection. In general, the management of acute and chronic dissection in Marfan syndrome follows standard practice, with several departures. First, all dissections of the ascending aorta should be repaired promptly, preferably with a composite graft. Second, regular evaluation with magnetic resonance imaging is important, as the diameter of any region of dissected aorta is likely to expand over time.[278] [279] Third, reduction of systolic blood pressure and administration of negative-inotropic doses of beta-adrenergic blockers should be even more strictly adhered to than in dissections without a connective tissue abnormality. In most instances, any region of the aorta should be repaired when complications of further dissection, branch vessel occlusion, or dilatation beyond about 50 mm occur. A staged approach to total replacement of the Marfan aorta is now both feasible and successful.[280]

DYSRHYTHMIAS.

Some patients develop serious ventricular or supraventricular dysrhythmia. The latter often accompanies chronic mitral regurgitation, but the former may be of high grade and difficult to suppress when only MVP is present. Some patients have the syndrome of autonomic dysfunction, atypical chest pain, and palpitations seen in some patients with MVP unassociated with a flagrant connective tissue abnormality.

MANAGEMENT.

Routine cardiological management of Marfan syndrome is multifaceted: regular clinical and echocardiographic examinations; routine endocarditis prophylaxis for dental and other procedures; restriction of activity from heavy weightlifting, contact sports, and any exertion at maximal capacity; and long-term beta-adrenergic blockade form the basic approach, with individual variation often appropriate. Support for the role of beta blockade comes from several prospective studies that show a reduction in the rate of aortic dilatation and the risk of aortic dissection in patients treated with negatively inotropic doses of propranolol or atenolol.[281] [282] However, short-term administration of propranolol to patients with large sinus of

---

2003

Valsalva aneurysms, although reducing heart rate and peak systolic pressure, did not improve the impedance characteristics recorded in the ascending aorta. However, in the presence of studies that emphasize the importance of central pulse pressure to aortic dilation,[284] use of beta blockade seems warranted.[283]

A woman with Marfan syndrome has two concerns about pregnancy (see also Chap. 65) . The first is the 50:50 risk that any child will inherit the condition; prenatal diagnosis can currently be attempted in selected situations. The second is the risk of dissection that the hemodynamic stresses of pregnancy place on the aorta. Several dozen case reports attest to the heightened incidence of dissection during the third trimester, parturition, and the first month post partum.[285] [286] However, in the majority of instances, serious aortic dilatation was present. Prospective evaluation of 21 women through 45 pregnancies confirmed our earlier recommendation that the cardiovascular risks are relatively low if the aortic diameter does not exceed 40 mm and cardiac function is not compromised[286] , a view shared by others.[287]

ETIOLOGY.

Marfan syndrome is caused by mutations in the gene that encodes fibrillin-1 (*FBN1*), the major constituent of microfibrils, components of the extracellular matrix that are widely dispersed and perform numerous functions.[262] [288] [289]

Microfibrils and tropoelastin form elastic fibers. Fragmentation and disorganization of elastic fibers in the aortic media have long been a histological marker (inappropriately called cystic medial necrosis) of Marfan syndrome,[263] although similar microscopic pathology occurs in familial aortic aneurysms and aging aortas of the normal population. A defect in microfibrils explains all of the pleiotropic manifestations of Marfan syndrome.[262] [290]

More than 100 distinct mutations in *FBN1,* the gene that encodes fibrillin-1, have been found in different families, and only a few have occurred, by chance, in unrelated patients.[290] [291] Because *FBN1* is such a large gene (
 9000 nucleotides in the mRNA), finding a mutation is still not a simple matter.[176] [292] Once the mutation is identified, diagnosis in that family is straightforward. In families with several alive and cooperative affected members, linkage analysis can be used for presymptomatic and prenatal diagnosis. The use of molecular testing is confounded, however, by the discovery that autosomal dominant ectopia lentis, familial tall stature, MASS phenotype, and familial aortic aneurysm all are phenotypes found to be due to mutations in *FBN1* and are exactly the conditions clinicians are interested in excluding in their patients of questionable diagnosis.[290]

Mutations in *FBN1* have distinct effects on microfibril formation: Some affect synthesis, others secretion, and others incorporation of fibrillin-1 monomers into the extracellular matrix.[293] [294]

MITRAL VALVE PROLAPSE AND THE MASS PHENOTYPE.

This heterogeneous group of conditions, described earlier (see p. 1993) likely contains large numbers of patients and families who have a defect of the extracellular matrix underlying the phenotypes. Some but not all have mutations in *FBN1.*[262] [290]

Ehlers-Danlos Syndrome

This group of heterogeneous conditions is linked by variable involvement of the skin and the joints, with hyperelasticity and fragility of the former occurring with hypermobility of the latter[261] [295] (Fig. 56-9) . Mitral valve prolapse is clearly increased in frequency in most of the clinical types,[296] but aortic root dilatation is an

uncommon finding.

The most serious cardiovascular problems occur in the *vascular form of Ehlers-Danlos syndrome* with spontaneous rupture of large- and medium-caliber arteries.[296A] Various defects of type III collagen are the cause of the phenotype in virtually all patients studied.[297] Analysis of collagen production by cultured skin fibroblasts should be

Figure 56-9 Legs of a patient with Ehlers-Danlos syndrome type IV who died of rupture of the subclavian artery. Note the mild joint hypermobility and the striking dermal abnormalities--elastosis perforans serpiginosa and thin, atrophic scars over areas of recurrent trauma.

used to confirm the diagnosis.[14] True aneurysms rarely form; rather, a rupture without dissection usually occurs as a catastrophic event. Most prone are the abdominal aorta and its branches, the great vessels of the aortic arch, and the large arteries of the limbs. False aneurysms and fistulas[298] may be one result in those patients who do not die of the initial rupture. Vascular surgery is difficult, as the normal-appearing vessels around the rent fall to hold sutures. As a consequence, elective surgery to repair vascular anomalies, such as false aneurysms, that are causing no immediate problem is contraindicated in most cases. The vascular form of Ehlers-Danlos syndrome is often sporadic but, when familial, is usually autosomal dominant.[298A] Prenatal diagnosis is possible by examining collagen production in amniocytes. However, pregnancy is particularly hazardous to women with this condition because of vascular rupture, although some mutations may not be as dangerous.[297] [299]

Pseudoxanthoma Elasticum (PXE)

This is a clinically variable and genetically heterogeneous disorder of unknown cause. Histopathological examination of affected tissues shows fragmentation and calcification of elastic fibers. The skin, the eyes, the gastrointestinal system, and the cardiovascular system are the organs most severely affected.[261] [300] The skin shows highly characteristic raised yellowish papules (pseudoxanthoma) overlying areas of flexural stress, such as the neck, cubital and popliteal fossae, and groin (Fig. 56-10) . Breaks in the elastic lamella, Bruch membrane of the choroid, produce the funduscopic finding of angloid streaks. Gastrointestinal hemorrhage is common and potentially fatal; mucosal arterioles bleed, and because the calcified elastic fibers prevent effective vessel retraction, hemostasis is difficult. Selective arterial embolization was life saving in one instance.[301] The heart is affected in a number of ways. Endocardial fibroelastosis is common, but because primarily the atria are involved, a restrictive cardiomyopathy is uncommon. One patient with marked endocardial fibroelastosis was helped by resection of calcified elastic bands within the left ventricle.[306] Mitral valve prolapse may be increased in frequency[302] [303] but is rarely a clinical problem. Coronary artery disease with myocardial ischemia and infarction is a common cause of early death.[304] [305]

Elastic and muscular arteries, including the coronaries, develop a type of arteriosclerosis similar to Monckeberg; progressive luminal narrowing occurs and can produce complete occlusion. This is initially most evident at the radial and ulnar arteries, where absence of pulses

Figure 56-10 Skin of a young man with pseudoxanthoma elasticum. The neck is a typical location to notice the raised, yellowish papules from which the name of the condition derives.

and a positive Allen test result are noted early in the course.[304] Because narrowing progresses slowly, collaterals form, and peripheral ischemia is a late complication. Because the arterial stenoses tend to be diffuse, bypassing them often involves extensive surgery. Because of a positive association between phenotypic severity and dietary calcium intake, patients can be advised to restrict consumption of dairy products and to avoid calcium supplements.[307] Hypertension and all risk factors for atherosclerosis should be aggressively controlled.

Through linkage analysis, both the recessive and dominant forms of PXE have been mapped to the same region of chromosome 16.[308]

Genetic Susceptibility to Acquired Disorders of Connective Tissue

Genetic factors are clearly implicated in the susceptibility to many of the rheumatic disorders and to specific complications of specific conditions.[233] The cardiovascular manifestations of these disorders are particularly interesting in this regard. For example, study of HLA-DR antigen frequencies suggests that immune-response factors are involved in the pathogenesis of chronic rheumatic heart disease in blacks.[309]

INBORN ERRORS OF METABOLISM THAT AFFECT THE CARDIOVASCULAR SYSTEM

Hundreds of biochemical defects that affect human metabolism have direct or secondary impact on the cardiovascular system (see Table 56-12) . Several examples are reviewed, selected for their relevance to clinical practice or their instructive lessons about pathophysiology.

Aminoacidopathies

Inborn errors of amino acid metabolism result in the accumulation of precursors and a deficit of end products, either or both of which can be detrimental.

Alkaptonuria

An intermediate of tyrosine catabolism polymerizes to homogentisic acid, which readily accumulates in the extracellular matrix.[310] Over many years, connective tissue of cartilage, heart valves, and arteries becomes increasingly abnormal. Aortic stenosis and arteriosclerosis are the cardiological sequelae.

Homocystinuria

This condition is caused by a deficiency of cystathionine beta-synthase; the pathogenesis of the pleiotropic manifestations is largely unknown.[13] [311] [312] Perhaps the amino acid sulfhydryl groups bind to collagen, fibrillin, and other macromolecules and interfere with cross-linking. The clinical features, once confused with Marfan syndrome, include tall stature, skeletal deformity, ectopia lentis, mental retardation, psychiatric disturbances, and a predilection for venous and arterial thromboses. Those patients with mutations that render the enzyme activity able to be increased by pharmacological doses of pyridoxine are less severely affected; early treatment can prevent most aspects of the phenotype.[313] [313A] Patients unresponsive to pyridoxine can be helped by a low-protein diet to reduce intake of methionine and by oral betaine, a co-factor essential for remethylation of homocysteine.

Myocardial infarction, pulmonary embolism, and stroke are the most common causes of death. The pathogenesis of the vascular complications was once thought to involve abnormal platelet function, but platelet survival in untreated patients is normal.[314] Growing evidence supports a susceptibility of heterozygotes, who have none of the external phenotype of the disease, to atherosclerosis.[315] [316] [317] Various actions of homocysteine on endothelial receptors, stimulation of smooth muscle growth, and production of extracellular matrix components are being explored for clinical relevance.[318] [319] Current therapeutic approaches are focused on maintaining physiological levels of the co-factors involved in metabolism of sulfurated amino acids--folate and vitamins B_6 and B_{12} .[320]

Disorders of Fatty Acid Metabolism

Although most organs can metabolize fatty acids when faced with hypoglycemia, only the heart depends on fatty acids as the primary source of energy generation. Thus, it is not surprising that virtually all genetic defects in fatty acid metabolism, including generalized defects in mitochondria and peroxisomes, are associated with myocardial dysfunction. Other substrates--glucose, lactate, and oxaloacetate--also generate energy in myocardial cells by entry into mitochondria and the tricarboxylic acid (Krebs) cycle. Thus, defects in conversion of pyruvate to acetyl coenzyme A and in any point along the tricarboxylic acid cycle and the respiratory chain have a major impact on myocardial energy generation. Quite likely, some sporadic and familial instances of idiopathic cardiomyopathy may represent undiagnosed or undefined metabolic disorders.

CARNITINE DEFICIENCIES.

Carnitine is a required co-factor for entry of long-chain fatty acids into mitochondria and is both synthesized endogenously and available from dietary sources.[321]

Deficiency of carnitine effectively blocks metabolism of long-chain fatty acids throughout the body and hepatic metabolism of ketones. Because of their relative dependence on fatty acids, muscle cells, including myocytes, suffer out of proportion to other tissue when carnitine levels are low for any reason. Cytoplasmic inclusions of lipid are characteristic findings in myocytes and hepatocytes.

Several mendelian defects produce primary or secondary carnitine deficiency. An autosomal recessive defect in carnitine palmitoyltransferase I leads to increased plasma carnitine and a skeletal muscle myopathy with little effect on the heart.[321] So-called systemic carnitine deficiency can have various causes: primary deficiency of intake, synthesis, or function, and secondary deficiency, the majority now known to be a result of defects in fatty acid metabolism. The latter group of conditions usually does not respond to pharmacological doses of carnitine.[321] [323]

Primary carnitine deficiency usually presents in infancy with hypoglycemia, coma, and congestive heart failure due to dilated cardiomyopathy. In the few cases reported, problems largely resolve with carnitine treatment; they can be prevented from recurring by oral supplementation with L-carnitine. [323] [324] Primary systemic carnitine deficiency is due to a defect in carnitine transport, which leads to excessive urinary loss and which affects muscle but not liver.[322] Thus, muscle cells still may be relatively deficient in carnitine, despite supplementation, and long-term prognosis is uncertain.

DEFECTS OF BETA-OXIDATION.

At least 20 steps are involved when a molecule of free fatty acid leaves the plasma, enters beta-oxidation in the mitochondrion, and generates electrons and acetyl-CoA[321] At each turn of the oxidation spiral, two carbons are removed from the fatty

acid, and the enzymes involved in this step are specific for substrates of only certain chain length: long-chain, medium-chain, and short-chain acetyl-CoA dehydrogenases, or LCAD, MCAD, and SCAD. Thus far, patients with defects in nine of the steps have been characterized.

Patients homozygous for these generally autosomal recessive disorders develop episodic hypoketotic hypoglycemia, usually associated with fasting or intercurrent illness. Deficiency of MCAD is the most common cause and occurs in about 1 of every 7000 newborns in the United States. Hypoglycemic crises can rapidly progress to coma and death, and 50 to 60 percent of affected infants die in the first 2 years of life.[325] Because infants between episodes or before a fatal crisis appear normal, MCAD deficiency accounts for a proportion of so-called sudden infant deaths.[326] Histopathological examination shows microvesicular accumulation of fat in cardiac and skeletal muscle. One mutation in MCAD (A985G) accounts for a large percentage of all alleles that predispose to this lethal disorder, and various approaches to newborn screening are being investigated.

MITOCHONDRIAL MYOPATHIES.

All of the enzymes of fatty acid oxidation are encoded by genes located on nuclear chromosomes, but the components of the electron transport chain are encoded by both nuclear and mitochondrial genes. Several syndromes involving various types of myopathies have been shown to be due to mutations in the mitochondrial chromosome.[10] [11] The *Kearns-Sayre* syndrome includes pigmentary degeneration of the retina, ophthalmoplegia, and cardiomyopathy as its most prominent manifestations; all of the affected tissues rely nearly exclusively on oxidative phosphorylation for energy generation.

The *MELAS syndrome* (*m*yopathy, *e*ncephalopathy, *l*actic *a*cidosis, and *s*trokelike episodes) is due to mutations in mitochondrial transfer RNA genes.[328] [329] In addition to the features that define the acronym, hypertrophic cardiomyopathy and diffuse coronary angiopathy are common. Various other mtDNA mutations are associated with hypertrophic or dilated cardiomyopathy.[185] [330]

Variations in both the actual mutations and the fraction of abnormal mitochondria in the cells of the different organs (heteroplasmy) account for many of the clinical differences in phenotype, severity, and age of onset among patients with this disorder. Inheritance is maternal for patients with mitochondrial mutations; apparent autosomal recessive and dominant inheritance may indicate that mutations of nuclear genes can impair electron transport similarly to mitochondrial mutations. Some patients have been treated with moderate success over the short term with coenzyme Q[331] and with cardiac transplantation in one case.[332]

Glycogenoses

Three of the glycogen storage disorders affect cardiac muscle.

GLYCOGEN STORAGE DISEASE II.

This autosomal recessive condition is due to deficiency of the lysosomal enzyme alpha-1,4-glucosidase and results in the lysosomal accumulation of glycogen in most tissues. Several allelic variants occur.[333] The condition with infantile onset is called *Pompe disease,* and cardiac involvement is profound.[334] Infants with Pompe disease appear well initially but soon fail to thrive and develop hypotonia, tachypnea, and tachycardia; the disease progresses during the first year to irreversible congestive heart failure and death due to pneumonia or cardiopulmonary failure. Auscultation typically reveals no murmurs until late in the course when obstruction develops, and hypoglycemia does not appear because the nonlysosomal pathway of glycogen catabolism is intact. The diagnosis is suggested by massive cardiomegaly on examination and chest radiography and by characteristic echocardiographic abnormalities of a short PR interval and markedly increased QRS voltage.[335] Echocardiography shows tremendously thickened (pseudohypertrophic) ventricles, and Doppler interrogation or catheterization may reveal subaortic and subpulmonic pressure gradients characteristic of obstructive cardiomyopathy.

Reduced diastolic function of a restrictive cardiomyopathy develops eventually, and endocardial fibroelastosis is common.[335] [336] With these findings, the diagnosis of Pompe disease is virtually certain, but it can be confirmed by analysis of alpha-1,4-glucosidase activity in cultured fibroblasts. Prenatal diagnosis is possible by enzymatic assay of amniocytes. Treatment is supportive, but cardiac transplantation could correct the cardiac problem; unfortunately, involvement of other organs, including the lungs, liver, and skeletal muscle, might eventually prove just as serious as the cardiomyopathy. Bone marrow transplantation might be a solution if performed early in the course. An animal model of alpha-1,4-glucosidase deficiency exists in cattle and develops cardiac pathology typical of human Pompe disease.[337]

Cardiomyopathy may develop in the juvenile-onset form of alpha-1,4-glucosidase deficiency,[338] but it is not invariable because of allelic heterogeneity. In one sibship without cardiac involvement, three brothers had extensive hepatic, skeletal muscle, and arterial smooth muscle accumulation of glycogen, and each died of rupture of a basilar artery aneurysm.[339] The adult-onset form usually presents with insidious onset of respiratory insufficiency, and clinically important cardiac disease is rare.[340]

GLYCOGEN STORAGE DISEASE III.

The striking clinical variability in phenotype associated with deficiency of alpha-1,4-glucosidase is due in large part to the extensive array of mutations that occur at the *GAA* locus.[341] This autosomal recessive deficiency of amylo-1,6-glucosidase results in infantile- and juvenile-onset syndromes of muscle weakness, wasting, and hepatomegaly. Clinical cardiac disease is not common, although both cytoplasmic (nonlysosomal) and intermyofibril glycogen is routinely present in the heart and causes pseudohypertrophy and increased voltage on electrocardiography. The diagnosis has been established by enzymatic assay of an endomyocardial biopsy specimen.[342] [343] [344]

GLYCOGEN STORAGE DISEASE IV.

This is caused by deficiency of alpha-1,4-glucan: alpha-1,4-glucan 6-glycosyl transferase. It usually causes a fatal disorder of early childhood characterized by hepatic failure; although extensive deposition of polysaccharide occurs in the heart, death intervenes before cardiac symptoms appear. In the most severe form, the fetus has hydrops and generalized muscle degeneration.[345] As with all of the glycogen storage diseases, extensive allelic heterogeneity results in milder forms of the classic disorders. Patients with diagnosis later in adolescence tend to have more severe cardiomyopathy.[346] [347] Liver transplantation has been life saving in some cases and has, somewhat surprisingly, resulted in a reduction of glycogen deposits in the heart and skeletal muscles.[348] [349]

CARDIAC PHOSPHORYLASE KINASE DEFICIENCY.

Few cases of this enzyme deficiency have been reported: deposition of glycogen is confined to the heart, which may be massively thickened and enlarged, and leads

to early death.[350] [351]

GLYCOPROTEINOSES.

This group of disorders results in the lysosomal accumulation of various compounds that cannot be catabolized further because of the specific enzyme deficiency (see Table 56-12) . Some have prominent cardiac pathology, generally of pseudohypertrophy and valvular thickening, which present with congestive failure, valvular dysfunction, conduction defects, or dysrhythmia.[352]

Hematological Disorders (See Chap. 69)

HEMOCHROMATOSIS.

This autosomal recessive disorder of unknown cause results in iron deposition in many tissues, including the myocardium. The manifestations include diabetes mellitus, skin hyperpigmentation, hypogonadism, hepatic failure with cirrhosis, hepatoma, and congestive heart failure; severity is less, and age of onset later in women because of the autophlebotomy provided by menstruation.[353] The cause of the most common form of hereditary hemochromatosis is a gene, *HFE,* that is closely linked to the major histocompatibility locus on chromosome 6. One specific mutation accounts for a large proportion of the mutant alleles among whites.[354] Fully 10 percent of the population is heterozygous for a hemochromatosis mutation, suggesting that at an incidence of 2 to 3 per 1000, this disease is underdiagnosed. This frequency has given rise to interest in population screening by molecular genetic techniques, but for now traditional clinical laboratory approaches are appropriate.[355] Diagnosis depends on finding increased serum iron, ferritin, and, especially, transferrin saturation in the absence of any obvious cause of excessive iron intake.[356]

Cardiac involvement often appears first as dysrhythmia or congestive heart failure. Dysrhythmia, conduction abnormalities, and low QRS voltage are typical electrocardiographic findings; cardiomegaly is seen on chest radiography, and a dilated cardiomyopathy with reduced systolic

function can be documented on echocardiography.[357] [358] Occasional patients have a restrictive pattern on cardiac catheterization.[359]

Treatment by repeated phlebotomy is most effective if begun before organ damage is irreversible. If a patient with congestive heart failure has not yet developed serious compromise in other organs, cardiac transplantation may be contemplated, as may combined heart-liver replacement.

HEMOGLOBINOPATHIES (See also Chap. 69) .

Sickle cell disease and other hemoglobinopathies associated with sickling can produce ischemia and infarction in numerous organs by occlusion of small vessels[360] ; however, the heart is relatively resistant.[361] Nonetheless, the combination of chronic hypoxemia and anemia produces a sustained high-output state that leads to congestive heart failure in many adults. The cardiovascular system can also be compromized by systemic hypertension due to renal infarction, pulmonary embolism and infarction (the chest pain of which often causes concern about myocardial ischemia), pulmonary hypertension,[362] stroke,[360] and hemosiderosis from chronic transfusions.

In addition to a hyperdynamic congestive failure, iron overload is the principal risk to the myocardium in other causes of decreased erythrocyte production *(thalassemias)* and increased erythrocyte consumption *(hemolytic anemias)* requiring repeated transfusions. Treatment with daily injections of deferoxamine can, if begun early, prevent the development of severe cardiac and hepatic disease.[363] Development of an oral iron chelator would greatly improve compliance and efficacy. Various approaches to management of sickle cell disease, including hydroxyurea, show promise.[364] Combined heart-liver transplantation has been used in a case of end-stage organ failure with homozygous beta-thalassemia.[365]

Mucopolysaccharidoses and Disorders of Targeting Lysosomal Enzymes

Many of the specific disorders in these two groups share phenotypical manifestations and are caused by various defects in the ability of lysosomes to catabolize proteoglycan and glycosaminoglycan. Short stature, progressive coarsening of facial features, a skeletal dysplasia termed dysostosis multiplex, corneal clouding, and protean effects on the cardiovascular system are common[366] [367] [368] [369] [370] (Fig. 56-11) . Only MPS IS (Schele syndrome), the mild form of MPS IH (mild Hunter syndrome), MPS IV (Morquio syndrome), and MPS VI (Maroteaux-Lamy syndrome) have minimal or no mental impairment.

CARDIOVASCULAR MANIFESTATIONS.

The cardiovascular complications (see Table 56-12) , which are all progressive and usually insidious, arise from engorgement of cells and tissues with macromolecular storage material.[371] First, the ventricular walls become pseudohypertrophic, and systolic function gradually deteriorates. The electrocardiogram shows reduced QRS voltages; rarely is any conduction disturbance present. Second, coronary arteries narrow because of intimal and medial thickening.[372] Myocardial infarction is common in MPS IH and the severe form of MPS II, although the patients are usually too retarded to complain of classical symptoms, and the diagnosis is made post mortem.[373] Third, valve leaflets thicken and cause progressive dysfunction that is oddly specific for individual disorders. For example, aortic stenosis is common in MPS IS, and mitral regurgitation is frequently found in MPS IH and MPS IV. Finally, narrowing of the upper and middle airways causes obstructive apnea, chronic hypoxemia and hypercarbia, pulmonary hypertension, and eventually cor pulmonale.[374] [375]

MANAGEMENT.

Treatment of children with those conditions that caused mental retardation has in the past been supportive. Increasing experience with bone marrow transplantation in many of the conditions shows that in the survivors of the transplant, somatic accumulation of mucopolysaccharide can be reduced, with clinical improvement in cardiopulmonary function.[366] [376] [377] However, improvement of central nervous system function has been marginal or absent. Nonetheless, bone marrow transplantation may have a role, especially in MPS IV and MPS VI, in which cardiopulmonary compromise can greatly shorten otherwise productive lives. Attempts at cardiovascular surgery, indeed of any procedure requiring general anesthesia, are fraught with risks of difficult intubation, hyperextension of the neck with cervical cord damage (the odontoid process is often hypoplastic), and prolonged efforts to wean from mechanical ventilation.[374]

Figure 56-11 Hurler syndrome in a 4-year-old girl. Note short stature and coarse facial features.

Sphingolipidoses

FABRY DISEASE.

This X-linked condition deserves comment because the diagnosis is often not made until adulthood, when serious end-organ damage has occurred.[378] As a result of deficiency of alpha-galactosidase A, ceramide trihexoside and other glycosphingolipids accumulate in lysosomes of many cells and organs, especially endothelial cells, glomerular and tubular cells of the kidneys, and the heart. Microangiopathy causes the characteristic skin lesion, angiokeratoma, and may contribute, along with primary nerve involvement, to acroparesthesias and painful crises. Proteinuria and hypertension precede renal failure, which has often led to death in males and often leads by the fourth decade to the need for long-term dialysis or renal transplantation. A successful kidney allograft does not correct the systemic metabolic defect,[379] and the disease usually progresses in other organs.[380] Infusion of purified human alpha-galactosidase A shows promise of reducing tissue storage of glycosphingolipid.[380A]

CARDIAC MANIFESTATIONS.

Structural and functional cardiac involvement is qualitatively similar to that in the mucopolysaccharidoses. Thickening of the myocardium is pseudohypertrophy due to deposition of glycosphingolipid in lysosomes; the diagnosis has been made by endocardial biopsy during the evaluation of unexplained ventricular hypertrophy or frank obstructive cardiomyopathy.[381] [382] [383] [384] Chronic hypertension can exaggerate left ventricular dysfunction, as can ischemia and infarction due to diffuse luminal narrowing of the coronary arteries. Echocardiography is useful for serial documentation of myocardial function.[385] Although valvular thickening and MVP are common, hemodynamically important mitral regurgitation is not.[386] The pulmonary vasculature becomes narrowed and right-sided pressures rise, but cor pulmonale is rarely a

problem. The electrocardiogram often shows a shortened PR interval, increased left ventricular voltages, and dysrhythmia. Medium-sized arteries throughout the body develop luminal narrowing, with cerebrovascular disease the most common cause of death after renal failure.

Heterozygous females generally show some clinical manifestations, especially in the eyes, and at much later ages than hemizygous males develop renal, cerebrovascular, and cardiac disease.[378] [385] [386] [387] Prenatal diagnosis is possible, and a detailed family history and genetic counseling are essential whenever the disease is found. Various mutations occur in the gene for alpha-galactosidase A and account for much of the clinical variability.[382] [384] [388]

Familial Amyloidoses (See also Chap. 48)

Various disorders, defined initially by clinical phenotype and due to progressive accumulation of amyloid in organs and tissues, are beginning to be categorized by the underlying biochemical and genetic defects.[389] The several conditions termed familial amyloidosis with polyneuropathy and originally classified as separate autosomal dominant disorders are now known to be due to different mutations in the

same gene encoding transthyretin, a thyroxine- and retinol-binding protein also called prealbumin. Although polyneuropathy dominates the early course during young adulthood, renal failure and restrictive cardiomyopathy supervene later and cause death in most cases. The age of onset, severity, and predilection for kidney and cardiac involvement are determined by the type of mutation, with males affected earlier and more severely.[390] [391] [392]

Liver transplatation can prevent progression of the disease and potentially reverse some tissue accumulation[393] ; when the myocardium is severely infiltrated, combined liver-heart transplant offers the only hope.

NEUROMUSCULAR DISORDERS (See Chap. 71)

CARDIAC TUMORS (See also Chap. 49)

The three most common tumors that originate in the heart are myxomas, fibromas, and rhabdomyomas. All occur as part of hereditary syndromes and as sporadic events. The new occurrence of any of these tumors, especially in a child, may represent the first manifestation of a systemic condition, so a detailed general examination and family history are always indicated.[394] [395] [396] [397] For example, 51 to 86 percent of cardiac rhabdomyomas occur because of tuberous sclerosis.[398] [398A] Tumors due to hereditary disorders tend to be multiple and to recur after resection. An example is the NAME syndrome (for *n*evi, *a*trial myxoma, *m*yxoid neurofibromata, and *e*phelides; the acronym ignores the numerous endocrine tumors) also called Carney complex, in which many myxoma can occur throughout the myocardium. [399] [400] [401] [402] [403] [404]

INHERITED DISORDERS OF THE CIRCULATION

Hereditary Hemorrhagic Telangiectasia

This autosomal dominant condition, often called Osler-Rendu-Weber disease, is more common than appreciated. Because of marked intrafamilial and interfamilial variability, the condition may remain undiagnosed in affected patients for years despite mild manifestations.[405] [406] [406A] Mucocutaneous telangiectases, 0.5 to 3 mm in diameter, occur on the tongue, lips, and fingertips most commonly. Small and moderate-sized arteriovenous fistulas occur in the nose, leading to recurrent epistaxis, in the gastrointestinal system, where they cause recurrent bleeding and occult anemia, and in the lungs, resulting in hypoxemia, hemoptysis, polycythemia, clubbing, paradoxical embolization through the right-to-left shunt, and a hyperdynamic circulation. Less common sites of vascular malformations are the brain,[407] [408] liver,[409] and the kidneys.[410] Diffuse ectasia of the coronary arteries was noted in one patient.[411] and hemorrhagic pericarditis with tamponade in another.[412] Bleeding is facilitated, even in the presence of normal platelet function and clotting function, because of the lack of resistance channels in the telangiectatic lesions.[413]

Patients with hereditary hemorrhagic telangiectasia (HHT) and their close relatives should be screened for pulmonary arteriovenous malformations through auscultation, arterial blood gas analysis, and chest radiography. A low Pa_{O_2} should prompt consideration of angiography and therapeutic balloon occlusion of the feeding arteries of any sizable malformation to prevent systemic embolization, especially to the brain.[414] In a few patients, epistaxis and gastrointestinal blood loss have been reduced by antifibrinolytic therapy with danazol or aminocaproic acid.[415] [416] [417] Controlled trials of various approaches to chronic management, taking into account clinical and genetic variables, are sorely needed.

At least three genes are capable of causing HHT, and two have been mapped, to 9q33-q34 and to 3p22. The former locus encodes a transforming growth factor-beta-binding protein called endoglin, and various mutations segregate with HHT in different families.[418] The other locus encodes an activin receptor-like kinase 1 gene,[419] which is a member of the serine-threonine kinase receptor family, expressed in endothelial cells. This suggests that defects in this gene might affect development or repair of vessels. Yet a third locus is likely.[420] Thus, by mutation detection or linkage analysis, presymptomatic and prenatal diagnosis is available to a large number of patients with a potentially life-threatening disorder.

Von Hippel-Lindau Syndrome

The features of this autosomal dominant condition involve malformations and abnormal growth of small blood vessels. Retinal angioma, hemangioblastoma of the cerebellum, and hemangioma of the spinal cord occur in association with renal cell carcinoma, pancreatic and epididymal cystadenomas, and pheochromocytoma.[421] [422] Secondary hypertension due to renal disease and pheochromocytoma, which is often bilateral, occurs and predisposes to subarachnoid hemorrhage. The cause is a tumor suppressor gene, *VHL,* at 3p26-p25. [423] Patients inherit a germline mutation (and there is great diversity among families in the actual mutations)[424] that is present in all cells. When a somatic mutation in the normal allele occurs in a susceptible cell, such as in the renal parenchyma or adrenal medulla, the cell becomes functionally homozygous for a lack of the gene product, and the cascade toward neoplasia is initiated.[425] How this gene product stimulates or permits angiomatous malformations is unclear.

Disorders Primarily Affecting Arteries

Mendellan disorders are associated with a diverse array of arterial pathology, and some were described or catalogued earlier in this chapter. This section deals with two categories of disorders caused by a single mutant gene: pleiotropic syndromes better known for affecting organ systems other than the vasculature, and primary abnormalities of arteries.

ADULT POLYCYSTIC KIDNEY DISEASE (APKD).

This relatively common autosomal dominant disease affects 0.5 million people and accounts for 8 to 10 percent of all long-term hemodialysis in the United States. Development of renal cysts is age dependent, and presymptomatic detection of heterozygotes, even by ultrasonography, can be uncertain into adulthood.[426] [427] About one-half of patients are hypertensive, one-half have hepatic cysts, one-half eventually develop severe renal failure, and an unknown (but probably high) fraction have colonic diverticula. Elevated plasma renin levels contribute to hypertension long before renal failure occurs.[428] The cardiovascular manifestations include MVP in one-quarter, mild dilatation of the aortic root, occasional thoracic and abdominal aneurysms, and a predisposition to regurgitation of the aortic, mitral, and tricuspid valves.[429] [430] [431] The association of diverticula, organ cysts, and cardiovascular lesions reminiscent of but milder than Marfan syndrome suggests some involvement of the extracellular matrix.

The most serious vascular problem is typical berry aneurysms of the cerebral circulation, which occur in about 10 percent of heterozygotes but may remain asymptomatic throughout life. Hypertension predisposes to subarachnoid hemorrhage. How to screen for and treat intracranial aneurysms in patients without neurological symptoms remains controversial. Cerebral angiography carries higher risks in patients with APKD because of dissection and heightened vascular reactivity.[432] Magnetic resonance imaging detects most saccular aneurysms down to 2 to 3 mm in diameter. Whether to attempt prophylactic repair when a small aneurysm is detected has not been investigated systematically. Without question, aggressive blood pressure control is indicated in any patient with APKD.

At least three genes cause APKD. The greatest portion of cases are due to mutations in a gene called *PBP* at the *PKD1* locus (16p13.3).[432A]

In most of the rest of families, the disease maps to the *PKD2* locus in the region 4q23-q23. Families affected by mutations in *PKD2* tend to develop renal failure later and have a milder course.[433] In both *PKD1* and *PKD2,* the multiorgan cysts develop when a somatic mutation occurs in the normal allele at the respective mutant locus, analogous to the two-hit model so familiar with tumorigenesis.[434] [435] A French Canadian family with disease typical of *PKD1* is unlinked to either locus, indicating that a *PKD3* gene exists.[436]

ARTERIOHEPATIC DYSPLASIA.

An autosomal dominant disorder of marked variability, *Alagille syndrome* causes neonatal jaundice due to aplasia of intrahepatic bile ducts and congestive heart failure in the most severely affected infants but may be asymptomatic in heterozygous relatives.[437] [438] The cardiovascular findings include peripheral pulmonic and systemic arterial stenoses in the majority, occasionally associated with septal defects or PDA. A diffuse vasculopathy is present in some patients.[439] Renal disease may produce hypertension. The locus was initially mapped by studying chromosomes and finding in some patients that part or all of band 20p12 was missing (an interstitial deletion). The *Jagged1* gene, which mapped to this exact region, was then identified as the cause.[440] [441]

ARTERIAL ANEURYSM, ECTASIA, OR DISSECTION

(see also Chaps. 30 , 40 , and 41) . Pedigrees abound in which dilatation of the aortic root, aneurysm of the abdominal aorta, aortic dissection without dilatation, or a combination of these problems occurs in an autosomal dominant pattern without evidence of a recognized heritable disorder of connective tissue.[442] [443] [444] Because of the variable presentation and natural history of the aortic disease, presymptomatic detection of presumed heterozygotes is uncertain, as is reassurance of relatives at risk who are of childbearing age and would prefer not to pass this condition to offspring.

The association of dissection of the ascending aorta with bicuspid aortic valve and aortic coarctation is well known, although the cause and pathogenesis remain unclear. In such cases, the aortic wall shows abnormalities of elastic fibers.[445] A person with a congenitally bicuspid aortic valve or aortic coarctation should be screened for dilatation of the aortic root, and first-degree relatives should be screened for both lesions. This recommendation is based, in part, on bicuspid aortic valve being a congenital heart defect of the left-sided flow category, with a relatively high recurrence risk.

In two families with autosomal dominant transmission of arterial aneurysms and mild increased skin fragility and bruisability, different mutations in the gene encoding type III procollagen occurred.[446] [447] Thus, depending on the mutation, deficiency of type III collagen can cause the vascular form of Ehlers-Danlos syndrome (see p. 2003) or a form of the much subtler but just as deadly syndrome, familial arterial rupture. For these families in which the mutations have been defined, reliable presymptomatic and prenatal diagnoses are at hand. However, suggestions that mutations in type III collagen would account for the majority of aortic aneurysms, including abdominal aneurysms in the elderly, have proved unfounded.[448]

A predisposition to cervical arterial dissection in young people was found to be associated with diffuse lentiginosis in several families, with a suggestion of autosomal recessive inheritance.[449] An association is also noted between cervical dissection and intracranial hemorrhage, which is increased when congenital casdiovascular defects are present, especially bicuspid aortic valve or aortic coarctation.[450] [451]

Formal genetic analysis of 91 families ascertained through a proband with *abdominal aortic aneurysm* suggests that an autosomal recessive predisposition exists for late-onset aneurysms.[452] This study and others [453] provide a rationale for offering ultrasound screening to sibs of patients with abdominal aortic dilatation.

FAMILIAL ARTERIAL TORTUOSITY.

This is a rare, possibly autosomal recessive condition of unknown cause. Diffuse ectasia of all systemic arteries occurs with, paradoxically, peripheral pulmonic stenoses.[454]

FAMILIAL INTRACRANIAL HEMORRHAGE.

In addition to APKD, three syndromes predispose to subarachnoid or cerebral hemorrhage. *Berry aneurysms* without pleiotropic manifestations in other organs are a rare but well-documented autosomal dominant trait.[455] How aggressively near relatives should be screened for intracranial aneurysms remains controversial because of the relatively low risk of hemorrhage compared with the morbidity and mortality of current surgical techniques for repairing defects.[456] [457] [457A] A defect in type III collagen was suggested by linkage analysis, but sequence analysis of the gene in 55 unrelated patients found no mutations.[458]

The *cerebral arterial type of familial amyloidosis* (type VI) is an autosomal dominant condition due to a defect in the proteinase inhibitor cystatin O.[459] This disease is rare outside of Iceland and Holland. The walls of cerebral arteries are thickened by a material resembling amyloid, and the vessels become tortuous and fragile. Recurrent cerebral hemorrhage is common in the fifth and sixth decades of life.[460]

Familial hemangiomas have been reported infrequently to occur as an autosomal dominant condition.[461] The brain and retina are the principal sites of vascular malformation, although in some pedigrees, cutaneous lesions occur. The intracranial hemangioma can be large and present with varied neurological symptoms, including hemorrhage. A more benign familial disorder of primarily isolated cutaneous hemangiomas also exists.[462]

FAMILIAL ARTERIAL OCCLUSIVE DISEASES[463]

Fibromuscular dysplasia of the renal and other arteries occurs in *von Recklinghausen neurofibromatosis* and, along with pheochromocytoma, can be a cause of hypertension.[464] [465] Severe deficiency of alpha$_1$ -antiprotease is another cause of fibromuscular dysplasia.[466] The arterial lesion can occur by itself in families and produce stroke, myocardial infarction, intermittent claudication, and hypertension at young ages, as early as childhood.[467] Inheritance is most consistent with autosomal dominance.[468]

Familial hypoplasia of the carotid arteries,[469] *familial arteriopathy* caused by concentric thickening of systemic and pulmonic arteries,[470] familial moyamoya disease (which has been mapped to 3p24.2-p26),[471] and generalized *arterial calcification of infancy*[472] all are rare, possibly mendelian, syndromes of unknown cause.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is due to mutations in the *NOTCH3* gene.[472A] Characteristic inclusions occur in vascular smooth muscle cells, and the deep, perforating cerebral arterioles develop occlusions that produce insidious onset of symptoms and transient ischemic attacks.

FAMILIAL HEMIPLEGIC MIGRAINE.

The migraine syndrome is commonly familial and occurs in many generations. A severe form, associated with recurrent hemiplegia, is inherited as an autosomal dominant trait and is due to mutations in a sodium channel gene.[473] [474] However, some families with hemiplegic migraine and others with simple migraine are unlinked to this locus.[475] [476] In the same region of 19p is a locus causing autosomal dominant cerebral arteriopathy with subcortical infarcts.[477] Whether the two conditions are related through allelism is unclear.

FAMILIAL PULMONARY HYPERTENSION

(see also Chap. 53) . Primary pulmonary hypertension (PPH) is occasionally familiar.[478] [479] [480] Inheritance is most consistent with an autosomal dominant predisposition with sex influence favoring expression in females. A locus for PPH occurs in the region 2q31-q32 and the defect in some way leads to monoclonal proliferation of endothelial cells.[481] [482] [483] Molecular defects favoring recurrent microemboli to the pulmonary circulation afford another area to explore.

Pulmonary hypertension can occur in *neurofibromatosis* due to pulmonary fibrosis. [484]

Disorders Primarily Affecting Veins

VARICOSE VEINS.

Although a familial susceptibility to varicosities of the lower extremities clearly exists and favors women in a ratio of 2:1, mendelian inheritance has not been confirmed. *Marfan syndrome,* various *Ehlers-Danios syndromes,* and an autosomal recessive condition featuring distichiasis (a double row of eyelashes)[485] predispose to varicose veins.

ATRETIC VEINS.

Some patients with the *Klippel-Trenaunay-Weber syndrome* of cutaneous hemangioma and hemihypertrophy have atresia of the deep venous system.[486] The concomitant superficial varicosities should not be stripped, lest the remaining venous drainage of the lower extremity be removed. This is a confusing syndrome that overlaps with several others; mendelian inheritance is uncertain. Renal arterial aneurysm and hemangioma occurred in one patient.[487]

CAVERNOUS ANGIOMAS.

Cavernous angiomas represent at least 15 percent of vascular malformations of the central nervous system, and familial occurrence is common.[488] These are not arteriovenous malformations but primarily a tortuous collection of veins. Seizure is the most common presenting feature, followed by headache, stroke, and progressive neurological deficit. Magnetic resonance (T_2 -weighted) imaging is the procedure of choice because it is sensitive, and arteriography is not likely to detect the venous malformation. In some families, hepatic angiomas are an important feature.[489] The cause of one form has been identified as a gene, *KRIT1,* of unclear function. [490] [491] [492]

ARTERIOVENOUS MALFORMATIONS.

The most common mendelian cause of arteriovenous malformations (AVM) is the various forms of hereditary hemorrhagic telangiectasia. However, AVM, especially of the brain, are relatively common findings,[493] and other genetic susceptibilities may exist.

Disorders Primarily Affecting Lymphatics

Several forms of *hereditary lymphedema* exist, with the best studied inherited as autosomal dominants. An early-onset form bears the eponym *Nonne-Milroy lymphedema* and can cause a protein-losing enteropathy and pleural effusion. *Meige lymphedema* does not appear until about the time of puberty and is most severe in the legs, although one family with late-onset edema had involvement of the arms

---

and face.[494] Considerable intrafamilial variability in age of onset is noted, however, and whether two or more distinct conditions exist remains unclear. Mutations in one of the receptors for vascular endothelial growth factor, *FLT4,* have been found in some families.[495] [496]

GENETIC FACTORS PREDISPOSING TO ATHEROSCLEROSIS (see also Chap. 31)

Various genetic factors, in addition to the well-studied errors of lipid metabolism, clearly predispose to atherosclerosis. Few genes outside of those involved in lipid metabolism have such an overwhelming impact as to be identifiable from the family history. However, genes that predispose to hypertension and diabetes mellitus; control arterial diameter, reactivity, and branching angles; affect platelet adhesiveness, thrombosis, and fibrinolysis; and regulate endothelial and smooth muscle function all can be considered candidate genes for study in families predisposed to atherosclerosis.[497] [498] [499] Screening numerous genes for common mutations and polymorphisms that convey risk information will be increasing possible.[501] [502]

ABNORMAL REGULATION OF BLOOD PRESSURE (see also Chap. 28)

Blood pressure is a quantifiable trait that shows continuous variation within the population. Although many genes and environmental factors undoubtedly affect a person's blood pressure, familial transmission of some arbitrarily defined disease "hypertension" follows neither mendelian nor multifactorial inheritance.[503] [504] [505] Various cybernetic systems operate to maintain the blood pressure within tolerable limits. When this physiological homeostasis goes awry or its limits are too lax, pathological and clinical consequences occur.[509] For example, sensitivity of the baroreflex was impaired in patients who had untreated essential hypertension and a positive family history of hypertension compared with hypertensive patients with no family history and to nonhypertensive controls.[506] The complexities of such systems are considerable, and two approaches have been taken in recent years to focus the analysis.[505] [507] [508] [509] One involves a candidate-gene approach in humans, based on loci known to be involved in physiological pathways, and the second involves naturally occurring and experimentally created strains of animals.

STUDIES OF HUMANS.

All of the classical approaches to detecting genetic influences in diseases--twin studies, familial aggregation, adoption--confirm that genes have a role, but less than 5 percent of patients with hypertension have a defined genetic cause.

Occasional families show striking mendelian segregation of hypertension without being associated with one of the identifiable syndromes listed in Table 56-13 . One example, in which early, severe hypertension is inherited as an autosomal dominant trait, is *Liddle syndrome.*[510] [511] Because of hypokalemia, aldosteronism was suspected, but both aldosterone and renin levels were low. Attention then focused on sodium resorption in the distal nephron and its regulation. Mutations discovered in the beta subunit of the epithelial sodium channel render the channel insensitive to the usual regulators.

Another example of successful application of the candidate gene approach is investigation of *glucocorticoid-remediable aldosteronism.*[512] The phenotype was mapped to chromosome 8q21, a region already known to contain two candidate genes, aldosterone synthase and 11beta-hydroxylase. By honing in on these loci, mutations creating a chimeric gene by unequal recombination were found to be the cause.[513] As a result of the fusion, aldosterone synthase comes under regulation of adrenocorticotropic hormone. The actual frequency of such mutational events is considerably higher than suspected in the population, and the molecular means are now available to assess the epidemiology of what will likely be a common cause of early hypertension.

Angiotensinogen, the gene for which is in the region 1q42-q43, is a logical candidate gene to investigate because of the central role of its product in blood pressure regulation. Several polymorphic variants involving single amino acid substitutions occur; at positions 174 and 235, either methionine (M) or threonine (T) can exist. The special effects of these polymorphisms on activity, if any, are unclear, but persons homozygous for the 235T allele have plasma angiotensinogen levels 20 percent higher than those with the 235M alleles. Some but not all studies have found an association between the 174M and 235T alleles and hypertension.[514] [515] [516] The importance of these polymorphisms seems to depend on the ethnic background.[517]

The ACE gene, at 17q23, contains a common insertion/deletion polymorphism, termed I and D, respectively, that permits both association and linkage studies. The three possible genotypes are DD, ID, and II, and the plasma level of ACE is highest, for unclear reasons, in persons who are DD and lowest in those who are II. The DD genotype has been associated with predisposition to coronary artery disease and to myocardial infarction, which may account for a relative decrease of hypertensive patients with the DD genotype at older ages.[518] [519]

Pregnancy is a clear risk factor for hypertension. A susceptibility locus for preeclampsia has been identified.[520] [521]

The opposite of hypertension, inappropriate control of pressure on the low side, also has numerous genetic bases (Table 56-15) . [504] [522] [523]

STUDIES IN ANIMALS.

The stroke-prone spontaneously hypertensive (SHRSP) rat is an example of an animal model for a human disease that arose in nature. The phenotype of the rat is clearly polygenic and is thus particularly relevant to much of essential hypertension in humans. Using polymorphic markers spread throughout the rat genome, it has been possible to conduct linkage analyses of hundreds of markers with hypertension when SHRSP animals were crossed with a nonhypertensive strain. Two loci have been identified, and one lies close to where ACE maps.[524] This general approach, called quantitative trait mapping or linkage (QTL), is increasingly being applied to

various phenotypes in animals and humans. Determining the actual gene involved in the animal model should then suggest that the homologous locus in the human is a candidate for participation in normal and abnormal regulation of the trait.

A second approach in animals involves transgenic or knockout techniques to create and breed a new, specific genotype. In simplest terms, a given gene can be eliminated, can be mutated in a specific way, can be moved to a different strain (genetic background), or can be overexpressed (See also Chap. 55) . For example, eliminating function of the gene that encodes atrial natriuretic peptide in the mouse resulted in moderate elevation of blood pressure when sodium intake was low or somewhat high. Mice heterozygous for the mutation had normal blood pressure on these salt loads but became abnormally hypertensive when fed a high-salt diet.[525] [526]

A number of mendelian conditions, most of which are rare, cause major deviations of blood pressure from an appropriate physiological range (see Table 56-15) . These disorders are likely to be underdiagnosed.

TABLE 56-15 -- MENDELIAN DISORDERS ASSOCIATED WITH ABNORMAL BLOOD PRESSURE

DISORDER	OMIM NO.*	PATHOGENESIS
Primarily elevated blood pressure		
Adrenal hyperplasia IV	202010,	11-beta-hydroxylase deficiency 11-deoxycorticosterone
Adrenal hyperplasia V	202110,	17-alpha-hydroxylase deficiency 11-deoxycorticosterone
Aldosteronism	103900,	Aldosterone
Alport syndrome	104200,	Renal failure
	301050,	
Amyloidosis, familial visceral (amyloidosis VIII)	105200,	Nephropathy
Arterial calcification of infancy	208000,	Arteriosclerosis
Arterial fibromuscular dysplasia	135580,	Renal artery stenosis renin
Arteriohepatic dysplasia	118450,	Renal dysplasia; renal arterial stenosis
Bartter syndrome	241200,	Secondary to hyperaldosteronism
Fabry disease	301500,	Renal failure; renal arterial stenosis; arteriolar stenosis peripheral resistance
Liddle syndrome	177200,	Defective epithelial sodium channel k^+ aldosterone, renin, angiotensin
Multiple endocrine neoplasia I	131100,	Adrenocortical adenoma Cushing syndrome
Multiple endocrine neoplasia II	171400,	Pheochromocytoma catecholamines
Nail-patella syndrome	161200,	Nephropathy
Neurofibromatosis type I	162200,	Pheochromocytoma catecholamines; and renal arterial fibromuscular dysplasia
Paraganglioma	168000,	Catecholamines Pheochromocytoma catecholamines
Pheochromocytoma, familial	171300,	Catecholamines
Polycystic kidney disease, adult	173900, 173910	Renin; renal failure
Porphyria, acute intermittent	176000,	?, but only during acute attacks
Pseudohypoaldosteronism, type I	264350,	Aldosterone receptor deficiency
Pseudohypoaldosteronism, type II	145260,	Defective renal secretion of potassium
Pseudoxanthoma elasticum	177850,264800,	Arteriosclerosis
Riley-Day syndrome	223900,	Dysautonomia
von Hippel-Lindau syndrome	193300,	Pheochromocytoma catecholamines
Wilms tumor	194070, 194071, 194090,	?
Primarily low blood pressure		
Dopamine beta-hydroxylase deficiency	223360,	Synthesis of epinephrine
Fabry disease	301500,	Peripheral vascular tone

Hyperbradykininism	143850,	Bradykinin
Pelizaeus-Merzbacher, late-onset	169500,	?
Peripheral motor neuropathy and dysautonomia	252320,	?
Pheochromocytoma, familial	171300,	Catecholamines (epinephrine)
Shy-Drager syndrome	146500,	Primary autonomic insufficiency

**Data from Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).*

Does not include hypovolemia, obstruction of blood flow, and cardiogeneic causes of hypotension, each of which subsumes numerous hereditary disorders as primary causes.

Part VII - CARDIOVASCULAR DISEASE IN SPECIAL POPULATIONS

Chapter 57 - Cardiovascular Disease in the Elderly

MELVIN D. CHEITLIN
DOUGLAS P. ZIPES

PATHOPHYSIOLOGY

The age at which patients become "elderly" is difficult to define because aging is a continuum, with blurred boundaries between middle and old age. Ideally, the term "elderly" should be marked by distinct changes in physiology, but the rate of physiological aging varies and may not advance in lock step with chronological changes, so that one can be physiologically young but chronologically old, and vice versa. In some reports the elderly are defined by eligibility for Medicare benefits (65 years). In others, age cutoffs of 70 or even 75 years are used.

Aging is characterized by a gradual loss of function in many organ systems, unrelated to a pathological condition. Certainly, in many old individuals comorbid diseases complicate the aging process; but independent of associated diseases, aging produces major cardiovascular changes, including decreased elasticity and compliance of the aorta and great arteries.[1] These alterations result in a higher systolic arterial pressure and an increased impedance to left ventricular (LV) ejection, and subsequent mild LV hypertrophy and interstitial fibrosis.[2] A decrease in the rate of myocardial relaxation also occurs. As a result, the LV becomes stiffer and takes longer to relax and fill in diastole, thus increasing the importance of a properly timed atrial contraction in contributing to a normal LV end-diastolic volume (Fig. 57-1) and forming the basis for diastolic dysfunction and congestive heart failure (CHF).[3] There is also a 50 to 75 percent loss of pacemaker cells in the sinus node, accompanied by a decrease in intrinsic and maximum sinus rate. The number of atrioventricular (AV) nodal cells seems to be preserved, although an increase in AV nodal delay (PR interval) is common. Increased fibrosis of the fibrous skeleton of the AV annuli occur, along with fibrosis and loss of specialized cells in the His bundle and bundle branches that can result in heart block. Heart valves thicken, and calcification results at the base of the aortic valve and mitral annulus.[4] Aging causes a decreased sensitivity of the heart to beta-adrenergic agonists and a diminished reactivity to chemoreceptors and baroreceptors.[5] There is no decrease in myocardial contractility solely as a result of aging, but diseases that do result in decreased contractility, such as hypertension (HTN) and coronary artery disease (CAD), are common in this age group.

Figure 57-1 Effect of age on early diastolic filling and on atrial contribution to diastolic filling by echo-Doppler in healthy Baltimore Longitudinal Study on Aging (BLSA) participants. *(From Geokas MC, Lakatta EG, Makinodon T, et al: The aging process. Ann Intern Med 113:455-466, 1990.)*

Figure 57-2 Exercise-related changes in heart rate *(A),* end-diastolic volume *(B),* end-systolic volume *(C),* and stroke volume *(D)* in young (ages 25-44 years) *(triangles)*, middle-aged (ages 45-64 years) *(open circles)*, and elderly (ages 65-80 years) *(closed circles)* healthy men, according to increasing cardiac output with exercise. All groups had similar increase in cardiac output up to a workload of 150 watts. Note that the elderly increase cardiac output by increasing end-diastolic volume and stroke volume with exercise. *(From Gerstenblith G, Renlund DG, Lakatta EG: Cardiovascular response to exercise in younger and older men. Fed Proc 46:1834-1839, 1987.)*

Cardiac output remains normal at rest, but with a slower heart rate there is an increased reliance on the Frank-Starling mechanism to increase stroke volume and keep the cardiac output normal.[6] With exercise, a decrease in the ability to achieve maximum heart rate and oxygen consumption is seen in older as compared with younger patients. However, ejection fraction (EF) is kept normal by the increased stroke volume sustained by the larger LV diastolic volume seen with exercise[6] (Fig. 57-2) .

Many of these alterations can be explained at cellular and subcellular levels. Cardiac fibrosis, reduction in the number of cardiac myocytes, increase in cell size and capacitance by 20 to 80 percent, and decreased responsiveness to beta-adrenergic receptor stimulation are typical changes found in older animal hearts. Interestingly, some of the same structural alterations parallel those that occur during development of myocardial hypertrophy. Aging hearts recapitulate the fetal phenotype in many aspects. Aging increases the magnitude of the L-type calcium current (ICa-L) in parallel with enlargement of cardiac myocytes, which may be important to help preserve contractile function (see Chaps. 14 and 15) . The increase in ICa-L is balanced by the enlarged cell size in aged myocytes so that, despite the increase in the numbers of ICa-L channels, the overall density becomes normalized by the increase in cell size and capacitance. However, ICa-L inactivation is slowed so that larger calcium influx can occur with each heartbeat.[7] Altered calcium homeostasis predisposes to calcium overload. Both the amplitude and the density of the transient outward current (Ito) are decreased with aging.[8] These changes in Ito, together with the delay in ICa-L inactivation, may largely account for prolongation in action potential duration as hearts age.

Drug Metabolism

The elderly consume a large percentage of all drugs prescribed. Three fourths of those 75 years of age and older receive drugs of some kind. Elderly outpatients in the community take 2 or 3 medications per day, and institutionalized geriatric patients take 3 to 8 or as many as 15 per day.[9] The pharmacokinetics of drugs have been evaluated mostly in the 65- to 75-year age group, and this information is extrapolated to old and very old patients of ages 80 to 85, because few studies in this age group have been done. Aging affects both the pharmacodynamics and pharmacokinetics of drugs (see Chap. 23) .

PHARMACOKINETICS

ABSORPTION.

Although drugs can be given intravenously, subcutaneously, or intramuscularly, most cardiovascular drugs are given orally and are absorbed by passive diffusion through the intestinal mucosa rather than by active transport. Aging decreases gastric acidity, slows intestinal motility, and decreases by 30 percent the mucosal area for absorption in, and decreases the blood flow to, the small intestine; yet none of these seems to affect cardiovascular drug absorption significantly.

DISTRIBUTION.

With aging, there is a decrease in lean body mass, and therefore a decrease in the volume of total body water. Diuretics, by decreasing the extracellular fluid, further decrease the volume of distribution and reduce the loading dose of the drug needed to achieve therapeutic levels.

With illness comes a decrease in serum albumin level, counterbalanced partly by an increase in alpha-acid glycoprotein.[10] Although these changes may not be of major importance to a drug's effect, diseases that result in the loss of all plasma proteins such as renal failure can have a major effect. Furthermore, highly protein-bound drugs that compete for binding sites on the albumin can displace other drugs, increasing the free-drug plasma concentration and increasing the effect of the drug. This explains why warfarin, which is 98 percent protein bound, has so many drug-drug interactions.

ELIMINATION.

The major sites of drug elimination are through the kidney and metabolism by liver enzymes. Hepatic metabolism biotransforms the drug to a biologically inactive or a hydrophilic polar compound, cleared by the kidney. There are two phases of liver metabolism: Phase I reactions are discrete oxidative pathways of cytochrome P450 (CYP) occurring in the endoplasmic reticulum, whereas phase II reactions, those of conjugation, including glucuronidation, sulfation, and acetylation, occur in the cytosome. Aging results in a

decrease in liver mass, and often also in the activity of the most important CYP enzymes involved in drug metabolism. Phase II conjugative reactions do not decrease with age.[11] Obviously, liver disease can affect the capacity of the liver to metabolize drugs.

Biotransformation can be influenced by drugs that either inhibit or cause induction of the CYP syndrome. Common drugs such as cimetidine, macrolide antibiotics, and quinidine inhibit the system, and drugs such as phenytoin and glucocorticoids induce the enzymes. For drugs metabolized by this CYP system, inhibition causes an increase in the plasma concentration and half-life, whereas induction causes a decrease.

Aging results in a decrease in the number of renal glomeruli and tubules, as well as in renal blood flow and glomerular filtration rate (GFR).[12] With a decrease in GFR, the dose of renally excreted drugs must be reduced parallel to this decline in GFR. Digoxin is an excellent example of a renally excreted drug.

Another important renal effect of aging involve angiotensin-converting enzyme (ACE) inhibitors and non-steroidal anti-inflammatory agents (NSAIDs). ACE inhibitors reduce conversion to angiotensin II and increase levels of bradykinin; aldosterone excretion is also decreased. This serves to decrease the constriction of the glomerular efferent arterioles and can result in decreasing renal function and even renal failure in the presence of renal artery stenosis. The decrease in aldosterone secretion with ACE inhibitors can increase serum potassium levels and result in hyperkalemia. These effects are exaggerated in the elderly patient.

NSAIDs inhibit the synthesis of prostaglandins, which are responsible in part for regulating renal blood flow. In elderly patients with a low GFR, CHF, or liver disease, NSAIDs can further reduce renal function, causing hyperkalemia or frank renal failure from tubular necrosis or interstitial nephritis.[13] In the elderly patient using ACE inhibitors or NSAIDs, reduced doses of these drugs, with careful monitoring of renal function and serum electrolytes, are required.

PHARMACODYNAMICS.

Aging is associated with a decrease in cardiovascular responsiveness to $beta_1$ -adrenergic stimulation, probably related to a decrease in adrenergic receptors[5] and in baroreceptor sensitivity. In the elderly patient, this accounts for less bradycardia with beta blockers than is seen in younger patients. The decrease in baroreceptor and $beta_1$ -adrenergic responsiveness can result in a lack of compensatory tachycardia and exaggerated hypotension with the use of vasodilators and nitrates in elderly patients. Sensitivity to various calcium channel blockers appears to be increased in elderly patients, with a greater decrease in heart rate and blood pressure (BP) to the same serum concentration of verapamil or diltiazem than seen in the younger patient.[14]

Drug Interactions and Adverse Drug Effects

Age brings an increased incidence of adverse drug effects, occurring in one fourth of older patients and accounting for 3 to l0 percent of all hospital admissions for elderly patients.[15] Elderly patients often take multiple drugs; the number of medications taken is the most important risk factor for adverse drug reactions.[16] This polypharmacy results in noncompliance, because the elderly often confuse the drug schedule, especially for drugs given more than once a day. Another reason for noncompliance is the high cost of drugs, which may result in patients electing not to have prescriptions filled. Polypharmacy also results in adverse drug reactions from drug-drug interactions, owing to the interference of the pharmacokinetics of one drug on another. Another common reason for drug-drug interaction is competition between two highly protein-bound drugs for receptor sites, with displacement of one drug and a resultant increase in free drug in the plasma and drug effectiveness.

Other factors predicting poor compliance include a complicated drug regimen, multiple drugs, noncomprehension of instructions, mental impairment, visual or hearing disabilities, and no helper or relative at home. Legible instructions in the patient's language on easily opened bottles, certain memory aids, and the aid of visiting nurses can all improve compliance.

Drugs with similar effect can produce an additive pharmacological action (e.g., excessive bradycardia from a combination of verapamil and digoxin). Cardiovascular drugs that cause the most drug interactions are digoxin, warfarin, lidocaine, quinidine, and amiodarone.[17]

Basic principles of therapeutics in the elderly are as follows:

1. Know all the drugs the patient is taking.
2. Regularly review the drug regimen; insist that the patient bring all medicines to the next visit.
3. Take a careful drug history because of multiple drugs from multiple sources, including self-medication with over-the-counter drugs.
4. Know the pharmacokinetics and side effects of the drugs.
5. Start the drugs in the elderly at a low dose and increase in small increments and larger intervals than in younger patients until the desired effect is obtained.
6. Use the simplest drug regimen possible.
7. Adjust the dose by the patient's response.
8. Educate patient, family, and friends about the medicines, what they are for, and how to take them; also tell them about the major side effects. Be alert to drug-induced illness; in the elderly, this can be subtle or mistaken for symptoms due to the patient's disease. Drug-related effects can present as somnolence, confusion and even delirium, nausea, frequent falls, or urinary incontinence.
9. Expect noncompliance, and tell the patient what to do if the dose is missed or in cases of confusion about whether or not the drug was taken.

EPIDEMIOLOGY

Average life expectancy has risen from 47 years in the United States in 1890 to 72 years for men and 79 years for women by the end of the 20th century. At present, a person reaching the age of 65 has an average life expectancy of 18 more years; at age 85, this is 7 years.[18] The average maximum length of life, however, is 85 to 90 years and has not changed much.[19]

The population 65 years and older has grown from 20 million in 1970 to 35 million in 2000, and it is estimated that there will be 69 million by the year 2030 (20 percent of the U.S. population, up from 13 percent in 1997). By 2030, the fastest-growing segment of that elderly population will be those aged 85 and older,[18] growing from 2 million in 1970 to 4.5 million in 2000, and 8 million (estimated) by 2030.[18] The number of persons in the world who are 60 years old or older is estimated to be nearly 600 million in 1999 and is projected to be about 2 billion by 2050. At that time, the elderly population will exceed that of children from birth to 14 years of age for the first time in human history. At present, one in every 10 people is 60 years or older. By 2050, this is projected to become 1 in every 5. The percentage is growing fastest in the developed regions of the world. The older population itself is aging: currently, the oldest old (80 years or older) comprise 11 percent of the population 60 and older;

by 2050, they are projected to comprise 19 percent. The number of those 100 years and older is projected to increase from 145,000 in 1999 to 2.2 million by 2050.[19] The aging pyramid, instead of becoming smaller in number as the age groups increase, will become more of a trapezoid, especially as the "baby boomers" become the elderly population.

In this older population cardiovascular disease plays a significant role and is the most common cause of morbidity and mortality.[20] Heart failure (HF) is the most common diagnostic-related group in the Medicare population 65 years old and older. In the Framingham Heart Study, 44 percent of men and 28 percent of women aged 75 to 84 had cardiovascular disease; in the 85 to 94 age group, the prevalence was 48 percent in men and 43 percent in women.[21] CAD and HTN (especially isolated systolic HTN) increase as the population ages. In the United States, in people older than 65, HTN is present in about half the patients (Fig. 57-3) .[22]

The overall cost of treating cardiac disease in people older than the age of 65 years was estimated at $58 billion in 1995.[18] Hospital and nursing home care is the largest proportion of this cost. A recent study in 80- to 98-year olds found that most would rather extend their lives in

Figure 57-3 Prevalence of isolated systolic hypertension by the midpoint of the age classes reported in various studies. As shown by the unweighted regression line, the prevalence of systolic hypertension increases curvilinearly with age. The 95 percent confidence interval for the prediction of individual points is presented for the age range of 50 to 90 years. *(From Staessen J, Amery A, Fagard R: Isolated systolic hypertension in the elderly. J Hypertens 8:393-405, 1990.)*

their present state of compromised health than live shorter lives in excellent health.[23]

VALVULAR HEART DISEASE (see also Chap. 46)

Although any valve lesion can be seen in the elderly population, the most common valve diseases are calcific aortic stenosis (AS) and mitral regurgitation (MR) due to myxomatous mitral valve. MR due to ischemia, or previous myocardial infarction, resulting in a failure of the papillary muscle/LV complex to allow proper coaptation of the mitral leaflets, is also a common cause, along with LV failure for any reason. Mild to moderate MR usually occurs in patients with calcification of the mitral annulus. Ruptured chordae, endocarditis, trauma, and aortic dissection are other causes of aortic regurgitation (AR) and MR.

Aortic valve sclerosis, as a result of stiffening and calcification of the aortic annulus and base of the semilunar cusps, causes an early-peaking systolic ejection murmur that is short and grade III-VI or less in loudness. It does not represent significant obstruction. No physical findings of obstruction are present, nor is LV hypertrophy, but it is associated with other manifestations of atherosclerotic disease, especially CAD,[24] and indeed it may result from the atherosclerotic process. It can be found in about 30 percent of the elderly, whereas significant AS is seen in 2 to 3 percent.[24] The cause of AS in the older age group is calcific or degenerative, almost always on a normally tricuspid semilunar valve. Calcification is at the base and body of the semilunar cusps, and the commissures are not fused. Rheumatic heart disease is much less common, as is congenital AS. Patients with a bicuspid aortic valve are seen in the elderly age group, but most who develop calcification and severe obstruction do so between the ages of 40 and 60.[25] In the elderly AR can be due to rheumatic heart disease, but more often it is due to myxomatous changes and prolapse of the aortic cusp, aneurysmal aortic root dilation, infective endocarditis (possibly on a bicuspid aortic valve), or dissecting aorta.

Primary valve disease in the elderly rarely causes tricuspid and pulmonic valve regurgitation, which is usually secondary to pulmonary HTN and dilatation of the right ventricle. Pulmonary HTN can be due to LV diseases such as ischemia or cardiomyopathy, mitral stenosis, or intrinsic pulmonary disease. Primary tricuspid regurgitation due to infective endocarditis almost always occurs in intravenous drug users, who are rare in this age group. Primary tricuspid valve regurgitation (TR) can rarely be seen in elderly patients after trauma. Infrequently, an elderly patient is found with Ebstein disease and TR, or pulmonic valve regurgitation after tetralogy of Fallot repair with a patchenlarged pulmonary outflow tract and annulus.

DIAGNOSIS.

The diagnosis of significant valve disease can be difficult in the elderly population; echocardiographic-Doppler imaging can be of great help (see Chap. 7) . The loudness of an aortic stenotic murmur depends on the generated LV systolic pressure as well as on the stroke volume and the loudness of MR murmur on the regurgitant volume. If the cardiac output is low, the murmur of AS or MR may be soft or even absent. The loudness of the murmur also depends on the nearness of the site of origin of

the murmur to the chest wall. Accompanying clues to severity can also be absent or confusing in the elderly. For instance, an S_4 gallop or the presence of LV hypertrophy in a young person with AS is a sign strongly suggesting hemodynamic severity of the AS. In the older patient, an S_4 is often present without AS, as is LV hypertrophy, especially in those patients who have had a long history of systolic HTN. In the elderly, the carotid upstroke can feel normal in severe AS because of the stiff aorta.

The severity of AR can be difficult to judge by physical examination in the elderly because of the frequent occurrence of a wide pulse pressure due to a stiff atherosclerotic aorta rather than to severe AR. Acute AR masks many of the peripheral signs of severe AR, because the LV filling pressure is high and the forward effective stroke volume is low, thus decreasing the rise of the systolic aortic pressure, increasing the diastolic pressure, and narrowing the pulse pressure. If the AR is very severe, the diastolic regurgitant gradient between the aorta and LV is small, and with tachycardia there may be little or no diastolic murmur. The collapsing quality of the carotid pulse and Duroziez sign, that is, the systolic and diastolic bruit heard on compression of the femoral artery by the bell of the stethoscope, remain as signs of severe AR.

Treatment

A problem with selecting therapy for the elderly is that, until recently, they have been excluded from most controlled trials, and information about treatment comes mostly from registries and observational studies. Medical therapy for elderly patients with valve disease is generally similar to that for younger patients.[26] In elderly patients, even with mild mitral valve disease, atrial fibrillation (AF) is common, and represents a markedly increased threat of systemic embolization and stroke. Anticoagulation, unless absolutely contraindicated, is essential.

VALVE SURGERY.

Deciding to send an elderly patient with significant valvular stenosis or regurgitation to surgery can be difficult and must be individualized because of the diversity of problems found in this age group. Generally, the patient younger than 75 has a similar morbidity and mortality to a younger patient with a similar problem. As the patient enters the late 60s and early 70s, a higher prevalence of comorbidity exists, with increased coronary, cerebrovascular, renal, hepatic, and pulmonary disease that add to surgical morbidity and mortality.[27] After age 75 to 80, surgical morbidity and mortality are increased, even beyond the impact of comorbidities, because age per se becomes an increasing risk factor for valvular surgery. In patients older than 75, the risk of neurological problems and stroke with cardiopulmonary bypass surgery increases.[28] The elderly have more problems than younger patients with mechanical valve replacement, mostly because of the increased complications from anticoagulation.[29]

The goals of valve surgery in the elderly are somewhat different from those in younger patients. In the older patient the major goal becomes relief of symptoms, with improvement in activity and quality of life rather than prolongation of life.

Aortic Stenosis.

After the occurrence of symptoms of HF, exertional syncope, angina, or myocardial infarction without obstructive CAD, mortality in patients with severe AS increases rapidly, so that the mean survival is 3 years for symptomatic patients, shorter with HF symptoms, and somewhat longer with angina. In all probability, survival is even less in the elderly. Also, the incidence of sudden death increases in the symptomatic patient with AS, accounting for one fifth to one fourth of all deaths (see Chap. 46) . Surgery should be recommended once symptoms begin, depending on the overall status of the patient and the number and severity of comorbidities. Only in the presence of a decreasing EF, or possibly with increasing runs of nonsustained ventricular tachycardia, should a patient not complaining of symptoms be offered

surgery.[26]

Patients with AR who undergo aortic valve replacement do not fare as well as patients with AS, especially if they are in New York Heart Association (NYHA) Class III or IV or have a decreased LV EF.[30] Long-term morbidity and mortality are increased in patients with moderate to severe AR if they have symptoms, an EF less than 50 to 55 percent, comorbidities, or an increased LV end-systolic diameter by echocardiography (>25 mm/m^2).[26] [31] Surgery is, therefore, indicated in these patients.

Aortic Valve Replacement.

In younger patients who have pliable valves and AS due to commissural fusion, successful commissurotomy, either surgically or by balloon valvotomy, is possible, with good results lasting 15 to 30 years.[32] In elderly patients with AS of whatever cause, the aortic valve is always severely calcified, and valvotomy, either by surgery or balloon, has a limited, short-lived success. With severe AR, valve replacement is the rule, except for ascending aortic aneurysm or AR with aortic dissection, in which ascending aortic grafting with valve resuspension can be done with long-term success.[33]

In most series of patients older than 70 years, perioperative mortality varies from 2.4 to 12.4 percent, depending on comorbid conditions, increasing patient age, the presence of other cardiac lesions or concomitant operations such as mitral valve repair or replacement, or coronary artery bypass graft (CABG).[34]

As experience has increased, perioperative mortality has fallen to 6 to 10 percent for aortic replacement and CABG[35] and 4 to 7 percent with isolated aortic replacement. Factors that predict perioperative mortality in patients older than 75 years are NYHA functional therapeutic Class IV, decreased LV EF, chronic HF, the presence of comorbid diseases such as pulmonary or renal disease or diabetes, and concomitant procedures such as mitral valve surgery, coronary artery surgery, or surgery performed as an urgent procedure. Other independent predictors of hospital mortality include cardiomegaly, serum creatinine level greater than 150 mmol, and operation as an emergency procedure. Predictors of late mortality are comorbid diseases such as severe renal, pulmonary, or coronary disease and poor LV function.[30] [36] Patients with coexisting minimal-to-moderate AS or AR who have cardiac surgery for other than aortic valve disease (e.g., coronary surgery or mitral valve replacement) generally experience very slow progression of the aortic valve disease. Consequently, there is no indication to replace the aortic valve at that time.[37] However, the higher the aortic valve gradient and the heavier the aortic valve calcification, the more likely the AS will progress, and therefore the more reasonable it becomes to replace the aortic valve at the time of the primary surgery.

As many as 40 percent of patients with AS in the elderly age group have at least one significantly obstructed coronary artery.[38] The presence of atheromas in the descending aorta by transesophageal echocardiography is a good predictor of CAD.[39] Although stress echocardiography has been recommended to detect CAD in patients with AS,[40] stress testing is generally unnecessary, because in this age group coronary arteriography is justified preoperatively to assess the status of the coronary arteries[26] (see Chaps. 6 and 7) . Aortic valve debridement can result in relief of severe calcific AS; however, it has been abandoned by most surgeons because there is a rapid restenosis and, with some techniques, a high incidence of increased AR (see Chap. 46) . Occasionally it can be beneficial. [41]

A biological tissue valve, rather than a mechanical valve, is most often placed in this elderly age group because of their shorter life expectancy, because biological valves are less subject to tissue failure in elderly patients,[27] [42] and because of the dangers of anticoagulants in the elderly.[29] For most tissue valves, even in younger patients, there is no significant failure for 5 to 10 years, long enough to last the natural life of the elderly patient.[42] With aortic valve replacement, operative mortality is slightly increased with age and more markedly increased with comorbidity and severity of disease; however, the results of surgery are excellent, with a definite increase in quality of life.

Mitral Valve Repair/Replacement.

With MR, because of multiple causes and especially CAD causing severe MR, the results of valve replacement are not as good as with AS; 5-year survival after both coronary surgery and mitral valve replacement is only about 50 percent.[43] With mitral valve replacement, the major risk factor for mortality is the presence of CAD.[44] Patients do well after repair of MR, with

perioperative mortality of 4 percent and 25 months late mortality of 6 percent.[45] Thus, the elderly undergoing mitral valve surgery do not do as well as those having aortic valve replacement or younger patients and fare better with mitral valve repair than with replacement.

Balloon Valvotomy.

For calcific AS, balloon valvotomy increases aortic valve area, but rapid restenosis follows. Because balloon valvotomy is not an alternative to valve replacement, its use is restricted to very old, extremely symptomatic patients who are poor candidates for surgery, where the procedure might improve cardiac output and peripheral organ perfusion, and relieve afterload on the LV enough to allow surgical valve replacement at a later time. It can also be useful in those patients who are not candidates for surgery because of comorbid problems and who are repeatedly hospitalized for HF. Balloon valvotomy can keep these patients out of the hospital for a variable period of time, and improve quality of life.[46] Balloon valvotomy for MS has become the procedure of choice when the valve is not heavily calcified and MR is absent or minimal. The results of balloon valvotomy are equivalent to those of open commissurotomy, and both are better than closed commissurotomy.[47] Mitral valve calcification, frequent in the elderly, reduces the success rate and increases mortality and complications.[48]

CORONARY ARTERY DISEASE (see also Chaps. 35 , 36 , and 37)

PREVALENCE AND INCIDENCE.

As the population ages, the prevalence and annual incidence of the development of overt CAD increases substantially with age, as does the total number of people with clinical CAD (Fig. 57-4) . The severity and diffuse distribution of the coronary obstruction also increases, presumably as a result of prolonged exposure to atherosclerotic risk factors. There is a striking gender difference, with men developing CAD at a younger age than women (37 percent in men aged 65 to 74 vs. 22 percent in women of the same age range). The prevalence of CAD in the Framingham cohort aged 75 to 84 years was 44 percent in men and 28 percent in women. In the 85- to 94-year age range, the prevalence of CAD was 48 percent in men and 43 percent in women.[49] The lifetime risk of developing CAD at age 40 is 49 percent for men and 32 percent for women, decreasing to 35 percent for men and 24 percent for women at age 70, or 1 in 3 for men and 1 in 4 for women.[50]

MORTALITY.

Almost 85 percent of people who die of CAD are age 65 or older. According to data from the Health Care Financing Administration, in 1995, $98 billion ($3,769 to $11,110 per discharge) was paid by Medicare to Medicare beneficiaries for CAD. Of 2.3 million Americans discharged from hospitals with a first-listed diagnosis of CAD in 1996, 57 percent were 65 years of age or older.[51] CAD mortality is about twice as high in men as in women and higher in blacks than in whites. After age 70, mortality in white men is higher than in black men. In women, mortality in blacks exceeds that in whites until age 85.[52] Although mortality from CAD has been declining since 1970, the decline is greater in white men and women than in blacks (average annual percentage change 3 to 4 percent vs. 2 to 3 percent), more robust than in the age groups up to 85 but still 1 to 2 percent in even the oldest age groups.[52] After adjustment for major risk factors, with each decade of advancing age, a twofold to threefold increase in coronary vascular mortality persists.

RISK FACTORS (See Chaps. 31 , 32 , and 39)

The impact of many risk factors for CAD, such as HTN, diabetes, and LV hypertrophy, increases with age. Although the benefits of risk-factor reduction in the elderly for some risk factors is incomplete, excellent evidence exists that control of BP, for example, reduces cardiovascular events even in the older age group.

HYPERTENSION (see Chaps. 28 & 29).

Because HTN is so common in the older population, and the number and type of effective drugs so numerous, this is one of the most controllable of the risk factors. Fifty-seven percent of men and 61 percent of women aged 65 to 74 and 64 percent of men and 77 percent of women aged 75 and older have HTN, as defined by at least one ambulatory BP reading of 140 mm Hg systolic or 90 mm Hg diastolic or higher.[18] Both systolic and diastolic elevation of BP is associated with an increased risk of CAD in men and women. People older than 65 years with systolic pressure greater than 180 mm Hg have a threefold to fourfold increase in risk of CAD compared with people with a systolic pressure of less than 120 mm Hg. A diastolic pressure greater than 105 mm Hg increased the risk two to three times compared

with a diastolic pressure of less than 75 mm Hg.[53]

Isolated systolic HTN (systolic pressure greater than 140 mm Hg with a diastolic pressure less than 90 mm Hg)[54] is very frequent in the elderly and is partially related to the loss of elasticity and compliance of the aorta and arterial branches. The risk of stroke, CHF, renal disease, renal insufficiency, and probably coronary artery events decreases with a decrease in the degree of systolic HTN, as shown in the Systolic Hypertension in the Elderly Program (SHEP trial) (see Chap. 29) . Treatment of HTN in the elderly population reduces the risk of cardiovascular events, especially stroke and CHF, and probably decreases the incidence of myocardial infarction.[55]

Figure 57-4 Prevalence of coronary heart disease by age and sex. (NHAHES III, US 1988-1991.) *(From Kannel WB, Wilson WF, Larson MG, et al: Coronary risk factors and coronary prevention in octogenarians. In Wenger NK [ed]: Cardiovascular Disease in the Octogenarian and Beyond. 1st ed. London, Martin Dunitz, 1999, p. 143.)*

SMOKING (see Chaps. 31 , 32 , and 39) .

Cigarette smoking declines in prevalence with advancing age to about 15 percent of men and 11.5 percent of women age 65 and older.[56] Although smoking is a powerful risk factor in the younger patient, it is unclear if smoking exerts the same risk in the older population[57] and whether smoking cessation in elderly patients decreases the incidence of coronary events. In the Coronary Artery Surgery Study (CASS) registry, patients older than age 70, all of whom had CAD, who continued to smoke, had three times the risk of death or myocardial infarction during a 60-year follow-up period compared with those who stopped smoking. In the British Physicians' Study[58] and the U.S. Nurses' Health Study,[59] smoking was an independent risk factor for coronary events in both younger and older age groups. However, the Framingham Heart Study showed that in individuals older than age 65 the incidence of lung cancer is accelerated, but there was no correlation between the incidence of smoking and CAD.[60] The explanation for the latter may be that, although there is increased risk of CAD from smoking, there is increased mortality from other smoking-related diseases in this age group. It is also possible that those susceptible to CAD from smoking died at a younger age, and among the persons who survive to age 65, fewer patients are susceptible to CAD from smoking.

HYPERLIPIDEMIA (see Chap. 31) .

Serum cholesterol concentration increases progressively until age 50 in men and age 65 in women and then begins to decline. High-density lipoprotein value is higher in both men and women and stays constant with aging.[61] Among people 65 to 74 years of age, 22 percent of men and 41 percent of women have a total serum cholesterol value of greater than 240 mg/dl; for those older than 75 years, 20 percent of men and 38 percent of women have cholesterol levels greater than 240 mg/dl.[18] Although the association between the risk factor of an elevated serum cholesterol level and the development of CAD is less striking in the elderly, the ratio of total to high-density lipoprotein cholesterol remains a strong predictor of CAD in the elderly.[62] Elevated triglycerides have been independently associated with an increased risk of CAD in elderly women but not men.[63] Treatment with HMG-CoA reductase drugs can reduce the incidence of acute cardiac events in patients up to 75 years of age; older patients have not been studied.[64]

DIABETES MELLITUS (see Chap. 63) .

In 1996, there were 503,000 Americans discharged from the hospital with a first-listed diagnosis of diabetes mellitus. Of these, 39 percent were older than 65 years of age. The prevalence of physician-diagnosed diabetes in patients aged 60 and older is 12 to 13 percent for men and women. The vast majority of patients older than age 70 have non-insulin-dependent (type II) diabetes. Its presence doubles the risk of CAD and, when combined with hyperlipidemia, increases the risk 15-fold.[65]

PHYSICAL INACTIVITY.

Approximately one third of men and women aged 65 to 74, and 38 percent of men and 51 percent of women aged older than 75 years, report no leisure-time physical activity. Frequent exercise raises high-density lipoprotein cholesterol, controls obesity, and lowers systolic and diastolic BP even in patients 60 to 80 years old and reduces insulin resistance.[66] Even moderate amounts of exercise have been shown to protect against CAD events in middle-aged and older men in the Framingham Heart Study.[67]

Other risk factors for CAD, such as lipoprotein (a) and other apolipoproteins, are still being investigated. A high homocystine level is not uncommon in elderly men and is strongly associated with increased prevalence of coronary heart disease and cerebrovascular disease.[68] After an acute myocardial infarction (AMI), patients with depression who are socially isolated have an increased recurrence rate and mortality[69] (see Chaps. 39 and 70) . This social isolation is more common in the elderly.

Clinical Presentation

Elderly patients have more multivessel disease and lower EF than do younger patients.[70] Although angina pectoris is a common first presentation of CAD in the elderly, angina may not occur until the CAD is well advanced because of often markedly decreased activity. For this reason, acute ischemic syndromes are common initial presentations of CAD.[70] Also, many symptoms of discomfort that would alert a younger person are explained away in the elderly patient as a consequence of "getting old."

When angina occurs, the precipitating factors and the description, with radiation and its relief by rest, are similar to that in younger patients. However, with advancing age, a frequent presenting symptom is increasing fatigability and shortness of breath during activity because of the ischemic effects on systolic and diastolic myocardial function. In patients with documented CAD, anginal pain without dyspnea is reported in 25 to 43 percent of persons older than age 65, dyspnea without chest discomfort in 8 to 25 percent, and both dyspnea and angina in almost 50 percent.[71] Others have reported the initial manifestation of CAD in the elderly to be angina in 80 percent.[72] As many as 30 percent have silent ischemia.

With increasing age, the gender composition of patients with AMI changes from 80 percent men younger than 55 to about 50 percent men aged 75 to 84 and only one third men aged older than 83.[73] Sudden pulmonary edema is a common presentation of AMI in the elderly, but chest pain is still the most common, as it is in younger patients. Neurological symptoms as a presentation of AMI, such as syncope, stroke, or confusion, are more likely seen in the elderly, as is painless AMI. Non-Q-wave myocardial infarctions are more common in the elderly. Physical examination, especially during the ischemic episode, can be very helpful. Unlike younger patients, an S_4 gallop rhythm is very common in elderly patients with and without CAD; however, the appearance or increase in the loudness of an S_4 or S_3 gallop or MR murmur during the chest discomfort or dyspnea and its disappearance with relief of the chest discomfort or dyspnea are strong evidence in favor of a transient decrease in diastolic ventricular function, the most common cause of which is CAD. For the same reason, an electrocardiogram (ECG) taken during the time of the discomfort that shows definite ST segment elevation or depression, or marked T wave inversion, which reverses after the discomfort abates, is excellent evidence of severe CAD. Because LV hypertrophy is common in elderly patients, ST segment/T wave changes can be present chronically on a resting ECG and are of limited help in diagnosing myocardial ischemia unless the ST segment/T wave changes are transient and associated with chest discomfort.

SILENT ISCHEMIA.

The presence of significant CAD without symptoms increases with age. Because only about 20 percent of people older than 80 have clinically evident CAD[74] and over 50 percent have significant CAD at autopsy,[75] a large number of elderly people must have significant CAD without symptoms. About one third of asymptomatic hypertensive elderly patients have a myocardial infarction discovered incidentally on ECG. An equal number have silent ischemia. The reason for increased silent ischemia in the elderly patient is not known, but it may be related to mental status changes impairing perception or recall of ischemic pain, to the development of collaterals that reduce the severity of the myocardial ischemia, to autonomic dysfunction, or to increased sensitivity to endogenous endomorphins.[76] Although the presence of silent ischemia may not predict a worse prognosis for the patient with CAD than its absence, most people with silent ischemia have a positive exercise test result and so probably have more extensive CAD.

Diagnosis

The diagnosis of CAD in the elderly can be suspected by finding a history of typical angina or atypical symptoms related to exertion, and by a careful physical examination, as indicated earlier. Stress testing is done to establish the diagnosis and to determine risk stratification and prognosis (see Chap. 6) . The high prevalence and increased severity of CAD in the elderly, by Bayesian principles, increases the sensitivity of stress testing but makes it harder to exclude significant disease

because of more false-negative test results.[77]

The criteria for a positive exercise test result in the elderly do not differ significantly from those in the younger patient.[77] As in younger patients, the test is less likely to be positive with single-vessel disease but is 80 to 85 percent sensitive in identifying patients with three-vessel or left main CAD. In patients older than 60 to 65 years, the sensitivity for diagnosing the presence of significant CAD varies from 62 to 84 percent, and the specificity from 56 to 93 percent, depending on the population studied. The ability to walk through the second stage of Bruce protocol (>6 minutes) predicts low risk.[77]

The increased number of false-positive test results seen in the elderly is probably attributable to an abnormal resting ECG, the presence of LV hypertrophy from HTN or valve disease, or intraventricular conduction defects. Prognosis depends on the amount of ischemic and nonfunctioning myocardium, reflecting the effect of severity and extent of CAD on LV function. For risk stratification, attention should be paid to the chronotropic and inotropic responses to exercise, exercise-induced arrhythmias, and the duration of exercise. Arrhythmias are common in the elderly, especially at high workloads, but are not necessarily an adverse feature unless they occur with other signs of ischemia.[77] Inability to increase the heart rate to 85 percent of age-predicted maximum, or a hypotensive response to exercise, are poor prognostic factors, similar to those seen in younger patients.

PROGNOSTIC VALUE OF STRESS TESTING.

Stress testing offers challenges to the elderly. Many have orthopedic or neurological problems that prevent active walking on a treadmill. Many are physically deconditioned and may have an abnormal resting ECG, making criteria of ST segment shifts for positivity less reliable. In a study of patients older than 65 years observed for 2 years, those with ST segment depression during stress testing had a 17 percent cardiac death rate, whereas the incidence was only 2 percent in those without ST segment depression. [78] In patients older than 70 years who had exercise stress testing 3 weeks after an AMI and were observed for a mean of 4.5 years, of those who failed to increase double product from rest to exercise by more than 1500, and also developed ventricular arrhythmias with exercise, only 25 percent were still alive at the end of the follow-up time, whereas in the absence of either response, 77 percent were still alive.[78A] Patients after AMI who are unable to increase systolic BP with exercise greater than 30 mm Hg have a 1-year mortality of 15 percent compared with 2 percent for those who did increase their BP.[78B] Using the Duke treadmill score combining ST segment depression, chest pain, and exercise duration is useful to predict significant (>75 percent) stenosis and severe three-vessel or left main disease.[77]

When the patient can exercise, but the resting ECG is abnormal or has a feature that makes it impossible to diagnose ischemia (left bundle branch block, pacemaker, or marked ST segment changes), then myocardial perfusion study at rest and after exercise, using tracers such as thallium-201, technetium-99m sestamibi or technetium-99m tetrofosmin single-photon emission computed tomographic imaging (see Chap. 9) , or stress echocardiography (see Chap. 7) can be used to detect areas of scarring or ischemia. When exercise cannot be done, pharmacological tests using dipyridamole or adenosine to vasodilate coronary arterioles and increase coronary blood flow maximally to areas without stenotic arteries, or dobutamine to increase myocardial oxygen demand and create ischemia, can be used. Dobutamine stress testing is safe in the elderly. These techniques are more sensitive than exercise testing in identifying single- and two-vessel disease, and, like exercise testing, are also useful for risk stratification. With the use of thallium-201 perfusion tests on 120 patients older than 70 years with known or suspected CAD, three variables were associated with a cardiac event: (1) a maximum ST segment depression of
2 mm (27 percent with vs. 6 percent without), (2) peak exercise beyond stage 1 of the Bruce protocol (18 percent event rate in those who could not go beyond this stage vs. 6 percent in those who could), and (3) the presence of either a fixed or a reversible thallium defect (18 percent event rate with vs. 2 percent without). The combination of inability to attain peak exercise beyond stage 1 and the presence of any thallium defect were the most powerful predictors, with a relative risk of 5.3 at 1 year.[79]

Acute Myocardial Infarction (see also Chap. 35)

In the elderly, AMI results in an increase in mortality compared with younger patients. Eighty percent of all deaths due to AMI occur in those 65 years of age and older.[74] In a population-based study over a 20-year period between 1975 and 1995, patients aged 55 to 64 were 2.2 times more likely to die of AMI during hospitalization than were patients younger than 55, whereas patients aged 65 to 74, 75 to 84, and older than 85 years were at 4.2, 7.8, and 10.2 times greater risk of dying.[73] In the Global Utilization of Streptokinase and TPA for Occluded Coronary Arteries (GUSTO)-I study of 41,021 patients, in-hospital mortality from AMI younger than age 65 was 3 percent as opposed to 9.5 percent at age 65 to 74, 19.6 percent at age 75 to 85, and 30.3 percent in those older than 85 (Fig. 57-5) . [80] Age alone can result in changes that increase mortality from AMI due to increasing diastolic dysfunction, altered baroreceptor and beta-adrenergic receptor responsiveness, and age-related decreases in renal and pulmonary function, all of which make the patient vulnerable to increased complications. Older patients have an increased comorbidity with pulmonary, renal, and hepatic disease. A more adverse baseline status in AMI prevails with higher NYHA functional class, prior history of CHF, prior myocardial infarction, angina, HTN or diabetes mellitus, low EF, and cardiovascular disease; and more of the elderly are women.[81] Complications of myocardial infarction are also more frequent in the elderly, including

Figure 57-5 Effects of age on mortality and stroke, GUSTO-1 trial. Of 41,021 patients, 24,708 were younger than 65 years, 11,201 were 65 to 74 years, 4625 were 75 to 85 years, and 412 were older than 85 years. All patients had ST segment elevation and were treated with thrombolytic agents. Postdischarge 1-year mortality remained high in the oldest groups (6.1 percent and 10.3 percent, respectively) and continued to be low (1.5 percent) in the younger than 65 group. *(From White HD, Barbash GI, Califf RM, et al for the GUSTO-1 Investigators: Age and outcome with contemporary thrombolytic therapy: Results from the GUSTO-1 Trial. Circulation 94:1826-1833, 1996.)*

CHF, atrial arrhythmias, cardiogenic shock, and cardiac rupture.[82]

Management

Management of AMI

MEDICAL TREATMENT.

Treatment of patients with angina, acute ischemic syndromes, and AMI is similar to that in younger patients (see Chaps. 35 and 36) . For angina and acute ischemic syndromes, aspirin, nitrates, beta-blockers, calcium-channel blockers, ACE inhibitors, and anticoagulants such as heparin have all been found to be as effective in elderly as in younger patients.[83] In the older population, attention should be paid to impaired baroreceptor reflexes, decreased beta-adrenergic responsiveness, and stiff aorta. With ACE inhibitors or nitrates, especially short-acting nitroglycerin with venodilatation, postural hypotension can result in falls and injury. Combinations of digoxin, amiodarone, and calcium channel blockers can also produce profound bradycardia more easily in the elderly. These drugs should be initiated cautiously, beginning with lower doses than in younger patients and carefully watching for toxicity.[84]

In a study of 10,018 patients older than 65, after an AMI with no absolute contraindication to aspirin use, aspirin was associated with a 22 percent reduction in 30-day mortality.[85] Beta blockers are the antiischemic drugs of choice in elderly patients with stable angina,[86] and all appear to be equally effective in controlling angina.[87] Many studies demonstrate the effectiveness of beta blockers in reducing mortality after AMI, including in patients older than age 65.[88] Beta blockers are often not given to patients with chronic obstructive pulmonary disease, type I diabetes mellitus, a low LV EF, or a history of HF, even though they have been shown to reduce mortality in these groups also. Despite evidence of effectiveness, aspirin and beta blockers are underprescribed in the elderly, and patients with the highest risk for in-hospital death appear to be least likely to receive beta blockers. ACE inhibitors have also been shown to reduce mortality, and to prevent LV remodeling and the onset of CHF in patients after a large AMI[89] (see Chaps. 35 and 39) . Calcium channel blockers are equally effective, as are beta blockers, in controlling anginal pain.[87] Because of the tendency of rapid-acting calcium channel blockers to cause vasodilation, a drop in BP, and increased sympathetic tone, short-acting calcium channel blockers should be avoided. The use of slow-release, or new-generation long-acting, dihydropyridines are the calcium antagonists of choice.[87] After an AMI, however, calcium channel blockers have not been shown to decrease mortality; and in certain patients there is evidence that they are harmful, especially in those with decreased ventricular function, CHF, or bradyarrhythmias.[84] It is a consensus of the American College of Cardiology/American Heart Association AMI group that calcium channel blockers are used too often in patients with AMI and that beta blockers are the more appropriate choice.[84] [90]

Heparin is recommended in acute ischemic syndromes and has been shown to decrease the development of AMI and/or mortality in patients given aspirin compared with those given aspirin alone.[91] Most studies have not investigated patients older than age 75, where the incidence of intracranial bleeding is higher than in younger patients. No trial has specifically investigated fractionated or low-molecular-weight heparin, with varying molecular weights that bind specifically to antithrombin III in

patients 75 years of age and older.[91] Two major trials of the platelet glycoprotein IIb-IIIa inhibitors have been reported, with reduction in combined endpoints of myocardial infarction and death, but the number of patients older than 65 was small and no specific comments can be made.[91]

FIBRINOLYTIC THERAPY.

There is evidence that the older population with AMI benefits from fibrinolytic drugs with reduced mortality and preserved LV function. Pooled results from five major thrombolytic trials showed an absolute reduction in mortality of 3.5 percent in patients older than age 65 compared with 2.2 percent in the younger population.[92] There was also an absolute excess of strokes and other bleeding complications of less than 1 percent. Elderly patients take longer to reach the hospital after the onset of chest pain and are less likely to receive thrombolysis.[93] [94] Depending on the study, 10 to 50 percent of the elderly are excluded from thrombolytic therapy solely on the basis of age.[95] Observational studies indicate that older patients are at slightly greater risk of hemorrhagic stroke after fibrinolysis than younger patients.[96] In the elderly, especially those older than age 75, the incidence of serious bleeding, especially intracranial bleeding, must be balanced against any possible benefit derived from the use of fibrinolytics during an AMI.

THROMBOLYSIS VERSUS PRIMARY ANGIOPLASTY.

Several trials have shown no advantage to early angioplasty compared with medical management in patients with non-ST segment elevation myocardial infarction, except for those with ongoing ischemia.[91] However, none of these has addressed the elderly specifically. In patients with ST segment elevation AMI, percutaneous transluminal coronary angiography (PTCA) can restore antegrade flow in the infarct-related occluded artery, with Thrombolysis in Myocardial Infarction (TIMI) grade 3 flow in 90 percent of patients.[84] In a post-hoc analysis of high-risk patients (those older than age 75 with anterior myocardial infarction or tachycardia on presentation), mortality was only 2 percent in those with primary angioplasty, and 10 percent in those receiving thrombolysis ($p < 0.01$).[97] The difference was in part related to an excessive incidence of cerebrovascular hemorrhage with death in the thrombolytic group. The cardiac-related deaths were similar in the two groups.

Management of CAD

PERCUTANEOUS CORONARY INTERVENTION (PCI).

Coronary arteriography is more likely to be performed in elderly patients who are symptomatic and have CAD than in younger patients.[98] Elderly patients with high-risk CAD or angina not responding to medical management are being sent for PCI in increasing numbers because it is a less invasive procedure than coronary bypass surgery.[99] Although patients in general do very well, some studies document increasing procedural morbidity and mortality with advancing age, particularly past 80 years.

Multivessel PCI is successful in patients aged 65 and older, with an overall angioplasty success rate of 96 percent. Complete revascularization was accomplished in 52 percent, and 3.2 percent had a myocardial infarction or other major in-hospital complications. Independent predictors of mortality were EF less than 40 percent ($p < 0.001$), three-vessel disease ($p < 0.01$), female gender ($p < 0.02$), and PTCA from 1985 or earlier.[100] In one study, the octogenarian was more likely to be a woman and have multivessel disease, with high-grade stenoses and more complex lesions than the younger patient.[101] Procedural mortality rose fivefold in those older than 80 years compared with those younger than 60 years. The rate of postprocedural myocardial infarction was also one and one-half times higher in the elderly than in the younger patients. Angiographic success was equal to that in younger patients, and the rate of in-hospital bypass surgery after intervention was less than that in younger patients.[101]

CORONARY ARTERY BYPASS SURGERY.

There are no randomized studies comparing surgery to medical management in patients older than 65 years. Although there is limited information from randomized studies of coronary

surgery compared with angioplasty that have included elderly patients,[102] and many reports of elderly patients from the same institution who had either CABG or angioplasty,[103] the conclusions from such studies are limited. With medical advances in the treatment of CAD, and with more patients with lesser degrees of CAD receiving angioplasty, coronary surgery is being done more often than in the past on older patients with more complicated CAD. As age increases, the proportion of men to women undergoing CABG increases, as does the prevalence of severe angina and CHF. The severity of the distribution of coronary stenoses also increases with age, as well as the incidence of complications, including neurological events, wound infections, and death, increasing in every decade after age 40. In most surgical series, morbidity and mortality are greater in the elderly, particularly in those older than 75 years. [104] Perioperative mortality in the elderly patient varies in different studies, from less than 2 percent to 10 percent.[102] [104] Morbidity and mortality depend on the presence of comorbidity, the EF, and the diffuseness of the CAD but are generally higher in the elderly.[104] The elderly patient also has a higher incidence of complications such as stroke, renal failure, prolonged ventilation, and postoperative cardiac arrest.[104] [105] Carotid artery disease is also more common in the elderly.

In the Bypass Angioplasty Revascularization Investigation (BARI) trial, 709 patients aged 65 to 80 with multivessel CAD were randomized to bypass surgery or angioplasty.[102] Mortality at 30 days was 0.7 percent for PTCA and 1.1 percent for CABG. For patients both older and younger than 65, it was 1.7 percent. CABG resulted in greater angina relief and fewer repeat procedures in both younger and older patients. In older patients compared with younger patients, stroke was more common after CABG than after PTCA (1.7 vs. 0.2 percent), and HF and pulmonary edema were more common after PTCA (4.0 vs. 1.3 percent). The 5-year survival rate was 91.5 percent after CABG and 89.5 percent after PTCA in the younger patients and 85.7 percent after CABG and 81.4 percent after PTCA in the older. Stents[106] and minimally invasive or "off-pump" coronary artery surgery[107] offer advantages in the elderly for low risk revascularization. There is evidence of substantial improvement in health-related quality of life after PTCA in the elderly similar to that seen in the younger patients.[107A]

CARDIAC REHABILITATION (see Chap. 39) .

Fewer than half of eligible patients, and most elderly patients after a myocardial infarction or CABG do not participate in rehabilitation programs.[108] Because exercise capacity is reduced in the elderly after a cardiac event, exercise rehabilitation is especially important in this age group. Women and older patients are less likely to participate, as are those with lesser degrees of education and employment.[109]

Psychological depression is common after AMI and coronary surgery, especially in the elderly.[69] [110] Education and reinforcement that this reaction is a normal response to a major cardiovascular event, and mostly transient, can be very helpful. Erectile dysfunction is especially common after coronary surgery or AMI and should be inquired about. The energy used during sexual activity is usually less than 5 METs.[111] Most patients can return to normal sexual activity within 3 to 4 weeks after an acute event. If erectile dysfunction is a problem, encouragement to resume sexual activity gradually should be given; and drugs such as sildenafil, or intracavernosal or intraurethral prostacyclin, can be very effective. The patient should be cautioned about the need to avoid taking nitrates within 24 hours of taking sildenafil.[111]

Exercise prescriptions designed for the individual show substantial evidence for benefit of exercise in the elderly, with an increase in exercise tolerance and capacity, obesity indices, lipid profile, overall levels of physical fitness, and quality of life.[112] The greatest reduction in mortality with exercise training may occur in elderly men.[113] The benefits of cardiac rehabilitation have been shown to occur equally well in elderly women.[114] Rehabilitation programs for the elderly are safe. Data from 57,000 patients with over 2 million exercise hours identified only 21 cardiac events, including three fatal and eight nonfatal myocardial infarctions, during exercise training, or one cardiac event per 100,000, one AMI per 300,000, and one death per 1 million exercise hours.[115] [116]

HEART FAILURE

Heart failure is the leading first-listed diagnosis among hospitalized older adults[117] (Fig. 57-6) . Among an estimated 4 million U.S. residents with HF, 70 percent were older than 60 years. The National Hospital Discharge Survey estimated 871,000 hospital admissions annually with a first-listed diagnosis of HF from 1985 to 1995; the numbers of hospitalizations for any diagnosis of HF increase to 2.6 million, or 53 percent, over the 10-year period in question. About 78 percent of men and 85 percent of women hospitalized with HF were older than 65 years.

The etiology of HF in the elderly is the same as that in the younger populations. In the Framingham Heart Study, the prevalence of HF increased from 0.8 percent in the 50- to 59-year age group to 9.1 percent in the population 80 years and older.[118] Also in the Framingham study, the annual incidence of HF in men increased from 0.2 percent in the 45- to 54-year age group to 1.4 percent in the 75- to 84-year age group to 5.4 percent in the 85- to 94-year age group.[118] Whereas the majority of patients with HF younger than 65 years are men, of those over that age 60 percent are women, and the proportion increases with age.[119] Furthermore, there was a 27

percent increase in the incidence of initial hospitalization for HF in those 65 years and older from 1986 to 1993.[120]

The mortality from HF is very high in the elderly, particularly with advanced HF, and may be 10 to 15 percent at 1 month and as high as 30 percent or more at 1 year. Mortality rate increases exponentially after age 65 in both men and women.[120A] HF is not only an important reason for

Figure 57-6 Incidence of heart failure by age and sex: 30-year follow-up from the Framingham Heart Study. *(From Kannel WB, Belanger AJ: Epidemiology of heart failure. Am Heart J 121:951-957, 1991.)*

hospitalization but also is second only to HTN as a reason for outpatient physician visits, accounting for 12 million office visits per year in the United States.[121] HF in the older population consumes the most resources, with an estimated annual expenditure of $40 billion.[121]

PATHOPHYSIOLOGY (see Chap. 16) .

With aging, LV hypertrophy occurs as a result of increased afterload, a slowing of LV muscle relaxation, and stiffening of the LV, all of which lead to diastolic dysfunction as a prominent feature of HF. With a stiff LV, atrial contraction becomes most important in delivering a normal LV diastolic volume and keeping stroke volume normal (see Fig. 57-1) . Therefore, AF often precipitates, or markedly increases, symptoms of HF in the elderly population.[122] In fact, with advancing age, the proportion of people with LV failure but normal systolic function approaches 50 percent or more.[123] Diastolic dysfunction as a pathophysiological function of HF occurs more often in women than in men and also more often with hypertensive cardiovascular disease and diabetes.

DIAGNOSIS.

The diagnosis of HF can be difficult in the older individual. Symptoms of dyspnea on exertion or easy fatigability are often taken as signs of "getting older" or deconditioning or can result from other diseases, especially pulmonary disease, thyroid abnormality, anemia, or depression. Edema of the lower extremity is not unusual in older patients, because the skin turgor decreases and the patient is increasingly sedentary, with legs dependent much of the time. Edema-related liver and renal disease is also not uncommon. Symptoms of increasing orthopnea or development of nocturnal cough, shortness of breath, or paroxysmal nocturnal dyspnea should alert the clinician to the possibility of the diagnosis of HF.

Physical examination is particularly helpful with the findings of rales, tachycardia, and an S_3 gallop rhythm; with right-sided HF, an elevated jugular venous pressure or positive hepatojugular reflux can be seen, as well as a right-sided S_3 gallop rhythm. Chest radiography showing cardiomegaly, pulmonary congestion, or vascular redistribution confirms the diagnosis.

Echocardiography is especially helpful in identifying the presence of a dilated, hypokinetic LV. With pure diastolic dysfunction as a cause of HF, the patient often has LV hypertrophy, although LV systolic function may appear to be normal, with normal or near-normal EF. An S_4 gallop rhythm and echo-Doppler signs of delayed LV filling and diastolic dysfunction are frequently present. Clinical signs and symptoms of HF in the presence of a normal EF makes the diagnosis of pure diastolic dysfunction.

Management (see also Chaps. 18 , 19 , and 21)

The management of HF in the elderly follows the same principles as those in younger patients[124] (see Chaps. 18 and 21) . The goals of therapy are also the same, including a decrease or elimination of symptoms, reduction in rehospitalization, and improvement in quality of life. Prolongation of life is desirable but of lower priority in the aged person with HF. Treatment requires consideration of the etiology of the heart disease, the factors that can precipitate HF, and the medical management. For instance, the patient with HF due to AS requires aortic valve replacement; HF due to ischemic but viable myocardium requires revascularization. Managing problems that precipitate HF in patients with underlying heart disease can be important in their medical management. For example, in the patient with diastolic dysfunction who develops HF along with AF, conversion to normal sinus rhythm or, less desirable, control of ventricular rate is the most important treatment.[125]

Noncompliance with medical therapy, excessive salt intake and volume overload in the patient with renal failure, and infection are all causes of exacerbation of HF requiring rehospitalization. These factors contribute to 30 to 50 percent of recurrent episodes of HF in the elderly[126] and are the major reasons why between one third and one half of all patients hospitalized with HF are readmitted within 3 to 6 months of initial discharge.[126]

An effective way of managing elderly patients with HF is through a multidisciplinary approach and follow-up of patients at home through telephone calls, home visits by nursing personnel, and other patient contacts between office visits. Such an approach decreased the 90-day readmission rate by 32 percent in a group of 137 patients 80 to 96 years of age,[127] with improved quality-of-life scores and decreased overall cost. This multidisciplinary approach involves ongoing patient education, dietary consultation, medication review, daily weighings, and help with psychosocial problems and results in better compliance with medication[128] and overall cost reduction due to decreased rehospitalization.[129]

Although medications for HF are the same as those for the younger population, care must be taken not to cause hypovolemia, with marked reduction in stroke volume. Also, electrolyte levels should be monitored closely, especially in those patients taking digoxin and ACE inhibitors, because of the danger of renal dysfunction, hypokalemia, and hyperkalemia. A danger of hypovolemia is precipitation of falls in elderly patients, with subsequent hip fracture.[130] Another problem in elderly patients is that many are receiving NSAIDs, which can increase the risk of HF in elderly patients taking diuretics.[131]

DRUG THERAPY

ACE inhibitors, underprescribed in the elderly, are as effective in improving quality of life and reducing mortality as in younger patients.[132] Digoxin is useful in patients with HF who are in AF and/or are symptomatic on diuretics and ACE inhibitors.[133] However, in the elderly, lean body mass is decreased and renal function frequently is impaired; digoxin dosage is therefore lower than in the younger patient, and the danger of toxicity is greater. The Digitalis Investigation Group (DIG) reported that there was no decrease in overall mortality, but there was a decrease in hospitalization and mortality due to HF in patients receiving digoxin. Older age was an independent risk factor for all-cause mortality and rehospitalization, as well as for HF rehospitalizations and deaths.[134]

Angiotensin II type 1 receptor antagonists are probably as effective as ACE inhibitors, but they are still being evaluated in the elderly, although side effects are probably less often noted.[135] Candesartan was effective in improving exercise tolerance, as well as symptoms and signs of HF.[136] In patients unable to take ACE inhibitors or angiotensin II type 1 receptor blockers, hydralazine and isosorbide have been shown to reduce mortality in patients with HF (see Chap. l8) .

Beta blockers, if started in the usual dosage in patients with HF, will worsen the patient's clinical status; however, beta blockers started in small doses with titration upward have been shown to be very effective in improving quality of life of patients with HF, as well as increasing EF and exercise tolerance.[137] In the U.S. carvedilol study, patients with chronic HF and EF less than 35 percent were randomized to carvedilol versus placebo. Mortality was 65 percent lower in the carvedilol group in a 6.5-month follow-up.[138] Patients older than 60 years had results similar to younger patients. In this study, few patients were older than age 75 years. After AMI, beta blockers have been shown to decrease late mortality in the elderly population.[139]

In general, first-generation calcium channel blockers have been associated with adverse effects in patients with HF and as a result are usually contraindicated. If calcium channel blockers are indicated for ischemia, then those with little negative inotropic effect, such as amlodipine or felodipine, should be used.

DIASTOLIC DYSFUNCTION

The treatment of diastolic dysfunction in the elderly has not been well studied. If the symptoms are predominantly pulmonary congestion, then treatment with diuretics and/or long-acting nitrates will lower the filling pressure and decrease shortness of breath. However, overdiuresis can markedly drop the stroke volume and cause hypotension and prerenal azotemia. Beta blockers, by slowing the heart rate and increasing the diastolic filling period, can lower the filling pressure and improve LV compliance by decreasing LV hypertrophy. Similar benefits can result from ACE inhibitors and calcium channel blockers, and all of these drugs have been used in patients with HF and EF greater than 40 percent. Verapamil has been shown to improve symptoms in exercise capacity and diastolic function in older patients with HF

and EF less than 45 percent.[140] Whether results with spironolactone will be similar in patients older than age 75 years is unknown but likely (see Chap. 18) .

HYPERTENSION (see also Chaps. 28 and 29)

Both essential and secondary HTN, especially with renoarterial disease, are found in the elderly (see Fig. 57-3) . Isolated systolic HTN, as defined by a systolic BP greater than 140 mm Hg and a diastolic BP reading less than 90 mm Hg, is especially prominent in the elderly as a result of the decrease in arterial compliance and concomitant LV systolic stiffening.[3] The diagnosis of HTN should be made only after the BP is found to be elevated on three separate occasions. In the elderly, there are several problems in obtaining a correct BP using the BP cuff.[141] With noncompliant arteries, changes in stroke volume can result in wide variations in systolic BP. The patient should therefore be allowed to rest for 3 minutes before BP is taken.[141] Each time, BP should be taken two or three times and the results averaged. The "white coat" effect can be seen in 15 to 20 percent of all hypertensives, and it is especially common in the elderly.[142] Systolic BPs can vary as much as 20 to 40 mm Hg. For this reason, home or ambulatory BP recordings can be helpful in ascertaining the patient's usual BP.[143]

Another problem, termed "pseudohypertension," is caused by a brachial artery that is calcified and sclerotic and therefore not easily compressed by the BP cuff. The diagnosis of pseudohypertension can be made for certain only by comparing cuff systolic BPs to intraarterial pressures. Recently, doubt has been cast on the validity and usefulness of "Osler's maneuver," that of continuing to palpate a radial pulse with the BP cuff above auscultated systolic BP.[144] Falsely low systolic BPs can also occur because of the "auscultatory gap" in 20 percent of the elderly.[145] Here, Korotkoff sounds may be heard at 180 mm Hg, disappear, and then reappear at 130 mm Hg. If the BP cuff is not inflated to more than 180 mm Hg, the systolic BP will be incorrectly read as 130 mm Hg. This auscultatory phenomenon, the cause of which is unknown, is associated with age, female gender, increased arterial stiffness, and increased prevalence of carotid atherosclerotic plaques.[145] Pseudohypotension occurs when the BP is measured in an arm with an atherosclerotic obstruction proximal to the brachial artery. It can be suspected when there is a 30 mm Hg difference in BPs between the arms. A unilateral supraclavicular bruit is often heard. BP should always be taken initially in both arms and followed in the arm with the higher pressure.

HYPOTENSION.

Orthostatic hypotension, defined as a drop of more than 20 mm Hg in pressure on going from a supine or sitting to a standing position for 1 to 3 minutes, was present in the Systolic Hypertension in the Elderly Program (SHEP) study before therapy in one of every six elderly patients with HTN.[146] Orthostatic HTN is more likely to occur in an elderly person because of the noncompliant vessels and is especially likely to occur with hypovolemia due to diuretics or drugs interfering with vasoconstriction, such as alpha-adrenergic blockade given for HTN or benign prostatic hypertrophy.

Postprandial hypotension is especially common in elderly patients, occurring 30 to 120 minutes after a meal and causing drops in BP of more than 20 mm Hg. It is associated with lightheadedness, syncope, and falls and may be caused by vasodilation associated with excessive insulin response to a glucose load.[147] Decisions regarding BP control or change in therapy for HTN should take into account how long after the last meal the BP is taken.

EPIDEMIOLOGY

HTN is more common in blacks than in whites: About 45 percent of white, but 60 percent of black, men and women have HTN at ages 65 to 74.[148] In a study from a university geriatrics practice of 459 men and 1360 women, mean age 80 ± 8 years (range 59 to 101 years), HTN was present in 58 percent.[149] Because of its prevalence in the elderly, isolated systolic HTN was thought to be a natural consequence of aging. To the extent that there are changes in the arterial wall with aging that lead to less compliant vessels, a rise in systolic BP is a consequence of aging. That isolated systolic HTN is not a normal consequence of aging is reflected in the fact that epidemiological studies show a rise in systolic BP with age occurring only infrequently in most nonindustrialized societies. In a study in which participants at ages 50 to 89 were surveyed as to leisure activity (classified into light, moderate, heavy, and no physical activity), BP decreased with increasing levels of activity.[150] It appears, therefore, that there are environmental and life-style influences on the late rise in systolic BP with aging.

HTN remains the most common cause of HF, both with systolic and diastolic dysfunction. It is a strong risk factor for the development of CAD in both men and women. The Framingham Heart Study found that people 65 to 94 years of age with systolic BPs greater than 180 mm Hg had a threefold to fourfold increase in the risk of CAD compared with those whose systolic BP was less than 120 mm Hg.[53] A diastolic BP greater than 105 mm Hg caused a twofold to threefold higher rise in CAD than in those with a diastolic BP less than 75 mm Hg. Mortality is increased in elderly patients with HTN, mainly owing to HF and CAD.[53] In addition to mortality, the complications of HTN can be especially devastating: almost two thirds of those older than age 60 with untreated HTN will have a cerebrovascular accident, HF, myocardial infarction, or aortic dissection within 5 years.[151] Similar morbidity and mortality have been shown to occur in patients with isolated systolic HTN as in those with systolic and diastolic HTN.[152]

Although there is no doubt that lowering BP will reduce mortality, in old patients aged 80 to 85, there is paradoxical evidence of higher mortality with lower than with higher systolic or diastolic BP.[153] In one study of 561 people, including 82 percent of women aged older than 85, the 5-year mortality was lower in hypertensive (41 percent) than normotensive (72 percent) patients. It was highest in those with the lowest systolic BP (<120 mm Hg) or diastolic BP (<70 mm Hg) and was lowest in those with systolic BP greater than 160 mm Hg or diastolic BP greater than 90 mm Hg.[153] Another study found that patients with a mean age older than 75 with the lowest diastolic BP (<75 mm Hg) had the highest cardiovascular disease and all-cause mortality, whereas the highest diastolic BPs predicted higher survival.[154] The higher mortality in patients with the lowest diastolic BP suggests the possibility of decreased coronary perfusion pressure and subendocardial ischemia. This paradox of increased mortality in very old patients with a lower systolic BP and diastolic BP has been termed the "J curve,"[155] which is probably related to the effects of cardiac, respiratory, and neoplastic disease in those with low BP versus good myocardial function in those with HTN. Therefore, one cannot conclude that patients older than 75 to 80 years will not benefit from BP reduction. The SHEP study found no evidence of a J curve in treated patients with isolated systolic HTN.[156] However, a recent population-based cohort study[157] reported a risk of myocardial infarction in elderly patients with treatment of diastolic BP to less than 90 mm Hg, after adjusting for all other coronary risk factors.

Treatment (see also Chap. 29)

The recommendations for the treatment of HTN in the elderly do not differ from those for younger patients.[54] [158] Lowering even isolated systolic HTN decreases cardiovascular and total mortality, as well as hypertensive complications of HF, renal failure, and stroke.[55] [156] The goal of treatment of HTN in elderly patients should be a lowering of systolic BP to less than 140 mm Hg without creating postural hypotension or symptoms of organ hypoperfusion, such as elevated blood urea nitrogen or renal insufficiency.[158] If this is not possible, lowering systolic BP by 20 mm Hg is considered an acceptable response and has been associated with useful reduction in clinical cardiovascular events.[64] Benefits occur regardless of the class of antihypertensive drugs used.

The Swedish Trial in Old Patients with Hypertension (STOP-H) randomized 1627 patients with systolic/diastolic HTN, aged 70 to 84, to placebo versus atenolol, metoprolol, pindolol, or hydrochlorothiazide and amiloride. In a 25-month follow-up, a 28 percent decrease in fatal myocardial infarction, a 67 percent decrease in sudden death, and a 47 percent decrease in stroke resulted.[159] A meta-analysis of

1670 patients aged 80 or more, from randomized controlled trials of antihypertensive drugs, suggested that treatment prevented 34 percent of strokes and decreased the incidence of major cardiovascular events by 22 percent and HF by 39 percent. However, there was no treatment benefit for cardiovascular or total deaths. This suggests, in patients older than age 80, that there is benefit in reducing nonfatal cardiovascular events but not total mortality.[160]

Because of the expense and potential benefit in patients with CAD, diuretics and beta blockers are often the first choice in antihypertensive treatment in the elderly. In the patient with HF, ACE inhibitors should be used together with other drugs to decrease BP. Nitrates have recently been advocated in patients with isolated systolic HTN because they have an effect on arterial distensibility, reducing systolic BP without affecting mean BP or diastolic BP.[161] This has the theoretical benefit of not decreasing myocardial perfusion and would benefit those patients with HTN and concurrent CAD and cerebrovascular disease.

Nonpharmacological therapy, consisting of increased exercise, salt restriction, weight loss, and limited alcohol intake can be useful for patients with mildly elevated BP.[54] [158] There are few studies in elderly hypertensives of the effectiveness of this approach in decreasing BP and no evidence (unlike in pharmacological therapy) that it would decrease complications of HTN and mortality. The elderly have increased sensitivity to salt, so that salt loading increases BP and salt restriction reduces it.[162] In a meta-analysis of 11 randomized controlled trials, 5 included patients older than 60 years of age and 6 included patients with a mean age of 60. When all trials were pooled, a chronic high sodium chloride intake significantly increased systolic BP and diastolic BP by 6 and 3.5 mm Hg, respectively, and there was a significant

association between salt intake and systolic BP. A high sodium chloride diet in elderly patients with essential HTN is associated with a higher systolic BP and diastolic BP, and the effect is more pronounced in the older patient.[163] In 300,000 elderly nursing home patients (mean age, 83 years), HTN was diagnosed in 27 percent. About one fourth had six or more comorbid conditions. Seventy percent of these patients were receiving antihypertensive drugs, with calcium channel blockers the most common (26 percent), followed by diuretics (25 percent), ACE inhibitors (22 percent), and beta blockers (8 percent). The oldest subjects (>85 years) and those with marked physical or cognitive impairment were less likely to receive treatment.[164]

CARDIOMYOPATHY (see also Chap. 48)

Both dilated (DCM) (congestive) and hypertrophic (HCM) cardiomyopathy occur in the elderly. Most DCMs are of unknown etiology, just as they are in younger patients.

Amyloid Cardiomyopathy

Amyloid DCM is noted primarily in older people. Although small deposits of amyloidosis (senile amyloidosis) are often seen at autopsy, they are of no clinical significance in people younger than 85 years. Reactive amyloidosis, seen in chronic rheumatoid arthritis or bronchiectasis, usually does not involve the heart. In amyloid heart disease the amyloid, an abnormal fibrillar protein, is deposited intercellularly and in the walls of small coronary arteries[165] (see Chap. 48) .

The amyloid can involve only certain organs, or it can be a generalized disorder. The heart and tongue, with and without skeletal involvement, and the autonomic nervous system, are frequently involved. Amyloid infiltration of the heart causes thickening of the ventricles, which become less compliant to diastolic filling, resulting in the picture of restrictive cardiomyopathy. Senile amyloidosis, in the past thought to be a consequence of aging without clinical significance, is now known to contribute to HF in patients older than 85.[166] Of 142 men and 90 women with primary immunoglobulin light-chain amyloidosis, the median age at diagnosis was 59 years, with a range of 29 to 85 years, and was unusual in those younger than 40 (3.0 percent) and in nonwhites (6.5 percent). Macroglossia was seen in 27 percent. Patients most often demonstrated features of multisystem dysfunction, and cardiac amyloidosis was seen in isolation in only 3.9 percent. With cardiac involvement, the median survival was 1 year from diagnosis; and with the onset of HF, it was 9 months. Cardiac amyloidosis should be suspected in elderly patients with HF and a hypertrophied LV, possibly with "sparkling" myocardial characteristics and normal chamber sizes on echocardiography (see Chap. 7) , low ECG voltage (see Chap. 5) , and evidence of multisystemic disease.[167] An abnormal echocardiogram and signal-averaged ECG predict both all-cause and sudden cardiac death mortality, whereas an abnormal signal-averaged ECG independently predicts SD in those patients with an abnormal echocardiogram.[168]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is another important disease that is being diagnosed increasingly in the elderly patient.[169] HCM in elderly patients has been found in 4 percent of an unselected population of 379 elderly patients (mean age = 83 years) in a long-term health care facility.[170] In an echocardiographic survey of 15,137 people in a 33-month period, 44 patients with HCM (0.29 percent) were found, aged 16 to 87 years (mean age 57), 14 of whom were older than 60 years. Eighty-three percent had few or no symptoms; in 8 patients, symptoms began at age 70 or older. Resting systolic gradients were found in 38 percent of the patients. It is clear that HCM can remain clinically silent and undetected for many years, often to an advanced age.[171]

Compared with younger patients, the elderly with HCM have more mild HTN and fewer have a history of syncope. Echocardiography shows that the elderly have relatively mild LV wall thickening, generally confined to the basilar septum.[172] Another study showed that elderly patients with HCM had more concentric hypertrophy than younger ones. Microscopically, there is less marked septal myocyte disarray and intramural coronary artery thickening and less sudden cardiac death (see Chaps. 26 and 48) in older patients with HCM than in younger patients.[173]

In the symptomatic patient, beta blockers and calcium channel blockers are still the first line of treatment. Controlled trials with synchronous AV pacing have yielded mixed results, although most find a moderate to marked decrease in systolic LV outflow tract gradient. Some note a decrease in symptoms, increased quality of life measures, and increased exercise capacity[174] ; but others find no subjective or objective benefits.[175]

When medical management fails, surgical septal myomectomy has proven successful over the years, with an early mortality from isolated myomectomy of 3.6 percent. During the past 10 years, mortality was only 1.9 percent.[176] In 346 patients followed up to 26 years after surgery, the annual mortality was 0.6 percent compared historically to an annual mortality in unoperated patients that varied from 1.7 to 4 percent. The surgical patients also had long-lasting improvement in symptoms, exercise capacity, and quality-of-life indices.

Alcohol-induced transcoronary ablation of septal hypertrophy has been reported, with low mortality and significant improvement manifested by reduction in septal thickness, LV outflow tract gradient, and improvement in NYHA functional class and exercise capacity. There is also a significant improvement in LV passive filling volume,[177] a decrease in LV filling pressures at rest, and during exercise.[178] High-grade AV block can result.[178]

In those patients surviving a cardiac arrest or who have ventricular tachycardia (see Chap. 25) , or those judged to be at high risk for a life-threatening cardiac arrhythmia, an implanted cardioverter-defibrillator (see Chaps. 24 and 26) has proven to be very effective.[179]

ARRHYTHMIAS (see also Chaps. 23 , 24 , and 25)

Supraventricular Arrhythmias

The frequency of both supraventricular and ventricular arrhythmias increases with age. Premature atrial complexes (PACs) are extremely frequent in elderly people. Isolated PACs can be seen in resting ECGs of 5 to 10 percent of normal people older than age 60. With 24-hour ambulatory ECGs, the majority of patients older than age 65 have PACs, and even short runs of supraventricular tachycardia (SVT) of mostly three to five beats.[180] In mostly healthy subjects 65 years of age and older in the Cardiovascular Health Study, short runs of paroxysmal SVT (PSVT) were seen in about 50 percent of subjects, nearly doubling in prevalence from the late 60s age group to the 80s.[180] Both isolated PACs and short runs of PSVT have no prognostic significance for CAD in elderly patients over a 10-year follow-up period in the Baltimore Longitudinal Study of Aging Project.[181]

In general, patients with PACs or short runs of asymptomatic PSVT need no treatment except reassurance. If the patient is unpleasantly symptomatic, type IA or IC antiarrhythmic drugs are effective but should not be given to patients with underlying heart disease. Amiodarone or sotalol can be tried. PSVT, either AV nodal reentry, atrial tachycardia, or SVT associated with a bypass tract, is treated just as in younger patients. Adenosine can be used effectively and safely in elderly patients.[182] Although beta blockers, calcium channel blockers, and type IC antiarrhythmic drugs are effective for patients with repeated prolonged episodes of some SVTs, radiofrequency catheter ablation is done with success rates similar to that seen in younger patients.[183]

ATRIAL FIBRILLATION.

This is the most common chronic arrhythmia and increases with age. It is seen in 3 to 4 percent of subjects 60 to 65 years of age, a prevalence 10 times as high as that in the general population. The incidence doubles for each decade after age 60,[184] reaching 8.8 percent of the population older than 80 years.[185] About one third of patients with AF have paroxysmal episodes on 24-hour ambulatory ECG, and two thirds have chronic AF.[184] The prevalence of AF in men and women without cardiovascular disease in the Cardiovascular Health Study was 1.6 percent, rising to 4.6 percent in patients with subclinical, and to 9.1 percent in those with overt, cardiovascular disease.[186] Age-adjusted prevalence of AF increases strikingly in men with a prior myocardial infarction (4.9 to 17.4 percent).[187] AF most often occurs with underlying heart disease such as HTN, CAD, mitral valve disease, and HF. The presence of any cardiovascular disease increases the risk of AF by twofold to fivefold.[188] In elderly patients, thyrotoxicosis can manifest mainly by the onset of AF with a rapid ventricular response, so-called apathetic thyrotoxicosis.[189]

Symptoms and morbidity occur in older patients with AF. The rapid ventricular response can cause unpleasant palpitations; but also, with loss of atrial contraction, the booster-pump function of atrial systole is lost and stroke volume decreases (see Fig. 57-1) . If the rate is very rapid, BP may drop significantly. In the elderly, because of the less compliant LV, loss of atrial contraction is especially important. Uncontrolled rapid ventricular response can lead to HF or "tachycardia-mediated cardiomyopathy." In elderly patients with sick sinus syndrome, paroxysmal AF can result in syncope when the arrhythmia terminates and there is a long pause before sinus node function returns or if the subsequent rhythm is marked bradycardia (see Chaps. 23 and 25) . A most important problem associated with AF is that of thromboembolism, because of stasis of blood flow, especially in the atrial appendage, with thrombus formation and possible thromboembolism. In the Framingham Heart Study, the incidence of stroke in patients with AF rose from 1.5 percent in the 50- to 59-year age group to 23.5 percent in those older than age 80.[190]

A small number of older patients with AF have neither HTN nor any other cardiovascular disease and represent cases of so-called "lone" AF. The Framingham study found lone AF in 17 percent of men and 6 percent of women, with a mean age of 71 and 68 years, respectively. Follow-up for new cardiovascular events over a mean of 16 years revealed similar rates of CAD and HF as in control patients without AF, but a fourfold increase in the rate of stroke.[191] Patients younger than 60 years with lone AF do not have an increased risk of embolic stroke,[192] but increasing age increases the risk.[193] Risk factors that increase the incidence of thromboembolism and stroke during AF include diabetes, HF, advanced age, smoking, recent myocardial infarction, HTN, and enlarged left atrial diameter greater than 40 mm.[185] Patients older than age 75 years with diabetes, HTN, or prior transient ischemic attack/stroke have an annual stroke incidence of 8 to 12 percent.[192]

Warfarin reduces the incidence of stroke in patients with nonvalvular AF (see Chap. 25) , but the risk of bleeding, particularly intracerebral hemorrhage, is higher, especially in patients older than 75.[194] Nevertheless, in elderly patients it appears safe to use adjusted-dose warfarin with a low risk of major hemorrhage, if the international normalized ratio (INR) is maintained in the 2 to 3 range.[195] [196] Therefore, it is recommended that all elderly patients with AF without contraindications (active ulcer, recent surgery, bleeding diathesis, dementia, frequent falls or trauma) be anticoagulated to an INR between 2 and 3, with avoidance of higher INRs. In those who cannot take warfarin, an antiplatelet drug such as aspirin, 325 mg/d, although clearly not as effective as warfarin, is recommended.[197] Patients younger than 65 with lone AF can be treated with aspirin, or without antithrombotic therapy. In those older than age 75, therapeutic benefit must be balanced against the risk of intracerebral bleeding, but anticoagulation with INR between 2 and 3 is recommended with risk factors present that increase the chance of stroke. In others, aspirin should be considered.

In elderly patients with AF, an attempt to convert to sinus rhythm, preferably by direct-current cardioversion after 3 to 4 weeks of anticoagulation, can be made. Maintenance of sinus rhythm is most successful if the AF is not long standing (i.e., less than a year) and with minimal left atrial enlargement.[198] If this is not possible, or if the patient reverts to AF despite antiarrhythmic drug therapy, control of ventricular response is necessary with beta blockers, calcium channel blockers, or digoxin. If drugs fail to slow the ventricular rate, modification of AV nodal conduction by radiofrequency catheter ablation is successful. Radiofrequency ablation can also be used to eliminate rapidly discharging foci causing AF (see Chap. 25) .

Atrial flutter responds to low-energy direct-current cardioversion, which is the procedure of choice when the ventricular response is rapid. It can be an unstable rhythm, reverting to sinus rhythm or AF. If atrial flutter persists, RF catheter ablation can eliminate further episodes (see Chap. 25) . Although the incidence of thromboembolism is lower than with AF, anticoagulation is generally indicated for patients with atrial flutter, as in patients with AF.[199]

Ventricular Arrhythmias

Premature ventricular complexes (PVCs), like PACs, increase in prevalence and frequency with age and include simple and complex PVCs, ventricular couplets, and short bursts of ventricular tachycardia.[180] [184] [200] With exercise, PVCs increase in prevalence from 11 percent in the third decade to 57 percent in the ninth.[200] The prognostic significance of isolated or even complex PVCs depends on the presence or absence of underlying cardiovascular disease.[201]

The treatment of PVCs, even complex PVCs, is not indicated in asymptomatic patients who have no underlying cardiac disease. In symptomatic patients, beta blockers are often the initial drug of choice. Treatment of nonsustained and sustained ventricular tachyarrhythmias in the elderly in general is no different than in younger patients (see Chap. 25) . [202]

Conduction Defects

The changes in the sinus and AV nodes due to aging, along with the decreased sensitivity to adrenergic stimulation, create an increased incidence of sick sinus syndrome, as well as AV and bundle branch conduction disease. Individuals older than 80 years without cardiovascular disease are reported not to have sinus bradycardia less than 43 beats/min or pauses of more than 2 seconds.[180] Consequently, sinus bradycardia less than 40 beats/min or sinus pauses of more than 2 seconds may be manifestations of sick sinus syndrome. However, pacemaker implantation is not indicated in asymptomatic patients with these findings. In contrast, in the patient with syncope or presyncope or taking medications that aggravate the sick sinus syndrome, a pacemaker is indicated.

With aging, the incidence of AV and bundle branch block is increased, possibly as a result of increasing fibrosis and calcification of the fibrous skeleton of the heart.[201] Types 1 and 2 degree AV block can be benign unless associated with digitalis toxicity or symptoms and are usually the result of enhanced vagal tone. The presence of Mobitz type II and third-degree AV block is unusual, even in older patients,[201] and is always associated with advanced conduction system disease, requiring pacemaker implantation[203] (see Chaps. 23 , 24 , and 25) . In paced patients 65 to 79 years of age with isolated AV block, the survival rate was similar to matched individuals without AV block, whereas in those older than 80 years, the survival rate was lower than in matched controls.[204]

The QRS axis shifts leftward with age, becoming -30 degrees in 20 percent by age 90, perhaps due to increased LV mass or interstitial fibrosis of the anterior fascicular radiation. Right bundle branch block is found in 3 percent of healthy people older than 85 years, and in 8 to 10 percent of those with heart disease.[201] [205] The presence of left bundle branch block correlates strongly with age and may be a marker of slowly progressive degenerative disease affecting the myocardium. In 855 men older than 50 years observed for 30 years, 1 percent of those aged 50 and 17 percent at age 80 developed bundle branch block. No relationship between bundle branch block and ischemic heart disease or mortality was found. Men who developed bundle branch block had a larger-volume heart at age 50 and developed diabetes and HF during follow-up more often than control subjects.[206] In the Framingham Heart Study, 2 percent of subjects older than age 70 developed a nonspecific intraventricular conduction defect exceeding 120 milliseconds, which was associated with the presence of organic heart disease.[207] The presence of bundle branch block should lead to a search for underlying cardiac disease, but unless it progresses to advanced heart block it needs no therapy.

Chapter 58 - Coronary Artery Disease in Women

PAMELA S. DOUGLAS

Approximately one third of all deaths in women are attributed to coronary artery disease (CAD), making it the most common cause of death in women as well as in men (Fig. 58-1) . The proportion rises to over half of all deaths if all forms of cardiovascular disease are included, and CAD is increasingly important as longevity is enhanced and the population ages.[1] [2] Yet, in contrast to the dramatic decrease in cardiovascular mortality achieved for men in the past 20 years, there has been little improvement for women.

An enormous amount of scientific investigation is directed at understanding the causes and cures of CAD. Recognizing the influences of gender on basic biology may provide important keys to cardiovascular pathophysiology that may eventually benefit both sexes. In the clinical arena, CAD is increasingly thought of as a preventable disease as medicine acquires the knowledge and tools to reduce its incidence and modify its consequences. However, the benefits have not been as readily extended to women. This chapter addresses the similarities and differences in CAD risk factors, symptoms, diagnosis, and treatment between men and women. Knowledge of these and their incorporation into clinical practice will improve care for women and reduce the large health risk and burden of CAD.

RISK FACTORS FOR CAD IN WOMEN AND THEIR MODIFICATION

Perhaps the most important risk factor for CAD in women is the misperception that coronary artery disease is not a woman's disease--that it is somehow more benign or less important in women than in men.[3] This misconception, shared by both patients and providers, is gradually being corrected but still has important influences on all aspects of prevention, diagnosis, and treatment. If CAD is not believed to pose a significant risk, it is unlikely that patients will implement difficult life-style changes to prevent it or seek emergency care on development of symptoms. This underestimation of risk extends to offspring of women with CAD, who, despite a significant burden of modifiable risk factors, perceive their risk of CAD as being below average.[4] Similarly, providers have been shown to underestimate the likelihood of CAD presence, leading to neglect of formal risk assessment and failure to aggressively treat CAD once it has been detected. In addition, a woman's presentation style alters physicians' estimates of the likelihood of CAD, so that an actress whose demeanor was more business-like was judged to have a much higher probability of disease than one who behaved histrionically, despite identical histories and test results.[5] To reduce CAD mortality in women, it is critical that patients, providers, and the public recognize the importance of CAD and its prevention and treatment.

Factors associated with higher cardiac risk in men, including age, family history, smoking, hypertension, lipoproteins, and diabetes mellitus (see Chap. 31) , are also associated with increased cardiac risk in women[6] [7] [8] [9] [10] ; however, they may have a different relative importance. Moreover, additional factors such as hormonal status are equally powerful predictors of CAD in women. These differences have been formally incorporated into a variety of gender-specific risk assessment algorithms published by the American Heart Association (AHA) and others.[1] [7] [11] Furthermore, the

Figure 58-1 Number of deaths due to the seven leading causes of death in women and men in the United States in 1997, ranked in order for women. *(Data from National Vital Statistics Report 47[June 30], 1999.)*

approach to management of CAD risk differs somewhat in women. In recognition of this, the AHA and American College of Cardiology have published comprehensive guidelines for primary and secondary prevention of CAD in women.[7]

LIPIDS

(see also Chaps. 31 , 32 , and 33): Elevated total cholesterol and low-density lipoprotein (LDL) levels are only weakly associated with CAD in women and only in women 65 years old or younger.[8] [9] [10] [11] [12] [13] Instead, high-density lipoprotein (HDL) cholesterol is closely and inversely associated with CAD risk.[10] [14] Triglycerides are an independent predictor of CAD, particularly in older women.[10] [15] [16] Lipoprotein(a), a composite of LDL, apolipoprotein B-100, and apoliprotein(a), is also associated with higher cardiac risk in women.[17] [17A]

Treatment of dyslipidemia is generally accomplished by the same life-style changes and medications in men and women, although dietary interventions may be less effective in women.[18] Although clinical trials have generally not included women in sufficient numbers for independent prospective analysis, several recent studies employing aggressive, multifactorial treatment for lipid lowering have documented an equal or greater effect in women, for both primary and secondary prevention,[19] [20] [21] and after bypass surgery (see Chap. 33) .[22] Women, as well as men, display angiographic regression of coronary atherosclerosis and reduction in coronary events and death, even with normal baseline cholesterol levels.

In general, recommended dietary and pharmacological lipid-lowering strategies are similar in men and women and should be as aggressively employed. However, hormone replacement therapy may be a preferred primary therapy for postmenopausal women with low HDL[8] [23] (Table 58-1) . Effects of estrogen may be additive to or even supplant those of conventional lipid-lowering medications,[24] [25] because they include other beneficial effects in addition to lipid lowering, such as coronary vasodilation and antioxidant properties (see later).[26] [27] However, estrogen increases triglycerides in 20 to 25 percent of women, particularly those with elevated baseline levels,[28] who may therefore be less likely to benefit from hormone replacement therapy. An elevated baseline level therefore mandates careful monitoring of lipid levels after institution of hormonal therapy and consideration of transdermal rather than oral administration. Newer regimens include selective estrogen receptor modulators (SERMs), soy compounds such as isoflavenoids, and phytoestrogens, all proven to have beneficial effects on serum lipids in women,[29] [30] [31] but their place in the therapeutic armamentarium has not been established by large-scale randomized clinical trials.

Current recommendations for initiation of treatment and therapeutic goals (National Cholesterol Education Program [NCEP]-II) are similar in men and women and are based on LDL levels.[23] Despite the fact that HDL is a more powerful determinant of CAD risk in women, the NCEP-II guidelines do not include HDL except as a modifying factor, and then at a fairly low level for women. Similarly, triglycerides are not considered as a primary indication for treatment. Strong arguments have been made to alter these recommendations in favor of more aggressive therapy for indications other than LDL-lowering in women, particularly because it is not clear how well NCEP-II guidelines address the needs of women or the very elderly, who are predominantly female. The strikingly positive results achieved in recent statin trials suggest that these agents should be included in most lipid-lowering regimens designed for primary or secondary prevention of CAD for women.

DIABETES

(see also Chap. 63) . Diabetes is a risk factor for the presence and severity of coronary artery disease in both men and women but carries a greater incremental risk in women, completely eliminating the "female advantage."[6] [9] [11] [32] The AHA awards twice the weight to diabetes in women in calculating CAD risk,[11] similar to that of a systolic blood pressure of 173 mm Hg or above or a cholesterol level of 316 mg/dl or above. Even more than in men, diabetes dramatically increases the mortality of myocardial infarction in women.[9] [33]

Non-insulin-dependent diabetes is associated with obesity, abdominal and upper body fat distribution, hypertension, and insulin resistance, all of which have been associated with higher coronary artery disease risk.[32] This complex of abnormalities may be causally related to high circulating insulin levels. More so than in men, obesity and body fat distribution appear to be independent coronary artery disease risk factors in women.[6] [32] Diabetes is also linked with the presence of hyperlipidemia (elevated triglycerides, reduced HDL), especially in women,[32] although the lipoprotein response to adequate diabetic treatment is variable.[34] Finally, diabetes is associated with a variety of platelet abnormalities and endothelial dysfunction, additional contributors to CAD.[35] Regardless of mechanism, recent data from the Diabetes Control and Complications Trial suggest that intensive diabetes therapy reduces cardiovascular complications in young (younger than age 40) men and women.[36]

HYPERTENSION

(see also Chaps. 28 and 29) . The prevalence of hypertension in women greatly increases with age so that nearly 80 percent of women older than age 75 are hypertensive.[37] Hypertension carries an independent coronary artery disease risk for both men and women and substantially enhances the risks associated with hyperlipidemia, smoking, obesity, and diabetes. Antihypertensive treatment reduces both overall mortality and cardiac morbidity as well as the incidence of stroke; these effects are most striking in the elderly.[37] [38]

TABLE 58-1 -- EFFECT OF HORMONE REPLACEMENT THERAPY ON LIPOPROTEIN LEVELS (% INCREASE OR DECREASE)

	PLACEBO	E ALONE	E+PA (CYCLIC)	E+PA (CONTINUOUS)	E+PA (CYCLIC)
TC	-11	-20	-36	-36	-20

Additional data from Espeland MA, Marcovina SM, Miller V, et al: Effect of postmenopausal hormone therapy on lipoprotein(a) concentration. Circulation 97:979, 1998.

SMOKING.

Smoking is a strong independent risk factor for coronary artery disease in both men and women; although smoking rates in the United States are falling overall, they are currently increasing among young women.[39] This risk is present even with minimal exposure (
5 cigarettes/day) and is not improved by use of low-yield cigarettes. Smoking risk is strikingly synergistic with that of oral contraceptive use, especially in women older than age 35, and leads to an earlier menopause, another coronary artery disease risk unique to women.[40] Cessation of smoking appears to gradually eliminate the excess risk in women,[41] although women more often smoke to lose or maintain body weight and find it harder to quit than do men.

HEMOSTASIS.

Elevated fibrinogen levels appear to be an independent cardiac risk factor in men and women, although women have not been as well studied.[42] The mechanism(s) by which fibrinogen enhances risk are poorly understood, although high fibrinogen levels have been associated with other CAD risk factors, including hypertension, diabetes, smoking, obesity, hyperlipidemia, and menopause, and lower levels have been associated with exercise, hormone replacement therapy, and high HDL.[43] Gender differences in platelet function and hemostasis are virtually unexplored. Factor V Leiden mutation may be a marker for atherothrombotic risk in postmenopausal women taking estrogen replacement or, conversely, may identify those who can take such medication without such side effects.[44]

EXERCISE.

A sedentary life style is associated with CAD in both men and women, although the data for women are sparse.[45] The reported beneficial effects of exercise on CAD risk profile are less marked in women compared with men, with lesser increases in HDL and less weight loss resulting from similar exercise training.[18] In prospective observational studies, a lower fitness level has been associated with a 4.7-fold increased risk for all-cause mortality in women,[46] and higher activity levels have been associated with decreased relative risks for CAD (0.44) and stroke (0.51), independent of other vascular risk factors.[47] Recent data from the Nurses' Health Study defines the amount of exercise needed to prevent CAD, with a convincing dose-response relationship between the intensity of exercise and the reduction in risk.[48] Two aspects of this study were particularly important: brisk walking conferred the same benefit as vigorous exercise, and sedentary women who became active late in life reaped similar benefits as those who remained active throughout.

PSYCHOSOCIAL FACTORS

(see also Chap. 70) . The interaction of psychosocial and biobehavioral factors and heart disease is complex but perhaps has been more extensively studied in women than in men.[49] [50] Several of the cardiovascular risk factors discussed earlier are related to behavior (obesity, smoking, exercise) and are optimally treated with its modification. Perceived stress and its balance with situational control have been found to affect CAD risk in women as well as in men. Acute and chronic stress are thought to "trigger" myocardial infarction in both sexes by contributing to plaque rupture.[51] Social networks and support influence CAD outcome both independently and through the likelihood of compliance with therapeutic strategies (e.g., cardiac rehabilitation). The lack of social support has been associated with a worse outcome in both men and women, but its impact may be greater in women and women are more likely to survive their partners and live alone. Depression appears to be an independent risk factor for poor outcome after cardiac events or surgery in women, and cardiovascular outcome can be improved by specific therapy.[52]

INFLAMMATION

(see also Chap. 31) . Inflammation is increasingly recognized as a risk factor for CAD in women. In the Women's Health Study, C-reactive protein was as powerful an independent predictor as any other single factor.[52A] [52B] Women with the highest quartile of C-RP had a fivefold to sevenfold increased risk of cardiac and vascular events over a 3-year follow-up period. Other markers with lower, but still significant, risk include serum amyloid A, soluble intercellular adhesion molecule-1, and interleuken 6.

HORMONES: RISKS AND BENEFITS OF ESTROGEN

The ovary produces both estrogenic and androgenic hormones until menopause, when production decreases gradually over several years but does not fully cease. The risk of CAD in women rises thereafter, equaling that in men by age 75. Women who have an early menopause and/or bilateral oophorectomy experience a higher risk of CAD. Menopause, or estrogen deprivation, is associated with detrimental changes in cardiovascular risk factors, including an increase in LDL cholesterol, a small decrease in HDL, and an increased total ratio of cholesterol to HDL.[53] [54] Furthermore, menopause decreases aortic root elasticity and blunts nocturnal reductions in blood pressure, in association with the more subtle changes of concentric left ventricular remodeling and reduced contractility.[55] [56] Natural menopause seems to have little immediate effect on blood pressure, glucose tolerance, insulin levels, body weight, or physical activity other than that of advancing age.[54]

ORAL CONTRACEPTIVES.

Current low-dose oral contraceptives generally contain a synthetic estrogen, such as ethinyl estradiol, and a synthetic progestin, and pose only a very negligible cardiovascular risk for most patients.[53] [57] [58] The risk of arterial and venous thrombosis is low but is magnified by advancing age and especially by smoking. The risk of myocardial infarction is not increased by oral contraceptives unless the patient is older than age 35 and/or smokes cigarettes, and it appears to be entirely caused by thromboembolism rather than by coronary atherosclerosis, because the angiographic coronary plaque burden is actually lower in oral contraceptive users than in age-matched nonusers with myocardial infarction.

Because most regimens employ a combination of hormones, the effect of any given oral contraceptive on circulating lipoproteins represents the sum of estrogenic effects (higher HDL and triglycerides, lower LDL) and progestogenic effects (higher LDL, lower HDL). Newer agents such as norethindrone, gestodene, desogestrel, and norgestimate have beneficial effects on lipoprotein levels but may increase thromboembolic complications.[58]

ESTROGEN AND CARDIAC RISK FACTOR MODIFICATION.

Observations of the low risk of CAD in premenopausal women led to the hypothesis that estrogen is protective and led to clinical trials of estrogen therapy in men in the 1950s and 1960s. These studies used high-dose conjugated estrogens (up to 10 mg/day) and generally resulted in poor drug tolerance, little in the way of favorable risk factor modification, and an excess of thrombophlebitis, cholecystitis, and embolic events without evidence of cardioprotection. Large, randomized trials in women have only begun recently; results from many trials will not be available for several years. Currently, our knowledge of the value of hormonal replacement therapy in women is based on its prospectively demonstrated beneficial effects on cardiac risk factors, observational evidence of primary and secondary protection, and the negative results of the one secondary prevention trial published to date (Heart and Estrogen/Progestin Replacement Study [HERS]).[59]

In postmenopausal women, exogenous estrogen results in higher HDL (especially HDL_2) and apolipoprotein A1, and lower LDL, apolipoprotein B-100, and Lp(a),[17A] [53] [60] [61] [62] (see Table 58-1) . Importantly, the Postmenopausal Estrogen/Progestin

Interventions (PEPI) trial showed that the addition of a progestin to estrogen did not interfere with the LDL cholesterol-lowering effect of the latter but reduced endometrial hyperplasia. The use of micronized progestin was associated with an increase in HDL cholesterol.[60] Triglycerides and LDL are often increased in a dose-dependent manner; and although these increases are highly variable in magnitude, they may limit the use of estrogen in some patients. Transdermal estrogens appear to have lesser effects on all lipoproteins, suggesting that first-pass liver metabolism is important in mediating these effects. This mode of drug delivery may be preferred in women with marked triglyceride elevations at baseline or in response to the oral route.[63] Indeed, the alterations in lipoprotein metabolism result largely from estrogen receptor-mediated actions on apolipoprotein gene expression in the liver.

Actions of Estrogen

Estrogen was once thought to mediate all of its beneficial effects through alterations in lipid metabolism; however, this mechanism accounts for only one fourth to one third of its actions. The other, multiple beneficial effects provide additional "biological plausibility" for the observed reduction in CAD among premenopausal women or postmenopausal women taking hormone replacement therapy.[64] [65] Estrogen mediates most of its effects through specific receptors (at least two types, alpha and beta, have been described) that function as transcription factors altering gene expression when they are activated. Estrogen receptors are found throughout the vasculature as well as in reproductive tissues, bone, liver, and brain. Estrogen decreases the atherogenic oxidation of LDL both in vivo and in vitro and decreases the incorporation of lipids into the vessel wall, both protective mechanisms for estrogen replacement.[66] [67] Data from the Atherosclerosis Risk in Communities (ARIC) study suggest that estrogen's effect is largely physiological and not structural or anatomical.[61] [68] In support of this, estrogen is a direct vasodilator, with effects on nitric oxide release and calcium and potassium ion channels. Estrogen acutely decreases the paradoxical coronary vasoconstriction response to acetylcholine[69] and potentiates the endothelium-dependent vasodilation of conductance and resistance coronary beds and forearm vessels in women.[70] This effect may account for its symptomatic benefit in women with Syndrome X.[71]

Estrogen also regulates expression of a variety of vascular-related genes important in CAD. These include prostacyclin, endothelin-1, collagen, matrix metalloproteinase 2, E-selectin, vascular adhesion molecule, and vascular endothelial growth factor. A similar array of actions is noted on nonvascular genes, also deemed to be important in CAD, including growth and development genes (TGF-beta, epidermal growth factor, platelet-derived growth factor, flt-4 tyrosine), coagulation- and fibrinolysis-related genes (tissue factor, fibrinogen, protein S, coagulation factors VII and XII, PAI-1, tPA, and antithrombin III) and signaling-related genes. Together, these actions suggest a powerful role for estrogen in regulating vascular tone, the response to injury and repair, atherosclerosis, and coagulation. Clinical studies confirm estrogen's association with many of these systems. These effects include a decrease in thrombotic potential,[60] [72] enhanced fibrinolysis,[73] and lowered serum angiotensin-converting enzyme activity.[74] Reports of an idiosyncratic elevation in blood pressure and improved insulin sensitivity have not been confirmed by more recent clinical studies.[60] [61] At present, which of the many beneficial effects of estrogen are most important for the prevention of CAD has not been determined. An active area of research, this knowledge is critical to future development of clinical tools for the prevention and treatment of CAD in both men and women.

CAD Prevention with Estrogen

More than 30 epidemiological studies have examined the utility of estrogen in the primary prevention of CAD, and the vast majority report a significant benefit.[53] [75] [76] [77] [78] [79] [80] [81] The largest of these studies, the Nurses' Health Study, reported a relative risk of 0.56 for myocardial infarction or death in women currently using estrogen and 0.83 in everusers, after adjustment for age and risk factors.[81] Metaanalyses[75] [77] [80] have determined composite relative risks of 0.50 to 0.65 for both the development of and death from CAD in estrogen users.

Other documented benefits of estrogen therapy include the alleviation of menopausal symptoms, including vasomotor instability, prevention of urogenital atrophy and urinary tract infections, prevention of osteoporosis and fatal hip fracture (relative risk for death is 0.75 for users of estrogen), and prevention of colon cancer (relative risk 0.80).[53] [75] [79] A possible protective effect against stroke has been noted in several studies[82] but is not significant in others, including the large Nurses' Health Study (relative risk 0.97 for current users) and another recent meta-analysis.[75] It is possible that the relatively young cohorts examined may have influenced these findings (median age for stroke in women is 83 years). Estrogen replacement may also have beneficial effects on cognitive function, particularly in symptomatic women.[83]

The beneficial effect of reproductive hormones also extends to selective estrogen receptor modulators (SERMs). Tamoxifen, a first-generation estrogen agonist/antagonist with selective tissue effects, has been shown to have salutary effects on circulating lipoproteins[84] and to reduce the number of hospital admissions resulting from CAD and deaths due to myocardial infarction and vascular causes.[85] Raloxifene, a second-generation SERM, also has a beneficial effect on cardiac risk factors[29] [86] and does not cause breast or uterine hyperplasia, although its clinical cardiovascular benefit is unproven. In rabbits, it is a nitric oxide-dependent coronary vasodilator acting through estrogen receptor binding.[87] Studies in monkeys fed an atherogenic diet showed that, whereas raloxifene reduced LDL, it did not prevent plaque formation, as conjugated estrogens did.[88] The data regarding phytoestrogens and soy products (isoflavenoids) are even less clear. However, some women may prefer these agents, because they are seen as dietary supplements rather than pharmacological interventions, and the U.S. Food and Drug Administration has approved labeling of soy products as possessing efficacy in lipid lowering. These are very active areas of investigation and drug development, and many new prescription and over-the-counter compounds will be introduced in the near future, including those suitable for use in men. Ultimately, recommendations regarding their use await performance of randomized trials with clinical (and not surrogate) endpoints and demonstration of relative merit to conventional estrogen replacement therapy.

A smaller number of studies have evaluated the utility of estrogen in the secondary prevention of coronary artery disease. Women who were current or ever-users of estrogen had less severe angiographic coronary artery disease than never-users, even after correction for age, cholesterol, smoking, diabetes, and hypertension.[89] Long-term survival in women with a similar extent of angiographically documented coronary disease or after coronary artery bypass grafting is greater in women taking estrogen,[90] [91] and restenosis is reduced after angioplasty.

Although these observations are compelling, completion of the first randomized prospective trial of hormone replacement

therapy, HERS, has caused a dramatic rethinking of the potential benefit.[59] Contrary to expectations, there were no reductions in nonfatal myocardial infarction, coronary death, and overall mortality during 4.1 years of follow-up in 3763 postmenopausal women with CAD (Fig. 58-2). Instead, there was an excess of thrombotic events, particularly in years 1 and 2. As an alternative to abandonment of the hypothesis that estrogen is protective, investigators have cited the possible mitigating effects of concomitant progestin. However, the hormone replacement therapy regimen used (0.625 mg conjugated equine estrogens plus 2.5 mg medroxyprogesterone daily) did have beneficial lipid effects, raising HDL 10 percent and lowering LDL 11 percent, but also caused more thromboembolic events and

Figure 58-2 Coronary artery disease (CAD) events *(left)*, nonfatal myocardial infarction *(center)*, and CAD deaths *(right)* in the Heart and Estrogen/Progestin Replacement Study (HERS): Kaplan-Meier estimates of the cumulative incidence of events. The number of women observed at each year of follow-up and still free of an event are provided in parentheses. Log rank *p* values are 0.91 for primary CAD events, 0.46 for nonfatal myocardial infarction, and 0.23 for CAD death.*(From Hulley S, Grady D, Bush T, et al: Randomized trial of estrogen plus progestin for secondary prevention of coronary heart disease in postmenopausal women. JAMA 280:609, 1998. Copyright 1998, American Medical Association.)*

gallbladder disease. Another possible explanation is attrition of women with an early increased risk, such as for thromboembolism.[92] This hypothesis is supported by close examination of the time trends that reveal excess CAD events early and fewer later in the follow-up period. Further, there are questions regarding the statistical power of the HERS population and follow-up.[92A] A final hypothesis, that estrogen may increase vascular inflammation, is supported by several recent studies showing increased C-reactive protein among estrogen users,[93] [94] which may override antiinflammatory effects of lowered E-selectin in some individuals and is associated with increased cardiovascular risk.[52A]

In the light of these data it is hard to recommend initiation of estrogen replacement therapy for secondary prevention of CAD, yet patients currently on therapy should probably continue. Many questions remain.[92] [92A] [95] Some have suggested that use of a lower dose or different hormone regimen or the addition of aspirin would modify the early thromboembolic side effects. It is also unclear how these results should be applied to decisions regarding use of estrogen replacement therapy for primary prevention. Trial participants are currently being followed for longer term results, and other studies are in progress.

In addition to the questions HERS raises about efficacy, and the methodological limitations in other available studies, there are significant risks associated with estrogen use and logistic problems with its prescription. Chief among the risks of estrogen use is endometrial cancer, for which unopposed estrogen therapy carries a fivefold to eightfold increased risk, associated with an estimated threefold increased risk of death.[75] [78] Women without a uterus obviously do not share this risk, and it has been proposed that the addition of a progestin nullifies it. A potential detrimental effect on the cardioprotective action of estrogen of adding progestins has been anticipated because of their androgenic effect on circulating lipids; however, recent studies suggest that this factor may have negligible effects or may even be beneficial.[60] [80]

BREAST CANCER.

Estrogen may increase breast cancer risk, with meta-analyses showing little increased risk for short-term therapy, whereas a higher relative risk, up to 1.5, has been associated with long-term use (over 10 years) in the Nurses' Health Study.[75] [96] [97] This a strong psychological, if not biological, deterrent to estrogen replacement, especially in women with a personal or family history of breast cancer and a low likelihood of developing (i.e., no risk factors for) CAD. Women with established CAD or with risk factors and no family history of breast cancer would remain good candidates for estrogen replacement, and SERMs, which may actually reduce breast cancer risk,[98] could be preferred agents in others. The effects of the addition of progestins to estrogen on the incidence of breast cancer are unknown, but they appear to be minimal.[97]

WEIGHING RISKS AND BENEFITS OF ESTROGEN.

Three recent meta-analyses of estrogen replacement reviewed all available data on its effects on endometrial and breast cancers, hip fracture, stroke, and coronary artery disease.[75] [76] [77] [80] Combining these data with other information regarding the incidence and mortality of these diseases, detailed estimates of the gain/loss in life expectancy or assessment of summed risk weights with hormone therapy were derived. In these analyses, for most women, estrogen replacement enhanced longevity somewhat and SERMs added little benefit. However, simple life expectancy calculations may not address some women's concerns adequately.[99]

Other considerations in the decision to use estrogen replacement include the drug's side effects, such as vaginal bleeding, the need for careful monitoring for breast and uterine cancers and endometrial hyperplasia, and the costs of therapy and of monitoring.[75] [76] [77] The risk of thrombophlebitis is unclear at the doses currently employed,[100] but

it is likely elevated[59] ; it is unclear if aspirin use offsets this risk or if testing for prothrombotic tendencies, such as factor V Leiden mutation, can be used to exclude women at higher risk.[44] Finally, compliance with estrogen replacement therapy taken to relieve menopause symptoms is poor; there is no reason to think that this will improve in asymptomatic women taking estrogen for the prevention of future disease.[95]

A full evaluation of the risks and benefits of estrogen replacement cannot be made without considering the methodological flaws inherent in all available data and those crucial areas in which information is lacking. For primary prevention, the reliance on observational studies in the absence of randomized trials raises issues of selection bias, especially because women using estrogen are more likely to see their physicians frequently, to adopt healthy behaviors such as exercise, prudent diet, and smoking cessation, and to be of higher socioeconomic status.[101] For any woman, patient preference after careful counseling should be a dominant factor. Published patient algorithms are helpful in this regard.[76] [99] [102]

The most commonly used estrogen is conjugated equine estrogens at a daily dose of 0.625 mg. There is no evidence that cardioprotection is enhanced or even preserved at a higher dose, and side effects are often worse; indeed there is evidence that a dose of 0.3 mg is equally cardioprotective.[102A] Similarly, the optimal formulation, dosage, and regimen for progestins are unclear. The optimal timing of estrogen replacement is also unknown. Some workers suggest starting the drug at menopause and continuing indefinitely for women at high risk. The usefulness of beginning therapy at a more advanced age (e.g., with the first manifestation of CAD) is unknown, particularly in light of the HERS study.

ESTROGEN REPLACEMENT THERAPY GUIDELINES.

The American College of Physicians and others have published guidelines for counseling postmenopausal women about primary preventive hormone therapy that are well grounded in available knowledge.[76] [102] These guidelines suggest that, based on available data, estrogen replacement is likely of value in women with a high risk of developing osteoporosis or CAD. This proposal represents an enormous potential change in cardiovascular therapeutics and practice, as yet unsupported by data from randomized controlled trials, such as the Women's Health Initiative, which will not become available until 2005. It is important to recognize that whereas salutary effects of estrogen replacement on lipids have been demonstrated in prospective randomized trials, clinical benefits in primary prevention thus far are limited to observational studies and secondary prevention was not beneficial in the single large study completed to date.[59] It may be that untested, newer agents such as the SERMs or phytoestrogens[102B] may ultimately be preferred treatment. Ongoing randomized trials of primary and secondary prevention will prove whether the use of estrogen replacement in postmenopausal women is a viable strategy.

EVALUATION OF CHEST PAIN IN WOMEN

Clinical Syndromes and Natural History

It has long been assumed that the clinical expression of CAD is similar in men and women, yet available information suggests that gender differences in presentation and disease manifestations exist and should be considered in the evaluation of the patient with chest pain. Several studies document that women are more likely than men to present with angina and less likely to present with a concrete event such as myocardial infarction as either the first

Figure 58-3 Prevalence of angiographically documented coronary heart disease (CHD) in men and women according to age and chest pain syndrome. *(Modified from DeSanctis RW: Clinical manifestations of coronary artery disease: Chest pain in women. In Wenger NK, Speroff L, Packard B [eds]: Cardiovascular Health and Disease in Women. Greenwich, CT, Le Jacq Communications, 1993, p 68.)*

or subsequent manifestations of CAD.[3] Furthermore, women are on average 5 to 10 years older at the time of presentation. Perhaps even more than in men, the

prevalence of angiographic coronary disease varies dramatically according to the nature of the chest pain, the patient's age, and the presence and type of coronary risk factors[103] [104] [105] (Fig. 58-3) . This underlines the importance of good history taking and careful cardiovascular risk factor assessment in the evaluation of women with chest pain.[106]

A variety of factors influence the evaluation of chest pain in women, including patient and physician perception of disease risk (see earlier). Compared with men, women with chronic stable angina are older and more likely to have hypertension, diabetes, and congestive heart failure but are less likely to have had a prior myocardial infarction or revascularization.[107] Although equally likely to have effort angina, such women are more likely to experience pain at rest, during sleep, or with mental stress. Similarly, women undergoing a myocardial infarction are more likely to have nausea and jaw, back, or neck pain, or palpitations, and are less likely to report diaphoresis than men.[108] [109] These differences make the evaluation of a new symptom or disability more complex and make essential a gender-based approach to education of both lay and health personnel in the presentation of acute ischemic syndromes.

The reasons for these differences in symptoms are unclear. Women with acute myocardial infarction have similar angiographic findings, suggesting that the mechanism of infarction does not vary by gender.[110] However, women do have higher prevalences than men do of vasospastic angina and of microvascular angina,[104] [105] both of which are associated with atypical chest pain patterns, are often treated differently, and have a more favorable prognosis than epicardial coronary disease. Recent data suggest that such chest pain syndromes are related to myocardial ischemia with altered phosphocreatine metabolism documented by PET scan.[110A] Even in the presence of angiographically documented disease, gender differences in plaque components (more cellular and fibrous tissue in women), endothelial function (estrogen-induced coronary vasodilation), and hemostasis (higher fibrinogen and factor VII levels in women) may influence the pathophysiology and, therefore, the clinical manifestations of coronary disease.[43] [111] Finally, women more commonly have noncoronary chest pain syndromes, further complicating their clinical assessment.

Women with chest pain are less likely to experience a subsequent myocardial infarction or coronary death than men.[3] [112] [113] Although overall age-adjusted rates of death or myocardial infarction in women with angina are less than those in men,[112] of subjects older than age 65, women and men with exertional chest pain have the same relative risks of CAD death (2.7 vs. 2.4).[114] Other data suggesting that the prognosis of coronary disease is not more benign in women include the similar (if not worse) early mortality after myocardial infarction in women.[115]

Thus, determination of the etiology of chest pain in women can be difficult, hampered by the onset of CAD later in life, a setting of greater frailty and concomitant disease, the more common appearance of symptoms such as rest angina in patients with otherwise stable patterns, and the higher likelihood of alternative mechanisms of chest pain.

NONINVASIVE DIAGNOSTIC TESTING

(see also Chaps. 6 , 7 , 9 , and 13) . Although noninvasive diagnostic testing for CAD does not fully resolve the difficulties inherent in evaluating chest pain in women, careful test selection and interpretation can provide valuable information regarding the presence and severity of CAD in women. The general principles underlying noninvasive diagnostic testing do not differ in men and women.[116] The simplest diagnostic test, the resting electrocardiogram, reveals a higher prevalence of repolarization (ST-T wave) abnormalities in women with suspected coronary disease than in men (32 vs. 23 percent).[103]

Treadmill exercise testing carries a higher false-positive rate in women (38 to 67 percent) than in men (7 to 44 percent) in the same studies, in part because of a lower pretest likelihood of disease.[104] However, women have a low false-negative rate (12 to 22 percent) that compares favorably to that in men (12 to 40 percent) and suggests that routine testing reliably *excludes* the presence of CAD in women with negative tests. The exercise electrocardiogram also provides useful prognostic information in women.[117] [118] Variables contributing to test accuracy are resting ST-T wave abnormalities, peak exercise heart rate, number of diseased vessels, typical angina, age, gender, drug use (digitalis, diazepam), hyperventilation, conduction abnormalities, left ventricular hypertrophy, mitral valve prolapse, vasospasm, and hormonal influences. Although less common in women, false-negative studies may be contributed to by gender-specific characteristics, including reduced exercise tolerance and the higher prevalence of single-vessel disease in women.

The addition of imaging to electrocardiographic stress testing markedly improves its accuracy in women, as noted by recent meta-analyses[119] [120] and reviews[121] (Fig. 58-4; Table 58-2) . Planar thallium scans during treadmill exercise testing suggest moderate increases in sensitivity and specificity in women.[118] [119] [121] The use of single-photon emission computed tomography (SPECT) may not improve accuracy in women as it does in men.[122] Much of the inaccuracy of thallium scanning in women has been attributed to breast attenuation, which is reduced by use of higher-energy isotopes such as technetium-99m-sestamibi and by newer algorithms for attenuation correction (see Chap. 9) . [123] Coupling exercise testing with echocardiographic visualization of wall motion (i.e., exercise echocardiography) also improves diagnostic accuracy in women,[119] [121] [124] even more so than in men.[120] Similarly, the use of pharmacological stress agents (e.g., adenosine, dipyridamole, dobutamine) in women coupled with either echocardiographic or nuclear imaging shows substantial improvements in test performance over electrocardiographic results alone.[121]

Because few direct comparisons between exercise echocardiography and exercise-thallium or sestamibi testing have been reported, the objective basis for selecting one

Figure 58-4 Posttest likelihood of coronary artery disease (CAD) in a 55-year-old woman, depending on test results (positive, top; negative, bottom), type of chest pain (CP), and pretest probability of disease (in parentheses) as described in CASS (Edmond M, Mock MB, Davis KB, et al: Long-term survival of medically treated patients in the coronary artery surgery study [CASS] registry. Circulation 90:2645, 1994) and type of stress test performed (exercise electrocardiogram [ECG], thallium perfusion [Thal], echocardiographic imaging [Echo]). *(Data from Kwok Y, Kim C, Grady D, et al: Meta-analysis of exercise testing to detect coronary artery disease in women. Am J Cardiol 83:660, 1999.)*

modality over another must rely on meta-analysis and cost-effectiveness modeling. Recent meta-analyses[119] [120] have shown exercise echocardiography to have similar sensitivity and superior specificity to nuclear perfusion studies, with the accuracy of exercise ECG and exercise nuclear studies showing gender dependence, whereas that of exercise echocardiography is similar in men and women. Several formal cost-effectiveness models show stress echocardiography to dominate over nuclear techniques,[124] [125] [126] suggesting that diagnostic testing strategies employing exercise echocardiography as the first test might be superior.

CORONARY ANGIOGRAPHY.

Few studies have examined gender differences in invasive diagnostic testing. Women are more likely than men to experience vascular and renal complications from diagnostic angiography, possibly due to more advanced age, higher prevalence of diabetes, and smaller body size; the incidence of myocardial infarction, stroke, and death are similar.[127]

GENDER BIAS.

A 1987 study reporting that men with positive nuclear exercise tests were 6.3 times more likely to

TABLE 58-2 -- WEIGHTED MEAN TEST CHARACTERISTICS FOR EXERCISE STRESS TESTING IN THE DIAGNOSIS OF CORONARY ARTERY DISEASE IN WOMEN

EXERCISE TEST	NO. WOMEN	SENSITIVITY	SPECIFICITY	LIKELIHOOD RATIO (+)	LIKELIHOOD RATIO (-)
ECG	3721	61%	70%	2.25	0.55
Thallium	842	78%	64%	2.87	0.36
Echo	296	86%	79%	4.29	0.18

Modified from Kwok Y, Kim C, Grady D, et al: Meta-analysis of exercise testing to detect coronary artery disease in women. Am J Cardiol 83:660, 1999.

be referred to cardiac catheterization than women[128] gave rise to concerns that female patients were receiving inadequate or inappropriate care, a conclusion that has been supported by several subsequent studies. Coronary angiography is performed 28 to 45 percent more often and revascularization 15 to 27 percent more often in men than in women with a diagnosis of CAD.[129] Although awareness of gender differences is growing, these discrepancies still exist, such that both gender and race influence management of chest pain.[130]

It is clear that less aggressive treatment strategies in women do not represent optimal care even for patient groups with differences in disease prevalence, nor do they accurately reflect the difficulties in diagnosing coronary disease in women. Although women undergoing diagnostic stress testing[131] were equally likely to have a positive stress electrocardiogram (29 percent in women vs. 30 percent in men) or stress thallium examination (23 vs. 27 percent), they were less commonly referred for additional noninvasive testing (4 vs. 20 percent) or catheterization (34 vs. 45 percent). However, subsequent event rates were higher in women, whether they had a normal initial test (1.6 percent/yr death or myocardial infarction vs. 0.8 per cent in men) or an abnormal one (14.3 vs. 6.0 percent/yr). Both male and female patients who did undergo revascularization had no events, whereas women who were not revascularized had a worse prognosis than similarly untreated men. These data demonstrate not only a gender-based difference in clinical practice but a worse patient outcome in women treated less aggressively.

MANAGEMENT OF CHRONIC CAD IN WOMEN

MEDICAL THERAPY.

Because fewer studies have examined the medical treatment of chronic CAD in women, there is less evidence as to whether women respond similarly to men to conventional therapy. A recent review of gender differences in the efficacy of CAD treatment found evidence for similar benefit of antiplatelet therapy, beta blockade, nitroglycerin, thrombolytics, and angiotensin-converting enzyme inhibitors[132] (Fig. 58-5). Calcium channel blockade was not effective in either men or women. Although early data regarding aspirin were conflicting, newer observational studies suggest benefit but still await confirmation by a randomized clinical trial. The Nurses' Health Study showed that women older than 50 taking one to six aspirin per week had a 32 percent lower likelihood of myocardial infarction, [133] a borderline significant reduction that did not apply to younger women or higher doses. Another observational study in women with CAD revealed reduced adjusted relative risk for cardiovascular (relative risk 0.61) and all-cause (0.66) mortality. Diabetic, elderly, and symptomatic women benefited most, as did women with prior myocardial infarctions.[134] Aspirin and other antiplatelet agents also reduced vascular events in women.[135]

Interestingly, glycoprotein IIb-IIIa inhibitors provide additional benefit over aspirin in unstable coronary syndromes in women but not in men.[136] This finding suggests that, in women, platelets may play a more important role or may require more aggressive inhibition.

Cross-sectional studies reveal that women with CAD are more likely than men to be receiving nitrates, calcium channel blockers, sedatives, diuretics, and other antihypertensive agents but are equally or less likely to have been prescribed aspirin and beta blockers.[107] [131] Although this has improved somewhat, treatment levels are not yet equal, especially in older patients. The impact, if any, of these differences on the prognosis of coronary disease is unknown. Although the Coronary Artery Surgery Study (CASS) shows that women treated medically had better 12-year survival with angiographically documented zero-, one- or two-vessel disease than did men with similar anatomy,[137] other studies suggest that undertreatment of women is related to a worse outcome.[138]

REVASCULARIZATION.

Many studies have addressed the relative effectiveness of revascularization procedures (angioplasty and coronary artery bypass grafting [CABG]) in men and women. Unfortunately, comparisons of the results of medical management and percutaneous and operative revascularization are few. Instead, these studies have focused on gender differences in the population under study, making difficult the application of these data to the optimal care of individual patients. Virtually all data for both angioplasty and CABG have been derived from post hoc subgroup analyses of studies designed to address other issues.

Percutaneous Coronary Intervention (PCI) (see also Chap. 38) .

Virtually all PCI studies note a greater prevalence of comorbidities in women, including advanced age, hypertension, congestive heart failure, diabetes, severe concomitant noncardiac disease, and hypercholesterolemia.[138] [139] [140] [141] [142] [143] [144] [145] [146] The severity of angina is also greater in women, the condition being more likely to be unstable or to be of Canadian Class III or IV severity.[139] [141] [142] [143]

The likelihood of *angiographic success* of the application of balloon angioplasty or of new devices is similar in men and women in current series,[141] [142] [143] with lower success rates in women reported only in the older studies. In contrast, in most balloon angioplasty series, women experience higher complication and mortality rates, including groin complications, acute closure, and death, but not myocardial infarction or emergency coronary artery bypass grafting[140] (Table 58-3) . Indeed, the proportional risk of death from procedural complications is greater in women.[145] [146] The difference in outcome has been variously attributed to women's older age, smaller body size, greater severity of angina, more fragile vessels, and greater burden of comorbidity.[143] [147] More recent preliminary data from the National Heart Lung and Blood Institute (NHLBI) Dynamic Registry (1997-1998) and Northern New England Data Bases (1990-1993 and 1994-1996) suggest that the gender gap is narrowing, particularly with the growing use of new devices.[145] [148] [149]

The late outcome of PCI appears to be similar in men and women, with women more likely to experience angina

Figure 58-5 Proportional effects of treatment strategies on morbidity and mortality in women versus men from randomized controlled trials. Antiplatelet trials evaluated aspirin, dipyridamole, ticlopidine, sulfinpyrazone, or suloctidil versus active or placebo control in vascular disease (not coronary artery disease); beta blocker trials assessed atenolol, metoprolol, or propranolol versus control; calcium channel blocker studies evaluated diltiazem or verapamil versus control; the nitroglycerin trial assessed transdermal glyceryl trinitrate versus control; fibrinolytic trials tested streptokinase, anistreplase, urokinase, or alteplase versus control; comparative thrombolytic trials assessed streptokinase versus alteplase; and angiotensin-converting enzyme (ACE) inhibitor trials assessed captopril, lisinopril, or enalapril versus control. Unless otherwise specified, summary frequencies and odds ratios with 95 percent confidence intervals (C.I.) are presented. Asterisk indicates multivariable-adjusted odds ratio, percentages of patients only.*(Modified from Fetters JK, Peterson ED, Shaw LJ, et al: Sex-specific differences in coronary artery disease risk factors, evaluation, and treatment: Have they been adequately evaluated? Am Heart J 131:804, 1996.)*

and men more likely to experience cardiac events (myocardial infarction, revascularization or death).[140] [141] [142] [143] [146] [147] Two observational studies have suggested that estrogen use in postmenopausal women reduces restenosis,[150] [151] perhaps through acceleration of endothelial repair.

Coronary Artery Bypass Grafting (see also Chap. 37) .

Gender differences in outcome after CABG are well established and remain present even in the mid 1990s.[152] [153] [154] As with angioplasty, virtually every study has shown women to have more comorbidities and less favorable patient characteristics preoperatively. Women are also more likely than men to undergo urgent or emergent surgery. Women and men undergoing CABG are equally symptomatic, but women are more likely to have preserved ventricular function and less likely to have multivessel or three-vessel disease.

The mortality of women is higher than of men, with risk ratios of 1.4 to 4.4. This is particularly true for low- and medium-risk patients, with no difference in highest-risk patients, suggesting that other factors predominate.[154] In addition, women are less likely to receive internal mammary grafts or undergo complete revascularization and are more likely to experience the complications of heart failure, perioperative infarction, and hemorrhage.[152] [153]

The causes of this higher mortality appear to be multiple, including technical factors such as smaller body size and coronary diameter, advanced age, comorbidities such as diabetes and hypertension, and clinical factors such as the urgency of the procedure. Disease-related factors such as the extent and severity of angiographic stenoses and left ventricular dysfunction are also important in determining outcome, yet these factors tend to be more favorable in women. As with angioplasty, patient-related factors and comorbidities seem increasingly important to outcome, with more recent studies reporting continuing gender differences in outcome.[154] The impact of new techniques such as minimally invasive bypass surgery and grafting performed without circulatory arrest is unknown, but it may be greater in the frailer, older female population.

Women have a lower likelihood of being free of angina than do men and experience greater physical disability and less return to work. Rates of long-term survival, infarction, and reoperation are similar.

ACUTE CORONARY SYNDROMES (see also Chaps. 35 and 36)

Women have a different clinical presentation and hospital course after acute coronary syndromes and acute myocardial infarction and respond differently to both medical and

procedural therapies. Gender differences in acute myocardial infarction have been reviewed.[155]

CLINICAL SYNDROMES.

Women suffering from an acute coronary syndrome or myocardial infarction are likely to be older and more likely to have a history of hypertension, diabetes, unstable angina, hyperlipidemia, and congestive heart failure, and they are less likely to be smokers than their male counterparts.[155] [156] [157] [158] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168] [169] [170] [171] Women are also more likely to experience neck and shoulder pain, abdominal pain, nausea, vomiting, fatigue, and dyspnea in addition to chest pain.[163] [164] It is unclear if they are more likely to have silent infarctions.[3] Perhaps due in part to these more atypical symptoms, women seek medical attention more slowly[166] and even after hospital arrival may experience greater delays in receiving care.[157] [159] [163]

Women admitted to a hospital for acute coronary syndromes are more likely to have experienced a prior nontransmural infarction.[161] Women with infarction have more serious presentations, with greater prevalences of tachycardia, rales, heart block, and a higher Killip class on initial presentation.[157] [159] [161] [164] [166] Nevertheless, women are less likely to receive thrombolysis (even after controlling for eligibility)[156] [163] [164] [166] [167] and receive it later than do men.[159] [162] Women are also less likely to be admitted to a coronary care unit[166] [168] or to be hospitalized in an institution in which catheterization is available.[161] Most[161] [163] [165] [168] but not all[169] [170] studies find that women with acute infarction are less likely to undergo diagnostic catheterization during their hospital stay, even after controlling for age and a variety of clinical characteristics. Some studies have reported equal or near-equal rates of angioplasty and bypass surgery among catheterized patients,[159] [160] [165] [169] suggesting that differences in treatment disappear once disease is documented angiographically.[169] [171] However, this is not true in all series.[163] [164]

Women have higher rates of in-hospital complications from infarction, including bleeding, stroke, shock, myocardial rupture, and recurrent chest pain, than do men, although most of these differences disappear on correction for controlling for age and comorbidities.[159] [160] [172] Women with acute infarction are more likely to be treated with nitrates, digoxin, and diuretics than are men and are less likely to receive thrombolytics, antiarrhythmics, antiplatelet agents, and beta blockers.[158] [162] [166] Even after discharge, women are less likely to be scheduled for exercise tests or referred for cardiac rehabilitation, and recovery from infarction appears delayed with slower return to work and full resumption of all activities, with more sleep disturbance and psychiatric and psychosomatic complaints experienced. [173]

MORTALITY.

Mortality in non-Q-wave myocardial infarction appears to be similar to that in men, whereas women with unstable angina are less likely to have angiographic CAD or reinfarction and death.[174] [175] In acute myocardial infarction, early or in-hospital mortality in women is greater than in men, and adjustment for age and/or clinical characteristics serves to reduce this difference but not to eliminate it fully. This is particularly true in younger women (Fig. 58-6) . [115] [156] [176] [177] Analysis of a very large scale, population-based data set (as opposed to post hoc analysis of thrombolytic trial study populations[178]) indicated that gender differences in mortality decrease with age.[177] In part, this gap may be due to a higher rate of prehospital sudden death in men,[164] but this cannot explain the twofold greater mortality in women younger than 50 years of age compared with similarly aged men. Mortality 1 to 3 years after hospital discharge is similar in men and women, when adjustments are made for age and other baseline characteristics.[115] [179]

TREATMENT.

The reduction in mortality from thrombolysis in men and women with acute myocardial infarction is likely similar.[110] [163] [176] [179] The efficacy of thrombolysis also appears similar in men and women with similar rates of intracoronary thrombosis on pretreatment angiography[110] and of thrombolytic-induced, infarct-related artery patency and left ventricular function.[157] [160] However, complication rates, particularly hemorrhagic stroke and recurrent myocardial infarction, appear to be higher in women.[159] [160] [180] [181] Primary angioplasty is equally, if not more effective in women, as demonstrated by the Primary Angioplasty in Myocardial Infarction (PAMI) trial, in part due to the reduction in hemorrhagic stroke.[182] [183]

Medical treatment after hospital discharge appears to carry somewhat different benefits for men and women. Aspirin likely prevents reinfarction in women[134] ; calcium channel blockers are not of benefit. Two studies suggest

Figure 58-6 Odds ratios for death during hospitalization for myocardial infarction in women as compared with men, according to age. *A,* The unadjusted odds ratios were derived from the model that included sex, age, the interaction between sex and age, and the year of discharge. *B,* The adjusted odds ratios were derived from the model that also included race, insurance status, medical history, severity of clinical abnormalities at admission, type of management in the first 24 hours after admission, and time to presentation.*(From Vaccarino V, Parsons L, Every NR, et al: Sex-based differences in early mortality after myocardial infarction. N Engl J Med 341:220, 1999. Copyright 1999, Massachusetts Medical Society.)*

that men may experience more benefit than women when treated with angiotensin-converting enzyme inhibitors post-infarction.[184] [185] In contrast, beta blockade clearly provides a substantial improvement in postinfarction survival in women that is equal to, if not greater than, that seen in men.[186] [187] [188] Unfortunately, women are less likely to be discharged on beta blockers.[158] [162] [166]

CONCLUSIONS

Although gender differences in the epidemiology of CAD have long been appreciated, we have only recently begun to critically examine and analyze differences in heart disease between men and women. Application of this new knowledge to patient care requires education of both patients and providers, yet it is essential for optimal medical practice. Although the diagnostic and therapeutic management of CAD are based on principles common to men and women, differences exist in risk factors, hormonal influences, clinical presentation, diagnostic evaluation, treatment, and outcomes of interventions for coronary artery disease. Similar differences exist

in heart failure.[189] The astute practitioner will be able to incorporate knowledge of these differences into the care of each individual.

In the past 5 years, knowledge of gender-based cardiovascular pathophysiology and therapeutics has dramatically increased and will continue to grow as the many studies in progress close the gaps in our understanding of CAD in women. In particular, hormones and hormone replacement therapy, central to women's care, remain a large and unresolved area awaiting further elucidation of the basic biology and its translation into clinical care.

Chapter 59 - Cardiovascular Disease in Athletes

BARRY J. MARON

During the past several years, the medical community and the lay public have become increasingly interested in and concerned about the causes of sudden and unexpected deaths in young trained athletes.[1] Such catastrophes are always unexpected events and, though relatively uncommon,[2] [3] nevertheless achieve high visibility and have a particularly tragic and devastating impact on the community.[4] As a consequence, the cardiovascular diseases[4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] and circumstances[16] [17] [17A] responsible for sudden death in athletes participating in sporting activities have been the subject of several reports, and a large measure of clarification has resulted.

CAUSES OF SUDDEN DEATH

Several autopsy-based studies have documented the cardiovascular diseases responsible for sudden death in young competitive athletes or youthful asymptomatic individuals with active sports-related life styles.[2] [5] [6] [7] [8] [9] Of note, these structural abnormalities should not be confused with the normal physiological adaptations in cardiac dimensions evident in many trained athletes and consisting of increased left ventricular mass with end-distolic cavity enlargement or occasionally increased wall thickness.[18] [19] [20] It is also important to be cautious in assigning frequency estimates for various cardiovascular diseases as causes of sudden death in athletes; patient selection biases unavoidably influence the acquisition of such data in the absence of a systematic national registry.

Young Athletes

It has been convincingly demonstrated that the vast majority of sudden deaths in young athletes (age 35 years) are due to various congenital cardiovascular diseases (>20) (see Figs. 59-1 , 59-2 , 59-3 , and 59-4 .) [2] [4] [5] [6] [7] [8] [9] Indeed, virtually any disease capable of causing sudden death in young individuals may also do so in young athletes. It should be emphasized that all of these diseases are uncommon within the general population and do not occur with the same frequency as causes of sudden death in young athletes; indeed, most of the diseases are responsible for just 5 percent or less of all athletic field deaths.[4] [5]

HYPERTROPHIC CARDIOMYOPATHY (HCM) (see Chap. 48) .

The majority of studies show HCM to be the single most common cause of sudden death in young athletes, accounting for about one-third of these catastrophes.[5] HCM is a primary and familial cardiac malformation characterized by asymmetrical left ventricular hypertrophy and nondilated ventricular cavities[21] [22] [23] [24] (Fig. 59-2) , with heterogeneous expression and diverse clinical course. Disease-causing mutations in nine genes encoding proteins of the sarcomere (and >100 mutations) have been reported.[23] [24] HCM is a relatively common genetically transmitted disease, occurring in about 0.2 percent (1 in 500) of the general population.[25]

Not uncommonly, HCM is responsible for sudden cardiac death in young and asymptomatic individuals and frequently occurs during moderate or severe exertion.[21] [22] Indeed, the stress of intense training and competition (and associated alterations in blood volume, hydration, and electrolytes) undoubtedly increases that risk to some degree.[26] In HCM, particularly strenuous physical activity may act as a trigger mechanism for generating potentially lethal ventricular tachyarrhythmias, given the underlying electrophysiologically unstable myocardial substrate composed of replacement fibrosis (which is probably the consequence of

Figure 59-1 Causes of sudden cardiac death in young competitive athletes (median age, 17 years) based on systematic tracking of 158 athletes in the United States, primarily 1985-1995. In an additional 2 percent of the patients, no evidence of cardiovascular disease sufficient to explain death was identified at necropsy.
(increased) cardiac mass = hearts with increased weight and some morphological features consistent with (but not diagnostic of) hypertrophic cardiomyopathy. *(From Maron BJ, Thompson PD, Puffer JC, et al: Cardiovascular preparticipation screening of competitive athletes. Circulation 94:850-856, 1996. Adapted and reproduced with permission of the American Heart Association.)*

Figure 59-2 Morphological components of the disease process in hypertrophic cardiomyopathy (HCM), the most common cause of sudden death in young competitive athletes. *A,* Gross heart specimen sectioned in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis; left ventricular wall thickening shows an asymmetrical pattern and is confined primarily to the ventricular septum (VS), which bulges prominently into the left ventricular outflow tract. The left ventricular cavity appears reduced in size. FW = left ventricular free wall. *B-D,* Histological features characteristic of left ventricular myocardium in HCM. *B,* Markedly disordered architecture with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles. *C,* An intramural coronary artery with thickened wall, due primarily to medial hypertrophy, and with apparently narrowed lumen. *D,* Replacement fibrosis in an area of ventricular myocardium adjacent to an abnormal intramural coronary artery, and probably a consequence of ischemia. Ao = aorta; LA = left atrium; RV = right ventricle. *(From Maron J: Hypertrophic cardiomyopathy. Lancet 350:127-133, 1997.)*

ischemia) and disorganized cardiac muscle cells (see Fig. 59-2) .

Disease variables that appear to identify those individuals at greatly increased risk include prior aborted cardiac arrest or sustained ventricular tachycardia, family history of sudden or other premature HCM-related death (or high-risk genotype), multiple-repetitive nonsustained ventricular tachycardia on ambulatory Holter electrocardiographic (ECG) recording, recurrent syncope particularly when exertional and in the young, massive degrees of left ventricular hypertrophy, and possibly hypotensive blood pressure response to exercise.[22] Patients who have HCM and who are judged to be at high risk for sudden death may be considered for primary prevention of sudden death with prophylactic cardioverter-defibrillator implants.[27]

Although HCM may be suspected during preparticipation sports evaluations by the prior occurrence of exertional syncope, a family history of HCM or premature cardiac death, or the presence of a heart murmur, these features are relatively uncommon among all individuals affected by the disease.[22] Consequently, screening procedures limited to customary history and physical examination cannot be expected to identify HCM reliably and consistently.[28]

In some young athletes, segmental ventricular septal thickening (13 to 15 mm) consistent with a relatively mild morphological expression of HCM may be difficult to distinguish from the physiological and benign form of left ventricular hypertrophy that represents an adaptation to athletic training (i.e., "athlete's heart").[28A] [28B] Athletes

within this morphological "gray zone" present an important and not uncommon clinical problem in which the differential diagnosis between HCM and athlete's heart can often be resolved by noninvasive testing[29] (Fig. 59-3) . This distinction may have particularly important implications, given that young athletes with an unequivocal diagnosis of HCM are discouraged from participation in most competitive sports to minimize risk (with the possible exception of those sports considered to be of low intensity).[30] Conversely, improper diagnosis of cardiac disease in an athlete may lead to unnecessary withdrawal from athletics, thereby depriving that individual of the varied benefits of sports.

In addition, hearts encountered at autopsy not infrequently have increased mass (and left ventricular wall thickness) and nondilated ventricular cavities suggestive of HCM, but with other objective morphological findings not sufficiently striking to permit a definitive diagnosis.[5] It is

Figure 59-3 Chart depicting the criteria used to distinguish hypertrophic cardiomyopathy (HCM) from athlete's heart when the left ventricular (LV) wall thickness is within the shaded gray zone of overlap (13 to 15 mm), consistent with both diagnoses. *Assumed to be the nonobstructive form of HCM in this discussion, because the presence of substantial mitral valve systolic anterior motion would confirm, per se, the diagnosis of HCM in an athlete.
May involve various abnormalities, including heterogeneous distribution of left ventricular hypertrophy (LVH) in which asymmetry is prominent, and adjacent regions may be of greatly different thicknesses, with sharp transitions evident between segments. Also, patterns in which the anterior ventricular septum is spared from the hypertrophic process and the region of predominant thickening may be in the posterior portion of the septum or anterolateral or posterior free wall.
= decreased; LA = left atrial. *(From Maron BJ, Pelliccia A, Spirito P: Cardiac disease in young trained athletes: Insights into methods for distinguishing athlete's heart from structural heart disease with particular emphasis on hypertrophic cardiomyopathy. Circulation 91:1596-1601, 1995. Reproduced with permission of the American Heart Association.)*

uncertain whether some of these cases represent mild morphological expressions of HCM or, conceivably, unusual examples of marked physiological left ventricular hypertrophy associated with deleterious consequences.

CONGENITAL CORONARY ARTERY MALFORMATIONS (see Chaps. 43 and 44) .

Second in importance and frequency to HCM are the congenital coronary artery anomalies of wrong aortic sinus origin (occurring in about 20 percent).[5] The most common of these lesions causing sudden death in athletes appears to be anomalous origin of the left main coronary artery from the right (anterior) sinus of Valsalva,[31] [32] [33] although the mirror-image malformation, anomalous right coronary artery from the left aortic sinus, has also been incriminated in these catastrophes[33] (Fig. 59-4). Such malformations are difficult to recognize during life because they are usually unassociated with symptoms (e.g., exertional syncope or chest pain) or alterations in the 12-lead or exercise ECG; therefore, diagnosis requires a high index of suspicion.[31] Indeed, occurrence of one or more episodes of exertional syncope in a young athlete

Figure 59-4 View of the aortic root in wrong sinus origin of the right coronary artery from the left sinus of Valsalva in a 22-year-old man who died suddenly during a soccer match. Incision has been carried out into the right sinus of Valsalva, but no coronary ostium was found. Both the anomalous right coronary artery (arrowhead) and the left main coronary artery originate from the left sinus of Valsalva. The left main trunk has been opened and divides into anterior descending and left circumflex branches. (From Basso C, Corrado D, Thiene G: Cardiovascular causes of sudden death in young individuals including athletes. Cardiol Rev 7:127-135, 1997.)

necessitates definitive exclusion of a coronary anomaly. It may also be possible to identify (or raise a strong suspicion of) anomalous coronaries of wrong sinus origin using transthoracic or transesophageal echocardiography,[4] [34] which can then lead to anatomical confirmation with coronary arteriography. However, congenital coronary artery malformations cannot be reliably identified by standard preparticipation athletic screening.

These coronary malformations should result in exclusion from intense competitive sports to reduce the risk of a cardiac event.[26] Also, wrong sinus anomalies are amenable to surgical correction with bypass grafting, which is the most common approach to restore distal coronary flow.[4] [31] [32] [33]

Myocardial ischemia (see Chap. 34) in young individuals with coronary artery anomalies involving wrong sinus origin probably occurs in infrequent bursts, cumulative with time, ultimately resulting in patchy myocardial necrosis and fibrosis; this process could predispose to lethal ventricular tachyarrhythmias by creating an electrically unstable myocardial substrate. Potential mechanisms that have been advanced include (1) acute angled takeoff and kinking or flaplike closure at the origin of the coronary artery and (2) compression of the anomalous artery between the aorta and pulmonary trunk during exercise. Furthermore, the proximal portion of the artery may be intramural (i.e., within the aortic tunica media), which could further aggravate coronary obstruction, particularly with aortic expansion during exercise.

Other unusual causes of exercise-related sudden deaths in young athletes include hypoplasia of the right coronary and left circumflex arteries, left anterior descending or right coronary artery origin from the pulmonary trunk, virtual absence of the left coronary artery, and spontaneous coronary arterial intussusception and coronary artery dissection.[5] [8] [9]

CORONARY ARTERY DISEASE (see Chaps. 35 , 36 , and 37).

Atherosclerotic coronary artery disease may be responsible for sudden death during physical exertion in youthful athletes[2] [5] [6] [7] [8] [9] and can be associated with acute plaque rupture[35] (Fig. 59-5) . Indeed, Corrado and colleagues [36] have emphasized the occurrence of premature atherosclerotic coronary disease as a prominent cause of sudden death in young persons (including some competitive athletes) in the Veneto region of northeastern Italy. The coronary disease is usually confined to the left anterior descending coronary artery and is due to obstructive fibrous and smooth muscle cell plaques in the absence of acute thrombus. In one study of sports-related sudden deaths, not limited to competitive athletes, atherosclerotic coronary artery disease (as well as HCM) was the leading cause of sudden death.[6]

MYOCARDITIS (see Chap. 48) .

Although myocarditis is an acknowledged cause of sudden death in young athletes, with or without prior symptoms, definitive diagnosis may be difficult clinically (and at autopsy), particularly in the healed phase.[30] Indeed, the importance of myocarditis as a cause of sudden death in the young may have been previously exaggerated owing to overinterpretation of histological data[37] or the lack of standardized morphological criteria[30] ; others have suggested that this diagnosis is now probably underestimated.[4] In a large autopsy-based series of 134 competitive athletes, only 6 percent showed areas of myocardium with acute inflammatory changes, consistent with acute myocarditis,[5] or areas of idiopathic myocardial scarring possibly representing healed myocarditis. The inflammatory process of myocarditis (see Fig. 59-5) is usually triggerred by several viral agents, often enterovirus but

Figure 59-5 Cardiac morphological findings at autopsy in four competitive athletes who died suddenly. *A,* Gross specimen from an athlete with greatly enlarged ventricular cavities, consistent with dilated cardiomyopathy. *B,* Histological section of the left anterior descending coronary artery (*left*) and diagonal branch (*right*) showing severe (>95 percent) cross-sectional luminal narrowing by atherosclerotic plaque. *C,* Foci of inflammatory cells consistent with myocarditis. *D,* Histological section of the right ventricular wall showing islands of myocytes within a matrix of fatty and fibrous replacement characteristic of arrhythmogenic right ventricular cardiomyopathy. *(Adapted from Maron BJ, Shirani J, Poliac LC, et al: Sudden death in young competitive athletes: Clinical, demographic, and pathological profiles. JAMA 276:199-204, 1996. Reproduced with permission of the American Medical Association.)*

also adenovirus.[38] Chronic cocaine use may provoke a similar clinical and pathological profile.[39]

Myocarditis does not necessarily require permanent withdrawal from competitive athletics. Athletes should, however, undergo a prudent convalescent period of about 6 months after the onset of clinical manifestations and should be allowed to resume competition when ventricular function and cardiac dimensions have returned to normal and clinically relevant arrhythmias are absent on ambulatory monitoring and stress testing.[30]

INTRAMURAL CORONARY ARTERY (see Chaps. 34 and 37) .

It is unresolved whether the presence of short segments of the left anterior descending coronary artery (1 to 3 cm), tunneled and completely surrounded by left

ventricular myocardium (i.e., myocardial "bridges"), constitutes a potentially lethal anatomical variant responsible for sudden unexpected death in otherwise healthy young individuals during exertion.[40] Some regard muscle bridges to have the potential for producing critical systolic arterial narrowing (and residual diastolic compression), resulting in myocardial ischemia and, in one report, increased risk for cardiac arrest in young patients with HCM.[41] Short-acting beta blockers may alleviate anginal symptoms and ischemia by increasing luminal diameter of tunneled coronary segments and normalizing flow velocities, thereby suggesting that myocardial bridges may have pathophysiological significance.[42] Nevertheless, coronary blood flow occurs predominantly during diastole, and necropsy studies have frequently documented tunneled coronary arteries in patients who had not died suddenly.

AORTIC RUPTURE (AND MARFAN SYNDROME) (see Chaps. 40 and 56) .

Young athletes uncommonly die suddenly as a result of rupture of the aorta,[2] [5] [8] [9] including some with the physical stigmata of Marfan syndrome, in whom disruption of the aortic media with decreased numbers of elastic fibers is usually evident at autopsy (i.e., cystic medial necrosis). Certain individuals with Marfan syndrome may successfully participate in strenuous competitive sports for many years without experiencing a catastrophic event, presumably before the time aortic dilatation becomes marked and predisposition for dissection or rupture increases critically. Indeed, the presence of aortic dilatation is the primary determinant of whether athletes with Marfan syndrome should be judged medically ineligible for competition.[26]

VALVULAR HEART DISEASE (see Chap. 46) .

Aortic valvular stenosis has proved to be an uncommon cause of sudden death in young athletes,[2] [5] [6] [8] [9] although older hospital-based studies suggested that this lesion much more frequently caused sudden unexpected death in children and young asymptomatic adults.[37] This is probably because aortic stenosis is likely to be identified early in life (including during preparticipation screening), by virtue of the characteristically loud heart murmur, thereby leading to disqualification from competitive sports.[28] Despite its frequency within the general population (probably <3 percent),[43] mitral valve prolapse appears to be a very uncommon cause of morbidity or sudden death in young competitive athletes.[30] [43] [44]

CARDIAC CONDUCTION SYSTEM ABNORMALITIES (see Chap. 25) .

A spectrum of congenital or acquired abnormalities confined to the cardiac conduction system (in the absence of other structural cardiac abnormalities) has occasionally been regarded as the cause of sudden death in competitive athletes and other young people, presumably by producing heart block and bradyarrhythmias.[45] [46] These

Figure 59-6 Arrhythmogenic right ventricular cardiomyopathy in a 25-year-old man who died suddenly at rest. *Top panel,* Heart specimen is sectioned in a four-chamber plane viewed from the posterior aspect. Fatty replacement of the anterior right ventricular free wall and infundibulum is demonstrated by transillumination. *Bottom panel,* Macrohistological section confirming that fatty replacement of myocytes is confined to the right ventricular wall, sparing the ventricular septum and left ventricular free wall. Heidenhain trichrome stain ×3. (Reproduced with permission from Basso C, Corrado D, Rossi L, Thiene G: Arrhythmogenic right ventricular cardiomyopathy/dysplasia. *In* Nava A, Rossi L, Thiene G [eds]: Morbid Anatomy. Amsterdam, Elsevier Publishers, 1997, pp 71-86.)

include malformations of the atrioventricular conduction tissue, such as accessory atrioventricular pathways, or morphologically abnormal small intramural arteries to the sinoatrial node or atrioventricular nodes with thickened vessel walls and narrowed lumen. Such vascular abnormalities have been incriminated as determinants of sudden death and myocardial ischemia by virtue of tissue degeneration, scarring, and hemorrhage in the surrounding conducting tissue.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY (ARVC) (see Chaps. 25 and 48) .

ARVC is an unusual, often familial condition that may be associated with important ventricular or supraventricular arrhythmias and has been cited as a cause of sudden death in young individuals, including athletes.[47] [48] [49] ARVC is characterized morphologically by cell death in the right ventricular wall, in which myocytes are replaced by fibrous or adipose tissue, often associated with myocarditis and evidence of programmed cell death (Fig. 59-6 ; see Chap. 48). This disease process may be segmental or may diffusely involve the right ventricle. In several autopsy studies of sudden death of young athletes, ARVC is uncommon (i.e., <5 percent).[4] [5] [6] [9] An exception is reports from the Veneto region of Italy, where ARVC is the single most common cause of sudden death in competitive athletes (and HCM is uncommon),[7] because of either a unique genetic substrate or the longstanding Italian national screening program for competitive athletes,[50] which has probably identified and disqualified far greater numbers of athletes with HCM than ARVC.[51]

APPARENTLY NORMAL HEARTS.

Occasionally, no evidence of structural cardiovascular disease is demonstrable in athletes dying suddenly even after careful examination of the heart. In such instances (about 2 percent of athletic field deaths),[4] [5] it may not be possible to preclude with certainty noncardiac factors, such as substance abuse (see Chap. 70).[39] It is also possible that such deaths are due to either occult conduction system disease,[45] [46] clinically unidentified Wolff-Parkinson-White syndrome, rare conditions in which structural cardiac abnormalities are characteristically lacking at necropsy such as idiopathic ventricular fibrillation[52] and long QT syndrome,[53] or unrecognized segmental ARVC (see Chap. 25) .[47] [49]

Older Athletes

Older athletes (age >35 years) may also harbor occult cardiac disease and die suddenly and unexpectedly while participating in intense (often competitive) athletic activities. Unlike in youthful athletes, in older conditioned athletes, the cause of death is usually atherosclerotic coronary artery disease (see Chaps. 35 to 37) . The remaining deaths in older athletes are due to diseases unrelated to atherosclerosis, such as HCM or valvular heart disease.[30] [54]

Older trained athletes who have died suddenly of coronary heart disease, reported in several necropsy-based investigations,[10] [11] [13] [14] [15] compose a heterogeneous athletic population including runners training for competitive long-distance races and recreational joggers, as well as participants in sports such as rugby, squash, and golf. Most of these deaths occur during or just after physical activity. In contrast to young competitive athletes, most older athletes who have died of coronary heart disease had either known risk factors, cardiovascular symptoms, or prior myocardial infarction, with severe coronary artery involvement (atherosclerotic narrowing of two or three major extramural coronary arteries) and myocardial scarring.

PROFILE AND DEMOGRAPHICS

Prevalence and Significance

In young athletes, the frequency of sudden unexpected death that occurs during competitive sports and is due to cardiovascular disease appears to be low, occurring in about 1:200,000 individual student-athletes per academic high school year[3] and in 1:70,000 during a 3-year career. In comparison, older athletes have somewhat higher rates of exercise-related sudden death, reported to be 1:15,000 to 1:50,000 per year, usually in apparently healthy male athletes,[12] joggers, [11] and marathon racers.[15] Such estimates may suggest that the intense and persistent public interest in these tragic events in young individuals is perhaps disproportionate to their overall numerical significance. However, the emotional and social impact of athletic field catastrophes remains high because competitive athletes, to much of the lay public and physician community, intuitively represent the healthiest element of society.[1] [4]

Demographics

Based primarily on data assembled from broad-based United States populations,[2] [3] [4] [5] [6] [9] a profile of young competitive athletes who die suddenly has emerged. Athletes had participated in a large number and variety of sports, the most frequent being basketball and football (about 70 percent[5]), probably reflecting the relatively high participation level in these team sports as well as their intensity. In European studies, the most common sport associated with sudden death is soccer.[47] [51] The vast majority of athletic field deaths occurred in males (about 90 percent), largely of high school age (about 60 percent[5]); however, others achieved collegiate or even professional levels of competition.

The vast majority of athletes who incur sudden death are free of cardiovascular symptoms during their lives, with their underlying cardiovascular disease completely unsuspected. Sudden collapse has been associated with exercise in 90 percent of athletes, predominantly in the late afternoon and early evening hours, corresponding

to the peak periods of competition and training (particularly for organized team sports).[5] These observations substantiate that, in the presence of certain structural cardiovascular diseases, physical activity represents a trigger and an important precipitating factor for sudden death on the athletic field.

Although the majority of reported sudden deaths in competitive athletes have been in white males, one study showed a substantial proportion (about 40 percent) to be in African Americans.[55] The substantial occurrence of HCM-related sudden death in young black male athletes contrasts sharply with the infrequent identification of black patients with HCM in hospital-based populations and may be explained by disproportionate access to subspecialty medical care, which makes it less likely for African American patients to achieve a cardiovascular diagnosis such as HCM.

Screening and Preparticipation Detection of Cardiovascular Abnormalities

Detection of preexisting cardiovascular abnormalities with the potential for significant morbidity or sudden death is an important objective of the widespread practice of preparticipation screening for high school- and college-aged athletes.[56] Athletic screening in the United States has customarily been performed in the context of a personal and family history and physical examination.[4] [28] [56] [56A] However, the utility of these routine evaluations for both U.S. high school- and college-aged student-athletes is limited by the complex nature of the responsible cardiovascular abnormalities and the infrequency with which they occur within the general population, as well as apparent inadequacies in the

preparticipation cardiovascular screening process.[56A] For example, the approved history and physical examination questionnaires (which serve as guides to examiners) may be suboptimal for 25 percent or more of high school- and college-aged athletes.[56] [56A] Indeed, one retrospective study reported that potentially lethal cardiovascular abnormalities were suspected by preparticipation history and physical examination in only 3 percent of high school and collegiate athletes who ultimately died suddenly of these diseases (including only 2 percent of the HCM victims examined).[5]

Citing medical and ethical considerations, an American Heart Association consensus panel[28] recommended preparticipation cardiovascular screening, as well as a more systematic approach to implementation, to enhance the likelihood of suspecting or identifying important cardiovascular abnormalities. These recommendations included a personal and family history and physical examination targeted to detect those lesions known to predispose to sudden cardiac death.

Although the addition of noninvasive testing (e.g., echocardiography or ECG) to the screening process would undoubtedly enhance detection of many of the responsible lesions (particularly HCM),[51] this would be an unrealistic aspiration on a national scale in the United States owing to the prohibitive cost and other practical obstacles. It should be emphasized that no available screening design (even with diagnostic testing) is capable of detecting all important lesions and affected athletes, and medical clearance for participation in sports does not necessarily connote the absence of cardiovascular disease.

Eligibility Considerations for Athletes with Known Cardiovascular Disease

When a cardiovascular abnormality is identified in a competitive athlete, the following considerations arise: (1) the magnitude of risk for sudden cardiac death (or disease progression) associated with continued participation in competitive sports and (2) criteria for discerning whether individual athletes should be withdrawn from sports competition. In this regard, the 26th Bethesda Conference[26] affords prospective consensus panel recommendations for athletic eligibility and disqualification, taking into account the severity of relevant cardiovascular abnormalities as well as the intensity of sports training and competition. These recommendations are predicated on the assumption that intense physical exertion in the context of competitive sports may act as a trigger in certain predisposed athletes with underlying structural heart disease. Although that risk cannot be quantified with precision, temporary or permanent withdrawal of selected athletes with cardiovascular disease from participation in certain competitive sports is regarded as a prudent strategy for diminishing the likelihood of sudden death.[5] [26] [30] The Bethesda Conference report[26] provides clear benchmarks for the expected standard of care that may be used to resolve future medicolegal disputes and has been cited by a U.S. Appellate Court as consensus expert guidelines that team physicians should rely on in formulating appropriate decisions regarding the eligibility of competitive athletes with cardiovascular disease.[57]

Cardiac Risks of Sports Unrelated to Structural Cardiovascular Disease

Although uncommon, virtually instantaneous cardiac arrest may result from a relatively modest and nonpenetrating blunt blow to the chest, in the *absence* of underlying cardiovascular disease or resultant structural injury to the chest wall or heart itself (i.e., commotio cordis) (see Chap. 51) .[16] [17] [17A] Such occurrences are produced either by a projectile (most commonly a baseball, softball, or hockey puck) or by bodily contact with another athlete. The blow to the chest is not perceived as unusual for the sporting event, nor of sufficient magnitude to result in a catastrophe. A common scenario is that of a young baseball player at bat struck in the chest by a pitched ball thrown from a standard distance. Of note, many of these catastrophes have occurred in purely recreational situations at home or on the playground, with the fatal injuries often inflicted by family members.

There appear to be three determinants of a commotio cordis event: (1) chest impact located directly over the heart, usually of relatively low energy[16] [17A] ; (2) precise timing of the blow to a narrow 15-msec segment of the cardiac cycle vulnerable to potentially lethal ventricular arrhythmias, just before the T wave peak,[17] apparently also involving activation of the potassium-ATP channel (K_{ATP})[58] ; and (3) a narrow, compliant chest wall, typical of young children.[16]

Certain measures aimed at prevention of commotio cordis events have been considered. Softer than standard (safety) baseballs reduced the risk for ventricular fibrillation in an experimental model of this syndrome, suggesting that sudden death prevention may be achieved through modification of athletic equipment.[17] [17A] Wider use of padding designed to cover the precordium would theoretically protect against the occurrence of commotio cordis in youngsters competing in sports such as baseball, ice hockey, karate, lacrosse, and football. However, the infrequency of commotio cordis events represents an obstacle to documenting the effectiveness of any protective intervention.

Commotio cordis events are not uniformly fatal; about 10 percent of the reported victims are known to have survived, usually because of reasonably prompt cardiopulmonary resuscitation and defibrillation.[4] With enhanced public awareness of this syndrome, emergency measures are likely to be implemented more rapidly on the athletic field, possibly avoiding many future catastrophes.

Chapter 60 - Medical Management of the Patient Undergoing Cardiac Surgery

DAVID H. ADAMS
ELLIOTT M. ANTMAN

Several advances have occurred in cardiac surgery that make operative repair of a variety of cardiac lesions a viable therapeutic alternative for an increasing number of patients with cardiovascular disease. These advances include improvements in tools for assessment of perioperative risk, surgical and anesthesia techniques for myocardial revascularization, valve repair and replacement, and repair of complex congenital cardiac defects, as well as new approaches to management of patients with left ventricular dysfunction and cardiac arrhythmias.[1] [2] [3] [19A] [19B] [117A] [120A] [142A] Advances relating to minimally invasive cardiac surgical procedures have added additional options in the comprehensive care of patients with surgical cardiovascular disease.[4] [5] [6] [7] [8] [9] [40A] [60A] [60B] [60C] [65A] Perioperative medical and surgical supportive measures have progressed, including the proliferation of intraoperative transesophageal echocardiography,[9A] ventricular assist devices, pharmacological supportive strategies, and comprehensive blood conservation programs. Evidence suggests that translation of these improvements into routine surgical practice and institution of regular quality control surveillance measures have led to a reduction in risk-adjusted operative mortality for coronary artery bypass grafting (CABG) to less than 2 percent for the general population and 3 to 4 percent for the Medicare population.[10] [11] [12] [117A] However, the profile of patients referred for surgery has also changed and is characterized by greater proportions of patients with advanced age, depressed left ventricular function, multiple comorbidities, prior revascularization operations, and failed acute interventional procedures, which has led to higher mortality rates in tertiary care referral centers that are called upon to operate on such patients with greater frequency.[13] [14] [15] [16] [17] [18] [19] [19A] [19B]

This chapter summarizes the information required by the cardiologist, whose important responsibilities include collaboration with the surgical team for both preoperative and postoperative care, especially care of the medical complications that may develop.

PREOPERATIVE EVALUATION

GENERAL MEDICAL CONDITION.

Except for life-threatening conditions (e.g., proximal aortic dissection,[20] cardiogenic shock caused by ruptured papillary muscle in acute myocardial infarction, penetrating wound of the heart), it behooves the consulting cardiologist to assess the overall medical condition of the patient and advise the surgical team if postponement of the operation seems warranted[21] [22] [23] [24] [25] [26] [27] [28] [29] (Table 60-1) . Particular attention should be paid to the patient's potential for development of one or more of the following complications: (1) bleeding during cardiopulmonary bypass while heparinized or while anticoagulated after

TABLE 60-1 -- PREOPERATIVE LABORATORY EVALUATION OF PATIENTS UNDERGOING CARDIAC SURGERY

PREOPERATIVE LABORATORY TEST	ABNORMAL FINDING	COMMENT
Complete blood count	1. Anemia, especially Hct <35%	1. Anticipate that hemodilution will occur on cardiopulmonary bypass and blood loss will occur intraoperatively. In stable patients, preoperative iron supplementation (weeks) or erythropoietin therapy (days) should be considered. Patients with unstable angina, congestive heart failure, aortic stenosis, and left main coronary artery disease should be advised against autologous donation of blood in the preoperative period.
	2. WBC >10,000	2. Search for possible infection
Coagulation screen	1. Prolonged bleeding time 2. Elevated PT and/or PTTlevated PT and/or PTT 3. Thrombocytopenia	All these laboratory abnormalities suggest that the patient is at risk for bleeding postoperatively and may have excessive chest tube drainage. Corrective measures (e.g., vitamin K, fresh frozen plasma, platelet transfusions) should be considered preoperatively, and surgery may need to be postponed. Hematological consultation may be required if an inherited defect in coagulation (e.g., von Willebrand factor deficiency) is suspected
Chemistry profile	1. Elevated BUN/creatinine	Abnormal renal function that may worsen in the perioperative period (caused by nonpulsatile flow on cardiopulmonary bypass and potential low flow postoperatively); may necessitate temporary or even permanent hemodialysis
	2. Potassium <4.0 mEq/liter and/or magnesium <2.0 mEq/liter	2. Electrolyte deficits may place the patient at risk of arrhythmias perioperatively and should be corrected before induction of anesthesia
	3. Abnormal liver function tests	3. Patient may clear anesthetic agents as well as other cardioactive drugs more slowly. Low albumin level may indicate a state of relative malnutrition that may need to be corrected with nutritional support perioperatively
Stool Hematest	Positive for occult blood	Because heparinization will take place while on the cardiopulmonary bypass apparatus, the patient may be at risk for GI bleeding perioperatively. The source of GI heme loss should be investigated preoperatively if clinical circumstances permit. The potential for bleeding in the future may influence the choice of prosthetic valve inserted.
Pulmonary function	Reduced VC or prolonged FEV_1	Anticipate longer than usual process of weaning from ventilator postoperatively if FEV_1 <65% of VC or FEV_1 <1.5-2.0 liters. Obtain baseline arterial blood gas analysis on room air to help guide respiratory management postoperatively
Thyroid function	These tests are not ordered routinely but should be performed in cases of suspected hypothyroidism or hyperthyroidism, known thyroid dysfunction during replacement therapy, and atrial fibrillation in patients who have not undergone evaluation of thyroid function	Hypothyroid patients require prolonged period of ventilatory support postoperatively because of slower clearance of anesthetic agents Hyperthyroid patients have a hypermetabolic state that places them at increased risk of myocardial ischemia, vasomotor instability, and poorly controlled ventricular rate in atrial fibrillation
Echocardiography	1. Decreased LV ejection fraction	1. Patients with decreased LV function are at higher perioperative risk for surgery. Selected patients should undergo viability assessment

	2. Decreased RV function	2. RV dysfunction increases perioperative risk and identification may lead to preoperative assessment of reversibility of pulmonary hypertension
	3. Aortic stenosis	3. Mild to moderate aortic stenosis (gradient <25 mm Hg) may be treated by prophylactic valve replacement in selected low-risk patients
	4. Aortic insufficiency	4. Ventricular dimension will help guide decisions to perform valve replacement in addition to revascularization in patients with combined aortic regurgitation and coronary disease.
	5. Mitral insufficiency	5. Moderate or severe mitral regurgitation may warrant valve exploration in patients undergoing coronary revascularization
	6. LV aneurysm	6. May alert surgeons to the need of aneurysmectomy in selected patients
	7. Ventricular septal defect	7. Identification will suggest the need for early surgical intervention
Cardiac catheterization	1. Elevated LV end-diastolic pressure and pulmonary capillary wedge pressure	1. May remain elevated in the early postoperative period and indicate a need for careful attention to maintenance of adequate preload postoperatively
	2. Elevated right atrial pressure	May reflect tricuspid regurgitation or RV dysfunction from prior infarction. Such patients require vigorous volume expansion postoperatively to maintain adequate cardiac output.
	3. Elevated pulmonary artery pressure (and pulmonary vascular resistance)	Fixed pulmonary vascular resistance should be suspected when the pulmonary artery diastolic pressure exceeds the mean pulmonary capillary wedge pressure. Vigorous oxygenation and pharmacological support with a pulmonary vasodilator (isoproterenol, prostaglandin E_1) are important in such cases. Patients with a pulmonary artery diastolic pressure equal to the pulmonary capillary wedge pressure usually have more rapid resolution of pulmonary hypertension postoperatively
	4. LV mural thrombus	4. Increased risk of stroke perioperatively
	5. Status of internal mammary arteries	5. Highly desirable arterial conduits for planned revascularization surgery. [40] [41] Particular care required during reoperation if patent internal mammary artery bypass is in place from previous surgery
	6. Status of saphenous vein grafts	"Pseudoextravasation" of dye outside the lumen in a patent graft with slow flow probably represents thrombus-filled atherosclerotic aneurysm of the graft

BUN=blood urea nitrogen; FEV_1 =volume of air expired at 1 second; GI=gastrointestinal; Hct=hematocrit; LV=left ventricular; PT=prothrombin time; PTT=partial thromboplastin time; RV=right ventricular; VC=vital capacity; WBC=white blood cell count.Dialysis or creatinine MORTALITY SCORE MEDIASTINITIS

insertion of a mechanical heart valve prosthesis [30] ; (2) deterioration in renal function; (3) arrhythmias secondary to electrolyte imbalance; (4) sepsis from incompletely treated pulmonary, urinary tract, or dental infection or dermatological infection over the sternum or saphenous vein harvest site; (5) need for prolonged ventilatory support postoperatively because of underlying pulmonary disease and preoperative malnutrition; and (6) exacerbation of a neurological deficit because of carotid artery disease or prior stroke.[22] When perioperative intraaortic balloon pump support may be needed, the status of the iliofemoral circulation should be assessed bilaterally. Of note, the risk of limb ischemia may be reduced by the use of sheathless, small-caliber balloon pump catheters.[31] Despite the increased risk of perioperative morbidity and mortality, recent data indicate that patients with combined coronary artery disease and peripheral vascular disease have a greater likelihood of long-term survival and freedom from myocardial infarction with CABG surgery versus medical therapy, particularly in the presence of two- and three-vessel coronary artery disease.[32]

The *protein-calorie malnutrition* associated with cardiac cachexia has been shown to compromise cardiac function and is associated with a greater risk of respiratory failure, sepsis, and prolonged hospitalization. If the clinical situation allows, patients in whom cardiac cachexia is diagnosed should receive a few weeks of preoperative nutritional support before undergoing elective cardiac surgery. The general principles of nutritional support in cardiac surgical patients are outlined in Figure 60-1 .

RISK FACTORS FOR CARDIAC MORBIDITY AND MORTALITY.

Risk factors for morbidity and mortality after coronary revascularization surgery have been analyzed extensively.[33] [34] [35] [36] [36A] [36B] A commonly used, simple clinical severity scoring system is shown in Table 60-2 . Although patients with low-risk scores may be considered candidates for "fast-track" cost-saving measures such as admission on the day of surgery or early extubation postoperatively, those with higher-risk scores are likely to experience increased morbidity, required longer intensive care unit (ICU) stays and more consultations by specialists, and consume a greater proportion of medical resources. Furthermore, clinical severity scoring is helpful in identifying patients at high risk for operative mortality (score >10). By assembling and reviewing the data necessary for accurate assessment of a patient's operative risk, cardiologists can help with the appropriate clinical triage of patients, contain hospital costs, and facilitate consultations with other medical specialists (e.g., dialysis team) as needed. Patients at increased risk of mediastinal infection include the elderly and those suffering from diabetes mellitus, malnutrition, severe pulmonary disease that is likely to lead to prolonged postoperative ventilatory support, and macromastia in women.[37] [38] [39]

VENTRICULAR DYSFUNCTION.

An especially important aspect of the preoperative evaluation of a cardiac surgical patient involves estimating the extent of underlying ventricular dysfunction. Evidence exists that unrevascularized viable myocardium after myocardial infarction serves as a substrate for recurrent ischemic events.[39] [40] [40A] [41] [42] [43] Also, patients with severe multivessel disease and akinetic myocardial zones who suffer from chronic congestive heart failure as a result of hibernating myocardium (see Chap. 37) experience improved ventricular function after CABG.[39] Contemporary techniques that should be used for assessing myocardial viability in dysfunctional regions include imaging procedures that correlate perfusion with cell membrane integrity (thallium reperfusion), metabolic activity (positron-emission tomography), or contractile reserve (stress echocardiography).[39] [40] [40A] Clinicians should rely on imaging modalities with which they are most familiar and that are available at their institution.

Careful consideration should be given to the possibility of *right ventricular dysfunction* (see Table 60-1) , which

Figure 60-1 The nutritional status of cardiac patients has a significant impact on their postoperative outcome. Patients who are cachectic before elective cardiac surgery should be nutritionally bolstered for 2 to 3 weeks prior to surgery. Postoperative patients are in a hypermetabolic state and require increased nutrition to meet metabolic demands and facilitate wound healing. Oral diet is resumed 24 hours after uncomplicated surgery, and the diet is advanced as rapidly as tolerated. For patients who have perioperative complications such as stroke, a swallow evaluation is needed to assess the patient's ability to protect the airway during meals. If the patient fails the swallow evaluation or if the patient is intubated, nutritional requirements are met by early enteral feeding except in cases of gastrointestinal dysfunction. Oral feeding tubes are useful in the short term, while prolonged nutritional supportt is best handled by placement of an enteral tube.

should be suspected in patients with preoperatively elevated pulmonary artery systolic pressure (>60 mm Hg), a history of inferoposterior left ventricular infarction (which may be associated with right ventricular infarction), and longstanding tricuspid regurgitation. Patients with right ventricular dysfunction should receive an inotropic agent with vasodilating actions such as milrinone (5 mug/kg/min) or dobutamine (5 mug/kg/min) in addition to supplemental oxygen perioperatively in an attempt to lower pulmonary vascular resistance and improve right ventricular systolic performance. Intravenous nitrate infusions, in the perioperative period have also been shown to reduce pulmonary hypertension and ameliorate right ventricular failure. Inhaled agents, including aerosolized prostacyclin and nitric oxide, have also been shown to effectively lower pulmonary

TABLE 60-2 -- PREOPERATIVE RISK FACTORS FOR ADVERSE OUTCOMES IN PATIENTS UNDERGOING CABG SURGERY: A CLINICAL SEVERITY SCORING SYSTEM AND EVENT CURVES (NORTHERN NEW ENGLAND CARDIOVASCULAR DISEASE STUDY GROUP)

Preoperative Estimation of Risk of Mortality, Cerebrovascular Accident, and Mediastinitis

For use *only* in isolated CABG surgery

Directions: Locate outcome of interest, e.g., mortality. Use the score in that column for each relevant preoperative variable, and then sum these scores to get the total score. Take the total score and look up the approximate preoperative risk in the table below

PATIENT OR DISEASE CHARACTERISTICS	MORTALITY SCORE	CVA SCORE	MEDIASTINITIS SCORE
Age 60-69	2	3.5	
Age 70-79	3	5	
Age 80	5	6	
Female sex	1.5		
EF <40%	1.5	1.5	2
Urgent surgery	2	1.5	1.5
Emergency surgery	5	2	3.5
Prior CABG	5	1.5	
PVD	2	2	
Diabetes			1.5
Dialysis or creatinine 2	4	2	2.5
COPD	1.5		3.5
Obesity (BMI 31-36)			2.5
Severe obesity (BMI 37)			3.5
Total score			

PERIOPERATIVE RISK

TOTAL SCORE	MORTALITY (%)	CVA (%)	MEDIASTINITIS (%)
0	0.4	0.3	0.4
1	0.5	0.4	0.5
2	0.7	0.7	0.6
3	0.9	0.9	0.7
4	1.3	1.1	1.1

vascular resistance and improve perioperative right ventricular performance.[44]

Patients with mitral regurgitation and severe heart failure should undergo preoperative afterload reduction with such agents as oral angiotensin-converting enzyme (ACE) inhibitors and intravenous sodium nitroprusside to a systolic pressure of about 90 to 100 mm Hg. Potential contraindications to such preoperative afterload reduction include

TABLE 60-2 -- PREOPERATIVE RISK FACTORS FOR ADVERSE OUTCOMES IN PATIENTS UNDERGOING CABG SURGERY: A CLINICAL SEVERITY SCORING SYSTEM AND EVENT CURVES (NORTHERN NEW ENGLAND CARDIOVASCULAR DISEASE STUDY GROUP) *Continued*

Definitions

EF <40% (left ventricular ejection fraction): The patient's current EF is less than 40%

Urgent: Medical factors require patient to stay in hospital to have operation before discharge. The risk of immediate morbidity and death is believed to be low

Emergency: Patient's cardiac disease dictates that surgery be performed within hours to avoid unnecessary morbidity or death.

PVD (peripheral vascular disease): Cerebrovascular disease including prior CVA, prior TIA, prior carotid surgery, carotid stenosis by history or radiographic studies, or carotid bruit. Lower extremity disease including claudication, amputation, prior lower extremity bypass, absent pedal pulses, or lower extremity ulcers

Diabetes: Currently treated with oral medications or insulin.

Dialysis or creatinine
2: Peritoneal dialysis- or hemodialysis-dependent renal failure or creatinine
2 mg/dl

COPD (chronic obstructive pulmonary disease): Treated with bronchodilators or steroids

Obesity: Find the approximate height and weight in the table below to classify the person as obese or severely obese. Obesity: BMI 31-36. Severe obesity: BMI 37.

Example: A patient 5
7
and weighing 200 lb is classified as obese. If the patient weighed 236 lbs or more, that patient would be classified as severely obese

HEIGHT (FEET AND INCHES)	WEIGHT (LB)		HEIGHT (FEET AND INCHES)	WEIGHT (LB)	
	Obesity: BMI 31-36	Severe Obesity: BMI 37		Obesity: BMI 31-36	Severe Obesity: BMI 37
5 0	158-184	189	5 8	203-236	244
5 1	164-190	195	5 9	209-243	250
5 2	169-196	202	5 10	215-250	258
5 3	175-203	208	5 11	222-258	265
5 4	180-209	215	6 0	228-265	272
5 5	186-217	222	6 1	235-273	280
5 6	191-222	228	6 2	241-280	287
5 7	198-229	236	6 3	248-288	296

BMI=body mass index; CABG=coronary artery bypass surgery; CVA=cardiovascular accident; TIA=transient ischemic attack.

concomitant severe aortic stenosis and hemodynamically significant cerebral or renal vascular disease. In these patients, early intervention with intraaortic balloon counterpulsation may be useful. Intraaortic balloon support is also commonly used in the setting of severe decompensation from acute mitral regurgitation secondary to conditions such as papillary muscle rupture. Infarct-related ventricular septal defect is another hemodynamically significant lesion that may require pharmacological and intraaortic balloon support in the perioperative period.

RISK OF MYOCARDIAL ISCHEMIA.

Acute thrombolytic and interventional catheterization treatment regimens for acute myocardial infarction may not successfully restore coronary perfusion because of inadequate thrombolysis, reocclusion of the infarct-related artery following initially successful thrombolysis, or dissection/acute thrombosis of the target vessel during angioplasty.[45] [46] Identification of patients for referral for emergency bypass surgery and decisions regarding the timing of such surgery remain a challenging clinical problem, particularly in view of the high perioperative mortality rate for patients who require surgery within 24 to 48 hours of thrombolysis.[46] [47]

Potential indications for emergency bypass surgery following failed attempts at reperfusion in acute myocardial infarction include significant left main stenosis and inability to maintain patency of the infarct-related artery, severe multivessel coronary artery disease with anatomy unsuitable for angioplasty and ischemic dysfunction of the noninfarct zones, and inability to maintain patency of an infarct-related artery that places a large amount of myocardium in jeopardy (proximal left anterior descending) in patients with an infarct of less than 6 hours' duration.[45] [46] Although some clinical reports suggest that patients in cardiogenic shock who undergo urgent revascularization have improved survival in comparison to those who are not revascularized, these series suffer from potential selection bias, and definitive recommendations regarding the management of patients with cardiogenic shock and acute myocardial infarction must await the results of ongoing randomized trials.[45]

Patients who are referred for emergency revascularization surgery should be supported by an intraaortic balloon pump and, if technically feasible, an intracoronary perfusion catheter. Other methods for mechanical assistance of the failing circulation are described in Chapter 19 . Because patients who undergo emergency bypass surgery within 6 to 12 hours of administration of a thrombolytic agent are at greater risk for intraoperative and postoperative hemorrhage, they should receive a hemostatic agent such as aprotinin (2 million kallikrein-inhibiting units [KIU] over a 20-minute period, followed by a continuous infusion of 500,000 KIU/hr).[48]

Patients with other manifestations of an acute coronary syndrome such as active unstable angina may also be in tenuous hemodynamic balance as they proceed to the operating room, particularly if significant left main coronary artery stenosis or severe three-vessel coronary artery disease associated with left ventricular dysfunction and/or mitral regurgitation is present. Delays while awaiting surgery and the time between the induction of anesthesia and the institution of cardiopulmonary bypass are high-risk periods during which a vicious spiral of myocardial ischemia and low-output syndrome can rapidly develop. Such patients should be protected by an intraaortic balloon pump inserted preoperatively and infusion of nitroglycerin.

ANESTHESIA FOR CARDIAC SURGERY.

The details of the practice of cardiac anesthesia are beyond the scope of this chapter and are available in other sources.[49] High-dose synthetic narcotics that do not cause vasodilatation, such as fentanyl and sufentanil, have replaced morphine in many centers. Early extubation protocols are now followed in most cardiac units for patients with low or moderate risk. Advantages of early extubation include a decrease in respiratory complications, ventilatory support, and length of stay in the ICU. To achieve early extubation within 6 hours of surgery, anesthetic techniques have included combinations of inhalational anesthetics, such as enflurane and isoflurane, together with low to moderate amounts of intravenous opioids, such as fentanyl and sufentanil, along with the intravenous anesthetic propofol. The newer, inhaled anesthetics that have replaced nitrous oxide still have the potential to cause vasodilatation. Patients with critical aortic stenosis, critical mitral stenosis, and large right-to-left shunts may experience a dramatic reduction in cardiac output as ventricular stroke volume falls with a reduction in preload. Preoperative volume expansion and even administration of vasopressor agents may be necessary to avoid this problem.

Cardiac Rhythm

Although supraventricular arrhythmias after cardiac surgery are seldom life threatening, they frequently provoke disturbing symptoms, may jeopardize hemodynamic stability, and are associated with an increased incidence of postoperative stroke, increased length of stay in the ICU, and increased hospital costs.[50] [51] [52]

In the past it was a common preoperative practice in many institutions to administer digitalis prophylactically to all patients undergoing cardiac surgery, not only for inotropic support but also for "control" of the ventricular rate if atrial fibrillation (AF) occurred postoperatively.[52] There is little reason to believe that digoxin prevents the development of AF; indeed, clinical trails do not clearly substantiate either a lower incidence of AF or a slower ventricular rate in AF in patients treated prophylactically with digoxin.[53] Futhermore, hypoxia, hypokalemia, elevated catecholamine levels, and reduced clearance of digoxin are common postoperatively, and these conditions may predispose the patient to digoxin toxicity.

ATRIAL FIBRILLATION

Because of the hazards of postoperative AF, considerable effort has been devoted to identifying preoperative factors associated with an increased risk of postoperative

arrhythmia.[52] Such factors include advanced age and male gender. It has been proposed that a prolonged P wave duration recorded on a signal-averaged electrocardiogram (ECG) and greater than 70 percent narrowing of the lumen of the right coronary artery are associated with an increased risk of postoperative AF.[54] [55] However, for a substantial number of patients with postoperative AF, no apparent preoperative risk factor can be identified. Cox has presented clinical data suggesting that about one-third of patients undergoing cardiac operations are vulnerable to postoperative AF because of mild nonuniformity in the distribution of their trial refractory periods.[56] Intraoperative atrial ischemia associated with rapid rewarming of the atria during prolonged periods of cold cardioplegic arrest may increase the dispersion of refractoriness in the atria of such patients and thereby increase the risk of postoperative AF.

Because of difficulties in reliably identifying patients at risk for AF preoperatively, it is common clinical practice to provide prophylactic therapy to the majority of patients undergoing CABG surgery. Beta-adrenoceptor blocking agents are most suitable for prophylaxis against AF.[52] [53] In the *absence* of an ejection fraction less than 30 percent, severe bronchospastic lung disease, or bradyarrythmias, we advocate the use of prophylactic beta blockers in patients undergoing CABG. Conclusive data regarding the use of prophylactic antiarrhythmic therapy to prevent postoperative AF are lacking, although prophylactic amiodarone in selected patients has appeared promising in several clinical trials.[57] [58]

BRADYARRHYTHMIAS AND ATRIOVENTRICULAR AND INTRAVENTRICULAR BLOCK.

Patients with high-grade (third-degree or type II second-degree) atrioventricular block and hemodynamic compromise (systolic pressure <90 mm Hg) are at high risk during general anesthesia unless a temporary transvenous pacemaker wire is inserted preoperatively.

In patients in whom a permanent pacemaker has been implanted, its specifications (model, mode, and settings) and, if possible, a statement regarding the pacemaker dependency of the patient should be noted in the medical record (see Chap. 24) . The possibility of postoperative malfunction in the permanent pacing system because of the effects of anesthesia, electrocautery, and surgical manipulation of the leads (e.g., during atrial cannulation) should be anticipated.[59] Clinicians should have the appropriate pacemaker programming equipment available postoperatively because many problems (secondary to electromagnetic interference from the electrocautery apparatus) can be quickly resolved by interrogation of the generator and reprogramming in the recovery area.

The risk of permanent, complete heart block postoperatively is increased with multiple valve replacements, particularly in patients who have had previous valve surgery. However, implantation of a permanent epicardial pacing lead is rarely needed at the time of surgery because of the ease of implantation of a transvenous endocardial system postoperatively. An exception would be patients who are undergoing tricuspid valve replacement with a mechanical prosthesis, especially if they are simultaneously undergoing an aortic or mitral valve operation. Because of the contraindication to passing a transvenous lead through the mechanical tricuspid prosthesis, the surgical team should be alerted to the need for placement of permanent epicardial leads intraoperatively.

Patients with previously implanted cardioverter-defibrillator devices should have their unit disabled prior to surgery to minimize the risk of inappropriate shocks from sensing of electrocautery signals intraoperatively. Until the device is reactivated in the postoperative period, equipment for rapid external defibrillation should be available.

Perioperative Drug Therapy

With the exception of oral anticoagulation with warfarin, most medications can and should be continued up to the time of surgery. Clinical trials of patients receiving saphenous vein bypass grafts demonstrated the importance of initiating antiplatelet therapy in the perioperative period.[60] Because of the increased risk of postoperative bleeding, some surgical groups discontinue aspirin use for several days preoperatively in elective cases. Many cardiologists are concerned about the risk of "breakthrough" episodes of ischemia if aspirin therapy is discontinued preoperatively and prefer to continue it up to the time of surgery and rely on preoperative donations of autologous red cells, cell saver techniques, autotransfusion of shed blood intraoperatively and postoperatively, and drugs such as aprotinin to minimize the need for and potential hazards of homologous blood transfusion. If aspirin is witheld preoperatively, it should be restarted within 24 to 48 hours after surgery to reduce the risk of vein graft occlusion.[60] Warfarin therapy should be stopped 2 to 3 days preoperatively and, if necessary, treatment with heparin or low-molecular-weight dextran initiated.

Although definitive data are not available, it is our usual practice to continue both aspirin and clopidogrel up to the time of surgery in patients who have undergone implantation of a stent in the coronary circulation within the preceeding 2 weeks in order to minimize the risk of stent thrombosis preoperatively. For patients who have had a stent implanted more than 2 weeks prior to surgery, we discontinue clopidogrel administration but continue aspirin up to the time of surgery. For patients receiving long-term clopidogrel as secondary prevention for vascular disease, we discontinue use of the drug 5 to 7 days preoperatively.

To minimize the risk of intraoperative bleeding, if patients are undergoing interventional catheterization procedures and have normal renal function and if cardiac surgery is likely to take place within the ensuing 24 to 48 hours, we prefer to use a short-acting intravenous glycoprotein IIb/IIIa inhibitor such as eptifibatide or tirofiban rather than a long-acting agent such as abciximab. Treatment with the short-acting agent is usually discontinued 6 to 12 hours preoperatively to permit platelet function to return toward normal. We prefer to use abciximab in patients with renal dysfunction since the small, short-acting inhibitors are cleared predominantly through renal elimination. When abciximab is used, we discontinue the infusion at least 12 hours prior to surgery.

For patients who have received an intravenous glycoprotein IIb/IIIa inhibitor and must proceed urgently to cardiac surgery, the antiplatelet effects of abciximab may be reversed by platelet transfusions.[60A] In contrast, the high excess of free drug versus bound drug in the case of eptifibatide or tirofiban limits the ability of platelet transfusions to restore normal platelet function. In cases in which urgent removal of epifibatide or tirofiban from the circulation is desired, hemodialysis may be necessary.

Calcium antagonists previously prescribed for control of ischemic heart disease should be continued up to the time of surgery to reduce the chance of myocardial ischemia from withdrawal of the drug. In the case of diltiazem and verapamil, the dose may need to be reduced because these agents may provoke bradycardia and a low-output syndrome postoperatively, especially if a beta blocker or amiodarone is given concurrently or the patient is elderly. Profound atropine- and isoproterenol-resistant bradyarrhythmias may occur postoperatively in patients treated with these calcium antagonists, particularly when the patient has not yet recovered from the hypothermia that is imposed intraoperatively; temporary dual-chamber pacing support should be available to manage such patients.

CONTINUATION OF ANTIARRHYTHMICS.

With the exception of amiodarone, antiarrhythmic drugs that have been prescribed for hemodynamically compromising or life-threatening ventricular tachyarrhythmias should be continued up to the time of surgery because of the risk of "breakthrough" of a potentially lethal ventricular arrhythmia in the preoperative period.

Patients with a documented history of resuscitation from sudden cardiac death who are receiving amiodarone should continue to receive this drug up to the time of surgery. However, in cases in which amiodarone was prescribed for a less overtly life-threatening arrhythmia (e.g., AF), the maintenance dosage has been greater than 200 mg/d, and the patient has a history of lung disease, we recommend at least a 3-month period of abstinence from the drug before subjecting the patient to elective cardiopulmonary bypass.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS.

Prophylactic implantation of cardioverter-defibrillators at the time of CABG in patients at high risk for ventricular arrhythmias (ejection fraction
35 percent, abnormal signal-averaged ECG) does not improve survival.[5]

INTRAOPERATIVE MANAGEMENT

Despite increased risks, particularly related to age and advanced disease, cardiac surgery patients today enjoy markedly improved outcomes when compared with patients operated on l0 years ago. Important intraoperative surgical advances that have contributed to this improval outcome include epiaortic echocardiographic scanning in patients with ascending aortic atherosclerosis, transesophageal echocardiography, retrograde blood cardioplegia, retrograde cerebral perfusion in patients requiring circulatory arrest, and performance of all vascular anastomoses with a single aortic cross-clamp under cardioplegic arrest. Emphasis on modern strategies to ensure blood conservation and minimize hemostatic complications has significantly decreased or eliminated homologous blood exposure for most patients undergoing cardiac surgery (Fig. 60-2) .

Until recently, nearly all cardiac surgical procedures were performed via a standard median sternotomy with the use of cardiopulmonary bypass and cardiac arrest to

provide a bloodless, motionless field (Fig. 60-3). Cardiac surgeons have recently explored less invasive approaches to coronary and valvular heart disease. The impetus for this change has been to decrease overall surgical trauma associated with full sternotomy and cardiopulmonary bypass without compromising the efficacy and safety of procedures. In valvular heart disease, cardiopulmonary bypass is essential, and therefore the focus has been on reducing trauma through a variety of less invasive incisions (Fig. 60-4). In coronary surgery, smaller incisions have also been used with or without cardiopulmonary bypass, particulary to perform single-vessel bypass to the left anterior descending artery. Recent technical advances in myocardial stabilization (Fig. 60-5) have now focused attention on off-pump multivessel coronary bypass through a full sternotomy.[60B] This approach is particularly appealing in selected high-risk patients, including those with ascending aortic atherosclerosis, renal dysfunction, and severe pulmonary disease. Wider adoption of less invasive cardiac surgical techniques can be anticipated if ongoing clinical trials demonstrate short-term patient benefit and medium- and long-term results comparable to those obtained with standard techniques.[60C]

Figure 60-2 Multimodality algorithm designed to optimize blood conservation in cardiac surgical patients. Preoperative, intraoperative, and postoperative strategies are all important to eliminate the requirement for homologous blood transfusion. ASA=aspirin; coag=coagulation; EPO=erythropoietin; Hct=hematocrit; Hx=history; IAD=intraoperative autologous donation; PLT=platelet; RAP=retrograde autologous priming; RCM=red cell mass. (From Rosengart TK: Open heart surgery without transfusion in high-risk patients. Am J Cardiol 83:31B-37B, 1999.)

Figure 60-3 Schematic diagram of a typical cardiopulmonary bypass circuit. Venous blood is drained by a cannula from the right atrium into a reservoir and then pumped through an oxygenator and heat exchanger and returned via an aortic cannula to the ascending aorta. Although cardiopulmonary bypass is extremely safe in the current era, morbidity may occur in selected patients. Cerebral emboli may result from aortic manipulation. End-organ perfusion may be reduced as a result of loss of pulsatile flow. Finally, the bypass circuit may cause hemodilution and trigger systemic activation.

POSTOPERATIVE MANAGEMENT

Fluid, Electrolyte, and Acid-Base Balance

Extracorporeal circulation is associated with an increase in extracellular fluid and total exchangeable sodium, along with a decrease in exchangeable potassium. The cumulative experience in many centers has led to the following basic principles of management:

1. For the first 48 hours after surgery, free water is limited to about 1000 ml/d and intravenous fluids are administered in the form of 5 percent glucose in water. Sodium replacement varies with volume needs.
2. Serum potassium levels can fluctuate dramatically; therefore, frequent measurement of serum potassium is indicated, especially in diabetics. We attempt to maintain serum potassium in the range of 4.5±0.5 mEq/liter and magnesium at 2.0 mEq/liter or greater to minimize the chance of cardiac arrhythmias.
3. Serum glucose levels are frequently elevated (250 to 400 mg/dl), as a result of glucose-containing intravenous solutions and surgically induced increases in cortisol and catecholamine levels. In nondiabetic patients, insulin therapy is not usually required, whereas it is routinely used in insulin-requiring diabetic patients to avoid uncontrolled hyperglycemia.
4. Mild metabolic acidosis or metabolic alkalosis may be present for the first 24 hours postoperatively, particularly during rewarming. These acid-base abnormalities usually do not require correction in the absence of preoperative renal dysfunction or development of acute renal failure postoperatively.[61] Significant metabolic acidosis (pH <7.35) should be avoided during the rewarming phase, particularly if patients are dependent on an inotropic agent. Hyperventilation (P_{CO_2} <35 mm Hg) and treatment with sodium bicarbonate should be instituted.
5. Serum total calcium, phosphorus, and magnesium levels are frequently depressed for about 24 to 48 hours in normally convalescing patients, partly because of the effects of hemodilution. These electrolyte abnormalities are usually self-correcting, and replacement therapy is not generally required. A possible exception is hypomagnesemia, which may predispose to the development of cardiac arrhythmias.[52]

Respiratory Management

EFFECTS OF ANESTHESIA, STERNOTOMY, AND CARDIOPULMONARY BYPASS ON PULMONARY FUNCTION.

Four broad areas should be considered, as outlined in Table 60-3 .[62] [63] most all patients experience alveolar dysfunction after open-heart surgery because of right-to-left intrapulmonary shunting of blood from various intrinsic alveolar abnormalities (e.g., atelectasis, edema, infection) and pulmonary vascular events (e.g., extravasation of fluid, inhibition of hypoxia-induced vasoconstriction). Central respiratory drive and respiratory muscle function are depressed postoperatively because of a combination of pharmacological effects and mechanical derangements of thoracic function. Patients with preexisting pulmonary disease may experience more profound depression of respiratory function necessitating vigorous pulmonary toilette.

EARLY EXTUBATION.

Historically, most postoperative cardiac surgery patients received between 6 and 18 hours of ventilatory support (Table 60-4) . Early extubation protocols have now been widely adopted in cardiac ICUs, and stable patients are extubated within 4 hours. Advantages of early extubation include improved patient mobility with early transition to step-down units. Patient selection for early extubation is outlined in Table 60-4 .

SPECIAL PROBLEMS

Failure to meet early extubation criteria may result from a variety of factors. Careful assessment will usually identify one or more etiologies resulting in respiratory dysfunction.

INCREASED ALVEOLAR-ARTERIAL GRADIENT.

An increased alveolar-arterial gradient postoperatively is a serious problem that demands thorough evaluation. The ventilator settings should be checked and a chest radiograph obtained to ascertain the position of the tip of the endotracheal tube (to exclude, for example, intubation of the right main stem bronchus) and to rule out pneumothorax, lobar atelectasis or pneumonia, or a large pleural effusion. Hemodynamic monitoring by means of a pulmonary artery catheter can cause pulmonary hemorrhage from overinflation of the balloon, and bronchoscopy may need to be performed to diagnose and manage the problem (e.g., occlusion of the bronchus draining the bleeding segment of the lung).

PULMONARY EDEMA (see also Chap. 17) .

The most common cause of pulmonary edema postoperatively is elevated pulmonary venous pressure arising from left ventricular dysfunction and/or a valvular lesion (e.g., mitral regurgitation). Such patients require aggressive diuresis, as well as vasodilator/inotropic and possibly Intraaortic balloon support. Mechanical ventilation with positive end-expiratory pressure (PEEP) is used until the patient's ventricular function improves. Repeat surgery may be needed if pulmonary edema persists despite attempts to control severe mitral regurgitation medically.

In a minority of patients, pulmonary edema after cardiac surgery is due to the adult respiratory distress syndrome. In its most extreme form, this disorder is associated with a generalized whole-body *postpump syndrome* characterized by increased capillary permeability, interstitial edema, fever, leukocytosis, renal dysfunction, and hemodynamic collapse.

UNDERLYING CHRONIC LUNG DISEASE.

General surgical preparation

Figure 60-4 Schematic representation of traditional incision and sternotomy (*A*) compared with a variety of less invasive incisions (dotted lines represent chest wall incisions). Limited skin incision/full sternotomy (*B*) is gaining in popularity because of improved cosmetics and reduced trauma from the limited chest wall retraction. Although once popular, the parasternal approach (*C*) is used less frequently because of the residual chest wall defect. Partial lower or upper sternotomy (*D* and *E*) has been used predominantly in valve procedures. Right anterior thoracotomy (*F*) is a useful approach, particularly in mitral valve reoperations. Left anterior thoracotomy has been described for coronary bypass procedures.

of patients with obstructive lung disease, including antibiotics, bronchodilators, and cessation of cigarette smoking, may help minimize the risk of respiratory failure from postoperative atelectasis and pneumonia.[62] [63] Inhaled bronchodilators should be continued postoperatively. Refractory patients may require a short course of corticosteroids (e.g., methylprednisolone 0.5 mg/kg every 6 hours for 3 days) to be weaned from the ventilator.[62] Previous enthusiasm for intravenous methylxanthines has waned because of evidence of limited efficacy and the risk of agitation, arrhythmias, and grand mal seizures.[64] Intravenous theophylline should therefore be reserved for extremely refractory cases and administered in a dose of 0.4 mg/kg/hr with careful monitoring of plasma levels to maintain them in the range of 10 to 15 mug/ml.

We have successfully operated on patients with severe respiratory compromise, including those with a forced expiratory volume in 1 second (FEV_1) of less than 0.8 liters who require home oxygen therapy. All patients with severe pulmonary dysfunction are considered for early extubation. It is important to maintain the arterial carbon dioxide tension close to the patient's baseline level to ensure an adequate respiratory drive.

DIAPHRAGMATIC FAILURE.

Diaphragmatic dysfunction after cardiac surgical procedures usually occurs as a result of injury to the phrenic nerve(s). An elevated hemidiaphragm may be seen on postoperative radiographs in 25 percent of patients who undergo myocardial preservation including topical ice slush and harvesting of an internal mammary artery.[65] A simple bedside test of diaphragmatic function is to ask the patient to protrude the umbilicus, a movement that requires diaphragmatic functional integrity. Of note, an elevated hemidiaphragm is not usually associated with increased postoperative morbidity or mortality.

Recovery of the hemidiaphragm to normal position occurs in 80 percent of patients at 1 year and nearly all patients by 2 years postoperatively. Clinically important diaphragmatic dysfunction caused by unilateral or bilateral phrenic nerve injury develops in less than 1 percent of patients after cardiac surgery.

Evidence of diaphragmatic failure includes an inability to wean the patient from the ventilator, vital capacity less than 500 cc, and paradoxical movement of the diaphragm on fluoroscopy (abnormal "sniff" test)[62] or ultrasonography.

PROLONGED VENTILATORY INSUFFICIENCY.

Patients who fail to be weaned from the ventilator within 48 hours require special attention. Because of the risk of stress-induced gastritis, H_2 receptor blockers (e.g., ranitidine 50 mg intravenously every 8 to 12 hours) or a mucosal cytoprotective agent (sucralfate 1 gm orally two to four times per day) is administered. Nutritional support is critical to provide metabolic needs and prevent the catabolism of respiratory muscles (see Fig. 60-1) . Pressure support ventilation strategies are particularly useful for patients in need of prolonged ventilation. Barotrauma is minimized and patient comfort improved while permitting incremental weaning in small steps.

High-compliance, low-pressure cuff (<20 mm Hg) endotracheal tubes have reduced the risk of mechanical complications (e.g., tracheal stenosis) and permit patients to remain intubated for several weeks. Nonetheless, we believe that patients requiring prolonged ventilatory support beyond 10 to 14 days will generally benefit from a decision to

Figure 60-5 Off-pump coronary bypass surgery on the beating heart has been facilitated by the development of platform stabilization systems to provide isolated immobilization during the performance of distal anastomoses. The left anterior descending artery is most amenable to platform stabilization as opposed to the posterolateral circulation.

proceed with early tracheostomy.[65A] Tracheostomy provides improved patient comfort and greater pulmonary toilet and enhances weaning by minimizing pulmonary dead space. Percutaneous tracheostomy offers the advantage of bedside insertion with minimal surgical trauma and is particularly useful in patients with reasonable ventilatory mechanics but heavy secretions.

TABLE 60-3 -- ABNORMALITIES OF RESPIRATORY FUNCTION AFTER CARDIAC SURGERY

EFFECTS OF ANESTHESIA, THORACIC SURGERY, AND CARDIOPULMONARY BYPASS ON PULMONARY FUNCTION	POTENTIAL CAUSES
Alveolar dysfunction (e.g., widened alveolar-arterial oxygen gradient because of right-to-left intrapulmonary shunting)	Scattered regions of atelectasis with preserved perfusion Pulmonary edema (e.g., cardiogenic, noncardiogenic "postpump" alveolar capillary leak) Infection Inhibition of hypoxic pulmonary vasoconstriction by anesthetic agents Exacerbation of ventilation/perfusion mismatch by vasodilating agents used postoperatively (e.g., nitroprusside)
Decreased central respiratory drive	General anesthetics Narcotic analgesics Cerebral insult in perioperative period
Decreased respiratory muscle function	Thoracic pain (incision, chest tubes) Persistent effects of muscle relaxants Age Obesity Depressed cardiac function Primary diaphragmatic dysfunction (e.g., phrenic nerve injury)
Exacerbation of underlying chronic pulmonary disease	Increase in airway resistance Increased secretions and worsening bronchitis Pneumonia

TABLE 60-4 -- CARDIAC SURGERY EARLY EXTUBATION PROTOCOL

Definition	Extubation within 4 hr after surgery
Patient selection	
Inclusion criteria	All patients 80 yr old, LV ejection fraction >25%
Exclusion criteria	High inotropic requirement, postoperative bleeding or ischemia
Anesthetic management	
Intraoperative	Low-dose synthetic narcotics and inhalation agents
Postoperative	Muscle relaxant reversal Propofol 0.1 ml/kg/hr Minimize narcotic use
Ventilatory management	

Postoperative	SIMV mode Check ABGs and decrease ventilatory support every 20 min Always keep between pH 7.35 and 7.45 Always keep P_{O_2} >75 mm Hg
Extubation guidelines	
Oxygenation	P_{O_2} >75 mm Hg at an F_{IO_2} 0.50
Respiratory drive	P_{CO_2} <45 mm Hg and pH >7.35 Spontaneously breathing
Mechanics	Respiratory rate <25 breaths/min Negative inspiratory pressure >20 cm H_2O Tidal volume >8 cc/kg Vital capacity >10 cc/kg
Airway protection	Alert with gag reflex Absence of heavy secretions
Cardiovascular	Cardiac index >2.0 liters/min/m^2 MAP >80 and <120 mm Hg

ABG=arterial blood gas; LV=left ventricular; MAP=mean arterial pressure; SIMV=synchronized intermittent mandatory ventilation.

Hypertension

Postoperative hypertension has been defined variably in the literature,[66] but we consider it to be present if systolic pressure exceeds 140 mm Hg.[67] The incidence of postoperative hypertension ranges from 40 to 60 percent. It occurs more commonly in patients with a preoperative history of hypertension, prior maintenance therapy with a beta blocker, and well-preserved left ventricular function.[68] Postoperative hypertension is especially frequent after CABG and surgical relief of left ventricular outflow tract obstruction (e.g., aortic valve replacement, correction of coarctation of the aorta).

The mechanism of postoperative hypertension probably varies from patient to patient but usually includes (1) a "rebound" effect from withdrawal of beta blockade administered preoperatively; (2) excessive sympathetic nervous system activity with elevated levels of circulating catecholamines (especially norepinephrine)[69] ; (3) pressor reflexes originating in the heart, great vessels, or coronary arteries[70] ; and (4) a drop in aortic pressure proximal to the site of the corrected coarctation with resultant stimulation of aortic and carotid baroreceptors by apparent "hypotension." The renin-angiotensin system is stimulated and peripheral resistance is increased. Sudden exposure of vascular beds downstream from the coarctation to "undamped" aortic pressure has also been reported to cause mesenteric arteritis.

The adverse consequences of elevated systemic pressure include an increased risk of postoperative bleeding, suture line disruption, and aortic dissection[61] ; elevated left ventricular afterload and a consequent reduction in left ventricular output; and injury to aortocoronary bypass grafts and postoperative stroke.

MANAGEMENT.

Although a variety of agents may be used for treating acute postoperative hypertension, we prefer those that are rapidly acting and titratable and have a short half-life. Nitroglycerin is our first-choice agent, beginning at a dose of 25 mug/min and titrating up to a dose of 300 mug/min. Sodium nitroprusside (0.5 to 2 mug/kg/min) may be required in hypertension refractory to nitroglycerin therapy. Because of its prominent vasodilatory effects, sodium nitroprusside should be administered with caution for the first 3 to 4 hours after surgery since volume shifts may occur during the rewarming phase. The ultrashort-acting beta blocker esmolol (50 to 250 mug/kg/min) may be useful in patients with a hyperdynamic circulation. It is initially preferred over longer-acting beta blockers when evaluating patient tolerance to beta blockade (e.g., moderately severe left ventricular dysfunction). The need for transition to oral antihypertensive therapy is assessed on an individual basis; chronic treatment is usually required in patients with a preoperative history of hypertension.

Perioperative Myocardial Infarction (See also Chap. 35)

Despite modern intraoperative myocardial protection and improvements in surgical technique, some degree of ischemia occurs nearly uniformly during CABG. Only a minority of patients (5 to 15 percent of patients undergoing CABG), however, actually experience a *perioperative myocardial infarction,* even in tertiary care centers currently operating on higher-risk patients, including those with failed interventional procedures.[71] [72] [73] Potential causes of myocardial ischemia and infarction in the perioperative period include incomplete revascularization; diffuse atherosclerotic disease of the distal coronary arteries; spasm, embolism, or thrombosis of the native coronary vessels or bypass grafts[74] [75] ; technical problems with graft anastomoses; inadequate myocardial preservation intraoperatively; increased myocardial oxygen needs, as in left ventricular hypertrophy; and hemodynamic derangements in the postoperative period (e.g., hypotension, hypertension, tachycardia). Although initially one might suspect that perioperative myocardial infarction results from occlusion of bypass grafts placed to circumvent diseased coronary arteries, autopsy studies have shown that bypass grafts are usually patent in patients dying of a perioperative myocardial infarction.[76] This observation lends support to the concept that poor myocardial protection or a mismatch between myocardial oxygen supply and demand postoperatively accounts for much of the infarction noted.

DIAGNOSIS.

The diagnosis of a myocardial infarction after cardiac surgery is more difficult than at other times because of the nonspecific ST-T wave abnormalities on ECG and nearly universal elevation of creatine kinase (CK) levels postoperatively. A number of diagnostic findings (Table 60-5) must be carefully interpreted and then integrated as shown in the algorithm displayed in Table 60-6 .

A 12-lead ECG should be obtained immediately on the patient's arrival in the ICU after surgery and no less frequently than once every 24 hours for the first few postoperative days. Measurements of total CK and CK-MB should be made every 8 hours for the first 24 to 36 hours if perioperative myocardial infarction is suspected.

TROPONIN.

Experience with newer, more sensitive serum markers of cardiac injury, such as troponin I and troponin T, is limited.[77] [78] However, initial reports suggest that cardiac-specific troponin I and

TABLE 60-5 -- DIAGNOSIS OF MYOCARDIAL INFARCTION AFTER CARDIAC SURGERY

DIAGNOSTIC FINDING	COMMENT
Symptoms	
Early (<24 hr postop)	Not reliable because of residual effects of anesthesia and postoperative analgesics
Late (>24 hr postop)	Potentially reliable but may be confused with incisional pain and pleuritic pain from chest tubes, pericarditis
Electrocardiogram	
New, persistent Q waves	Most reliable diagnostic finding, but only if the Q waves persist on serial ECGs over several days
Evolutionary ST-T changes	Supportive data favoring the diagnosis of MI only if a typical evolutionary pattern is observed. Because of the effects of cardiopulmonary bypass, hypothermia, postoperative pericarditis, mediastinal chest tubes, and medications (e.g., digitalis), a variety of nonspecific ST-T wave abnormalities may be seen and should not be relied on for diagnosing perioperative MI
Myocardial-specific enzymes	

Total CK	Elevated total CK levels postoperatively may arise from multiple sources, including skeletal muscle in the thorax and calf, as well as myocardium
CK-MB	Myocardial-specific CK may be released from ischemia occurring during cardiopulmonary bypass, as well as myocardial and aortic incisions made intraoperatively (e.g., right atrium for cannulation of the cavae). Because of the nearly universal release of CK-MB, a diagnosis of MI should not be made unless CK-MB is significantly elevated (e.g., >30 units/liter)
Echocardiogram	A regional wall motion abnormality is a helpful finding, particularly if it can be shown to be a new finding by comparison with a peroperative study. Paradoxical motion of the high anterior portion of the interventricular septum is a common finding postoperatively in the absence of MI and should not be taken as the sole evidence of new perioperative myocardial necrosis

CK=creatine kinase; MI=myocardial infarction.

TABLE 60-6 -- ALGORITHM FOR DIAGNOSIS OF PERIOPERATIVE MYOCARDIAL INFARCTION AFTER CARDIAC SURGERY

NEW Qs ON ECG	CK-MB >30 IU/LITER	NEW RWMA ON ECHO*	DIAGNOSIS	COMMENT
Yes	Yes	Yes	Definite MI	
Yes	Yes	No	Probable MI	New zone of necrosis not evident on ECHO. The persistence of new Q waves and abnormally elevated CK-MB suggests that Q waves are not a "benign" postoperative finding
Yes	No	Yes	Definite MI	CK-MB peak probably missed because of infrequent sampling
Yes	No	No	Possible MI	New Q waves may be false-positive finding
No	Yes	Yes	Probable MI	Non-Q-wave MI
No	Yes	No	MI unlikely	Small non-Q-wave MI cannot be entirely excluded
No	No	Yes	MI unlikely	Removal of "restraining" effect of pericardium may result in new RWMAs, especially in high anterior septal area
No	No	No	No MI	Although small patchy areas of necrosis may be seen histologically, these abnormalities are probably not of clinical significance

*Perioperative echocardiography is not *required* for the diagnosis of a perioperative MI but can provide useful supportive data or aid in the diagnosis in unclear cases, especially if obtained acutely.
ECHO=echocardiography; MI=myocardial infarction; RWMA=regional wall motion abnormality.

troponin T are elevated postoperatively in virtually all patients who undergo CABG surgery. Patients who experience a perioperative myocardial infarction release greater quanitities of troponin such that serum measurements may remain 10- to 20-fold higher than the upper limit of the reference interval for at least 4 to 5 days postoperatively. Even in patients not experiencing perioperative myocardial infarctions by conventional diagnostic criteria, the relative increase in proteins such as cardiac troponin I over preoperative baseline values is greater than that of CK-MB, which suggests that troponin measurements can detect small amounts of myocardial tissue damage that are not detected by CK-MB.

ELECTROCARDIOGRAPHY.

The ECG is the most reliable tool for diagnosing a perioperative myocardial infarction. New and persistent Q waves accompanied by new, persistent, and evolutionary ST-T wave abnormalities are the most helpful criteria. Pathological Q waves resulting from perioperative myocardial infarction may appear with an earlier time course (i.e., immediately on arrival from the operating room) than in a nonrevascularized patient.

ECHOCARDIOGRAPHY.

Bedside echocardiograms (transthoracic and if necessary transesophageal) play an important role in establishing the diagnosis of a perioperative myocardial infarction by detecting new regional wall motion abnormalities in cases in which the ECG or serum marker measurements are unclear. It is especially helpful to compare new echocardiograms with the preoperative studies that are almost always available.

RISKS AND CONSEQUENCES OF PERIOPERATIVE INFARCTION.

Variables that have been found to correlate with the development of perioperative myocardial infarction in patients undergoing CABG include emergency surgery, aortic cross-clamp time greater than 100 minutes, a recent myocardial infarction (within the prior week), and a history of previous revascularization (either percutaneous transluminal coronary angioplasty or CABG surgery).[73]

Patients with a perioperative myocardial infarction have increased hospital mortality (about 10 to 15 percent) when compared with patients undergoing CABG who have not sustained a perioperative myocardial infarction (about 1 percent).[73] [79]

Characteristics of patients who are especially at risk of increased short-term mortality after a perioperative myocardial infarction include age older than 65 years, unstable angina preoperatively, a myocardial infarction within 1 week before surgery, left ventricular aneurysm, intraventricular conduction disturbance (e.g., left bundle branch block), and the need for reoperation for bleeding. About two-thirds of the postoperative mortality is due to pump failure and one-third is due to malignant ventricular tachyarrhythmias.[79] Perioperative myocardial infarction also adversely affects the long-term prognosis, particularly if associated with inadequate revascularization and depressed left ventricular function.[80]

MANAGEMENT OF MYOCARDIAL ISCHEMIA AFTER CABG.

Patients with evidence of myocardial ischemia after coronary bypass surgery require an integrated assessment of clinical findings and laboratory tests on an individualized basis to define the appropriate management strategy. At the center of the decision pathway are the 12-lead ECG and hemodynamic observations (Fig. 60-6) . Patients with ST elevations and a low cardiac index require intraaortic balloon pump support. Two-dimensional echocardiography is useful to detect new wall motion abnormalities that may necessitate coronary angiography and a percutaneous revascularization procedure in selected patients.

Low-Output Syndrome and Shock States

RECOGNITION.

Sometimes, diagnosis of low-output syndrome and a shock state after cardiac surgery is difficult. Because cold extremities and mottled skin may result from hypothermia postoperatively, these observations lack sufficient specificity. Although reduced systolic pressure is the most striking manifestation of this disorder, low-output syndrome may be present even if the arterial systolic pressure exceeds 100 mm Hg because increased systemic vascular resistance (>1500 dyne-secccm^{-2}) may be supporting the peripheral perfusion pressure. It is important to recognize this syndrome because of the strong relationship between cardiac index in the early postoperative period and the probability of cardiac death after surgery. Common clinical features of the low-output syndrome and shock states after cardiac surgery include cold extremities, mottled skin, reduced systolic pressure (<90 mm Hg), decreased urine output (<30 ml/hr), low cardiac index (<2.0 liter/min/m[2]), low mixed venous oxygen saturation (<50 percent), and acidosis.

One should make careful hemodynamic measurements and integrate them with bedside echocardiographic recordings to confirm the diagnosis of low-output syndrome and attempt to segregate the findings into one of the patterns (*reduced preload, cardiogenic shock,* or *sepsis*) in Table 60-7 . Although the hemodynamic findings among these patterns overlap and the coexistence of multiple disorders (e.g., bradycardia and hypovolemia) may blur the distinction between patterns, they offer a

clinically useful approach to the evaluation of a patient with low-output syndrome. In addition to the specific treatment measures discussed below, a number of general measures are applicable to all patients who are in a shock-like condition after cardiac surgery, including prompt correction of any electrolyte and acid-base disturbances, transfusion to a hematocrit

Figure 60-6 Myocardial ischemia after coronary bypass grafting is frequently observed. Hemodynamic assessment and ensurance of adequate coronary and systemic perfusion dictate early management strategies. Echocardiographic evaluation helps further tailor postoperative care. CABG = coronary artery bypass graft surgery; ECG = electrocardiogram; ECHO = echocardiography; IABP = intraaortic balloon pumping; MAP = mean arterial pressure.

over 30 percent for improved oxygen-carrying capacity of the blood, and a "low threshold" for mechanical ventilatory support to minimize the work of breathing and thereby reduce total-body oxygen needs.

REDUCED PRELOAD

Hypovolemia.

Low ventricular filling pressure, normal systemic vascular resistance, and a reduced cardiac index, coupled with echocardiographic demonstration of small ventricular volume with preserved systolic function, are indicative of *hypovolemia.* Possible causes include bleeding, excessive diuresis, the "leaky capillary state" associated with the postpump syndrome, and less frequently, inadequate vascular volume because of insufficient return of fluids at the conclusion of cardiopulmonary bypass. Rarely, adrenal cortical insufficiency as a result of perioperative hemorrhage into the adrenals has been reported as a cause of hypovolemic hypotension after cardiac surgery.

Therapeutic maneuvers include the administration of intravenous fluids (normal saline solution, lactated Ringer solution), transfusion with packed red blood cells if the hemoglobin is less than 8 gm/dl, and administration of colloid-type volume expanders. It is also important to discontinue any vasodilators or antihypertensives that may have been prescribed during a period when the patient was hypertensive. While waiting for the above measures to take effect, the patient may require transient infusion of a vasoconstrictor (usually phenylephrine [Neo-Synephrine]) or an inotropic pressor (usually dopamine or epinephrine).

Vasodilatation.

Inhibition of sympathetic tone by the effects of anesthetic agents may cause peripheral vasodilatation. In combination with the increased venous capacitance that may occur during rewarming, a low-output syndrome may develop as a result of markedly reduced systemic vascular resistance (<1000 dyne-secccm^{-5}). This situation is best treated by infusion of a vasoconstrictor such as norepinephrine in a dose of 1 to 10 mug/min until the systemic vascular resistance returns to a normal level.

CARDIOGENIC SHOCK.

When right ventricular and left ventricular filling pressures are in the normal range and systemic vascular resistance is not reduced, a frequent cause of a cardiac index less than 2 liters/min/m^2 is *bradycardia.* Because the cardiac index is the product of stroke volume and heart rate, this abnormality is easily corrected by atrial or atrioventricular pacing at 85 to 100 beats/min.

Left Ventricular Failure.

The pattern of predominant *left ventricular failure* in the early postoperative state is characterized by a disproportionately elevated pulmonary capillary wedge pressure in comparison to right atrial pressure, a low cardiac index, and normal or elevated systemic vascular resistance. Echocardiography usually reveals a dilated, poorly contractile left ventricle, often exhibiting multiple regional wall motion abnormalities.

DIAGNOSIS.

The differential diagnosis of left ventricular failure after cardiac surgery includes the following conditions (which may coexist in the same patient): preoperative left ventricular dysfunction, inadequate surgical correction of the cardiac lesion (e.g., residual left ventricular outflow tract obstruction after repair of idiopathic hypertrophic subaortic stenosis, residual ventricular septal defect), complication of a surgical procedure (e.g., prosthetic valve leak or thrombosis, depression of stroke volume after correction of mitral regurgitation caused by elevation of afterload), dysrhythmia, depressant effect of a pharmacological agent (e.g., antiarrhythmic drug), acid-base or electrolyte disturbance, or myocardial ischemia and/or infarction. Bedside echocardiography can usually help identify mechanical disorders such as prosthetic valve dysfunction and dysrhythmias, and metabolic abnormalities and toxic drug levels can be readily recognized by ECG and laboratory measurements.[81]

Management.

The objectives of hemodynamic management of patients with *left ventricular failure* postoperatively are to correct hypotension if present, increase forward left ventricular output, and return left and right ventricular filling

TABLE 60-7 -- HEMODYNAMIC DISTURBANCES FOLLOWING CARDIAC SURGERY

	REDUCED PRELOAD		CARDIOGENIC SHOCK				
	Hypovolemia	**Vasodilatation**	**Bradycardia (Inappropriately Slow HR Postoperatively)**	**LV Failure**	**RV Failure**	**Cardiac Tamponade**	**SEPSIS**
Hemodynamics							
RA	<8	<8	10	10	>10	>15	<10
PCW	<15	<15	>15	>20	15*	>15	<15
CI	<2.0	<2.0	<2.0	<2.0	<2.0	<2.0	2.0
SVR	>1200	<1000	>1200	>1000	>1000	>1000	<1000
Other			HR <60		PCW >15 if LV failure is present	RA=PCW=PAd (within 5 mm Hg) unless "asymmetrical" tamponade occurs because of pericardial clots	Narrow A-V O_2 difference

Echocardiogram	Small ventricular chambers with vigorous systolic contraction unless LV dysfunction was present preoperatively	Small ventricular chambers with normal systolic contraction unless LV dysfunction was present preoperatively	Normal-sized ventricular chambers with vigorous systolic contraction, albeit at a slow rate	Dilated LV with reduced systolic performance; regional wall motion abnormalities may reflect old or new myocardial ischemia and/or infarction	Dilated RA and RV with reduced RV systolic contraction. TR often present on Doppler study. LV contractile performance is variable	Small cardiac chambers with diastolic collapse of RA and RV. Systolic contraction of RV and LV usually normal unless dysfunction was present preoperatively or coexistent LV or RV failure has occurred postoperatively	Small ventricular chambers with normal or slightly depressed contractile function (myocardial depressant factor)
Management	IV fluids Transfusion if Hgb <10 Inotropes	Vasopressors	Cardiac pacing	Search for correctible lesion, offending agent, or laboratory abnormality Inotropes Vasopressors and vasodilators Mechanical assistance	Supplemental O_2 Pulmonary vasodilators Inotropes Mechanical assistance	Reexploration Supportive measures: IV fluids, inotropes	IV fluids Antibiotics Vasopressors Inotropes

CI=cardiac index; Hgb=hemoglobin; HR=heart rate; IV=intravenous; LV=left ventricular; PAd=pulmonary artery diastolic; PCW=pulmonary capillary wedge; RA=right atrial; RV=right ventricular; SVR=systemic vascular resistance; TR=tricuspid regurgitation.

pressures to the normal range. These parameters are intimately related, and treatment may require careful titration of several intravenous agents for pharmacological support of the failing circulation. Boluses of calcium chloride (0.5 to 1.0 gm) increase myocardial contractility, but the effect is modest and short-lived. A continuous infusion of dopamine (5 to 10 mug/kg/min) or epinepherine (1 to 4 mug/kg/min) is preferable if the primary goal is to increase systemic arterial pressure and cardiac output. Dobutamine (2 to 5 mug/kg/min), amrinone (bolus of 0.75 mg/kg and infusion of 5 to 10 mug/kg/min), or milrinone (bolus of 50 mug/kg/min and infusion of 0.375 to 0.75 mug/kg/min) also augment cardiac output and should be selected if a reduction in ventricular filling pressure is desired; systemic arterial pressure is usually unchanged or may even drop slightly because of the peripheral vasodilatory effects of these drugs.[61] [82] [83] A commonly used combination is dopamine (2 mug/kg/min) to achieve greater renal perfusion in conjunction with dobutamine (2 to 5 mug/kg/min) for augmentation of cardiac output. If the mean arterial pressure is equal to or greater than 90 mm Hg, vasodilator therapy with nitroglycerin increases forward cardiac output and lowers pulmonary capillary wedge pressure further. When hypotension is profound (e.g., systolic pressure <70 mm Hg), norepinephrine or epinepherine 1 to 10 mug/min may be necessary to prevent coronary hypoperfusion.[61] [82]

We prefer to use an intraaortic balloon pump (see Chap. 19) for mechanical support of the circulation along with pharmacotherapy early in the course of management of postoperative left ventricular failure that does not respond to the initial pharmacological maneuvers already discussed. This protocol has the advantages of avoiding a continuous upward titration of the dose of sympathomimetic inotropic agents and vasoconstrictors associated with downregulation of beta-adrenoceptors and diminished perfusion of the renal, mesenteric, and coronary vascular beds. Also, intraaortic balloon counterpulsation does not increase myocardial oxygen demand. The intraaortic balloon pump is particularly helpful if significant mitral regurgitation is present but may be contraindicated in the presence of severe aortic regurgitation and if an abdominal aortic aneurysm is present. Delayed sternal closure is another important adjunct in the management of cardiogenic shock following surgery (Fig. 60-7) . If the patient fails to improve despite a combination of intraaortic balloon pumping, open-chest management, and pharmacotherapy, a ventricular assist device may be inserted for temporary support or as a "bridge" to cardiac transplantation until a donor is located.[84] [85] Serial evaluations of left ventricular function over time and under different loading conditions and supportive measures are best obtained with transesophageal echocardiograms.[86]

RIGHT VENTRICULAR FAILURE.

The pattern of predominant *right ventricular failure* is characterized by a disproportionate elevation in right atrial pressure in comparison to pulmonary capillary wedge pressure. In severe cases of postoperative right ventricular failure, right atrial pressure may exceed 20 mm Hg while pulmonary capillary wedge pressure remains equal to or less than 15 mm Hg. When left ventricular failure is present simultaneously, the difference between right atrial and pulmonary capillary wedge pressure lessens and differentiation from cardiac tamponade becomes difficult. Bedside echocardiography is useful for making a proper diagnosis (see Table 60-7) .

Postoperatively, predominant right ventricular failure may be seen as a result of one or more of the following conditions: elevated pulmonary vascular resistance (persistently elevated from preoperative elevations in pulmonary artery pressure; postoperative hypoxia, pulmonary embolus, or pneumothorax), primary right ventricular ischemia/infarction,[87] or a mechanical lesion (tricuspid regurgitation, residual shunt flow, right ventriculotomy).

Massive pulmonary embolism is a rare occurrence after cardiac surgery (see Chap. 52) . The diagnosis should be suspected when sudden deterioration in oxygenation occurs in association with confusion, systemic hypotension, tachycardia, ECG abnormalities (unexplained right axis deviation, right bundle branch block, a right ventricular strain pattern), and elevation of right atrial pressure. Angiographic confirmation of the diagnosis is not usually necessary. Expeditious

Figure 60-7 Patients in a low output state may not tolerate immediate sternal closure, particularly in the setting of significant mediastinal and myocardial edema associated with prolonged cardiopulmonary bypass. A modified barrel syringe is inserted between the sternal tables and the wound is then covered with an Esmarch dressing. After resolution of edema and recovery of myocardial function, the patient is returned to the operating room for a standard sternal closure.

noninvasive confirmation by echocardiography is advisable in patients in whom the diagnosis remains uncertain.

MANAGEMENT.

Hemodynamic management of predominant right ventricular failure should focus on improvement in right ventricular output to allow adequate filling of the left ventricle. Supplemental oxygen and hyperventilation to decrease P_{CO_2} levels help lower pulmonary artery pressure. Bradycardia (>60 beats/min) is corrected by atrial or atrioventricular pacing, isoproterenol (1 to 2 mug/min in an average adult) increases right ventricular contractility and also causes pulmonary vasodilatation. Pulmonary hypertension may also be reduced by prostaglandin E_1 [88] and intravenous nitroglycerin.

Cardiac Tamponade (see Chap. 50) .

Postoperative echocardiography has shown that virtually all patients have pericardial effusion after cardiac surgery and that many

such effusions are asymmetrical and loculated.[89] Even with mediastinal drains in place, it is possible for cardiac tamponade to develop postoperatively; recognition of this condition requires a high index of suspicion and assessment of hemodynamics at the bedside.[90]

Recognition.

Important clinical features of tamponade, such as diminished heart sounds and pulsus paradoxus, may be obscured by mechanical ventilation. Asymmetrical, loculated accumulation of blood and clots in the mediastinum and pericardial space may cause isolated tamponade of one or two cardiac chambers and produce unusual elevations in diastolic pressure (e.g., right atrial tamponade with elevation of central venous pressure without an increase in right ventricular end-diastolic pressure or pulmonary capillary wedge pressure).[91] Beside two-dimensional transthoracic and transesophageal echocardiography is usually helpful for diagnosing pericardial effusions and assessing the hemodynamic significance of fluid collections.[92] Diastolic collapse of the right atrium and right ventricle is an indication of a

hemodynamically significant external compressive force and should prompt urgent treatment.

Treatment.

Although pericardiocentesis may be helpful in nonsurgical tamponade, it is unlikely to be successful in evacuating the organized pericardial and mediastinal material that develops after cardiac surgery; subxiphoid drainage and/or emergency sternotomy is preferred. Supportive measures that can be attempted in the interim include volume expansion with intravenous fluids (Plasmanate, whole blood) and inotropic agents (dobutamine).

SEPTIC SHOCK.

Low ventricular filling pressure, markedly reduced systemic vascular resistance, and a normal or unexpectedly high cardiac index in the setting of hypotension and a shocklike state should raise suspicion of the early stages of *sepsis.* With progression of septic shock, a capillary leak syndrome develops (hypovolemia) and myocardial depression may occur and result in a somewhat reduced contractile pattern of the ventricles on echocardiography. Combined therapy with intravenous fluids, antibiotics, and inotropic agents is required to interrupt the vicious cycle of hypotension, acidosis, and diminished coronary perfusion. Most patients in a septic state during the first several days after cardiac surgery are infected with a skin organism (e.g., indwelling catheters) or from seeding the bloodstream from a pulmonary or urinary source. Broad antibiotic coverage (e.g., vancomycin plus ceftazidine) should be instituted. Because the offending organism is likely to be resistant to the prophylactic antibiotic given preoperatively, it is wise to not include it as one of the empirical antibiotics selected to treat sepsis.

Perioperative Arrhythmias (See also Chap. 25)

EVALUATION AND TREATMENT.

There appear to be two peaks in the incidence of arrhythmias perioperatively: The first occurs in the operating room (most commonly during induction of anesthesia, weaning from cardiopulmonary bypass, rewarming), and the second occurs in the ICU between the second and fifth postoperative days. The electrophysiological mechanisms underlying perioperative arrhythmias are incompletely understood, but they can probably be ascribed to a combination of the effects of circulating catecholamines, alterations in autonomic nervous system tone, transient electrolyte imbalance, myocardial ischemia or infarction, and mechanical irritation of the heart.

APPROACH TO THE PATIENT.

Several factors may predispose to the development of arrhythmias, including ventilatory dysfunction, fever, electrolyte imbalance (hypokalemia, hypomagnesemia, hypocalcemia), anemia, myocardial ischemia or infarction, low cardiac output and reflex increase in sympathetic tone, hypertension, pericardial inflammation, and toxic effects of cardioactive medications (e.g., digitalis toxicity, bradycardia induced by diltiazem).[52] [93] *Every effort should be made to look for and eliminate any of the factors that may be provoking the arrhythmia.*

Although antiarrhythmic drug therapy and direct-current cardioversion are traditional methods for treating postoperative arrhythmias, cardiac pacing techniques have a number of advantages, including more rapid onset and offset of action, avoidance of potential drug toxicity (especially proarrhythmia), elimination of the need for anesthesia (required for cardioversion), reduced anxiety for the patient, greater safety in patients receiving digitalis, and perhaps most important, the ability to repeat the pacing protocol if the arrhythmia should recur, a not infrequent event. In addition to terminating arrhythmias, cardiac pacing can be used to suppress arrhythmias in many patients by atrial, atrioventricular sequential, or ventricular stimulation at a critical rate (e.g., 85 to 100 beats/min).

Surface Electrocardiogram.

The value of a 12-lead ECG and simultaneously recorded multiple standard ECG lead rhythm strips cannot be overemphasized if one is attempting to analyze a wide complex tachycardia. Unfortunately, a number of the criteria for differentiating supraventricular tachycardia with aberrant conduction from ventricular tachycardia (VT) (see Chap. 25) may not be applicable to postoperative patients because of previous or newly acquired infarction patterns, transient conduction defects (seen in 5 to 15 percent of patients in the early recovery period), and nonspecific repolarization patterns.

Epicardial Electrodes.

It is desirable to place two wires on the free wall of the right atrium and the right ventricle to allow for bipolar atrial recording and pacing or dual-chamber pacing. The advantages of bipolar pacing include a smaller stimulus artifact, the ability to record a bipolar atrial electrogram during ventricular pacing, and a reduced likelihood of precipitating undesired atrial arrhythmias if an atrial wire is used as the indifferent electrode during unipolar ventricular pacing. Schematic diagrams showing the typical intrathoracic positioning of the atrial and ventricular wires are shown in Figure 60-8 .

Supraventricular Arrhythmias

ATRIAL PREMATURE DEPOLARIZATIONS.

The hemodynamic consequences of atrial premature depolarizations are almost always minor, and one should resist the urge to suppress them with antiarrhythmic drugs. Instead, they should be considered a signal that the patient is possibly hypoxic or that an electrolyte imbalance is present and a warning that the patient is at risk for more serious arrhythmia such as AF or atrial flutter. In the absence of such correctable abnormalities, one may want to administer a beta blocker to inhibit the effects of circulating catecholamines and also to slow the ventricular rate if AF should develop.

ATRIAL FLUTTER.

Control of the ventricular rate in atrial flutter is more difficult than in AF because of the limited number of ventricular responses to atrial activation (usually 2:1, 4:1, but rarely an odd-numbered multiple). Atrial flutter may be difficult to terminate with antiarrhythmic agents. Cardioversion with an energy of 25 to 50 watt-seconds delivered as a single discharge can be expected to terminate atrial flutter in more than 90 percent of patients.

Atrial flutter can also be terminated by rapid atrial pacing with the temporary epicardial atrial wires placed at the time of surgery (Fig. 60-9). The likelihood of success is increased if one uses sufficiently rapid rates of pacing (up to 140 percent of the spontaneous atrial rate), a sufficient duration of pacing (10 to 30 seconds) with adequate strength (5 to 20 mA), and pretreatment of the patient with procainamide.[94] To achieve the high drive rates required, a special stimulator is used.

ATRIAL FIBRILLATION.

Despite the fact that AF is an extremely common arrhythmia following cardiac surgery, the optimal management strategy has not been established. Even after prophylactic therapy with beta-adrenoceptor blockers, transient symptomatic AF occurs in at least 25 to 30 percent of patients after CABG and in 50 percent of patients following valvular surgery; AF appears with greatest incidence on the second or third postoperative day.[52]

Management.

Unless hemodynamic collapse is present, in which case direct-current cardioversion should be performed, the initial treatment of choice in a postoperative patient is to slow the ventricular rate. Provided that the patient's ventricular function is adequate, acute intravenous administration of beta blockers (e.g., metoprolol 5 mg every 5 minutes for up to three doses), verapamil (5-mg bolus every 5 to 10 minutes for three or four doses), or diltiazem (0.25- to 0.35-mg/kg bolus over a period of 2 minutes) is a more desirable option. Esmolol, an ultrashort-acting cardioselective beta blocker, when administered intravenously in a dose of 50 to 250 mug/kg/min, provides the option of rapid onset; in the event of hemodynamic deterioration, the effects of the drug are usually dissipated within 15 to 30 minutes after discontinuation of the infusion. In addition, the probability of conversion to sinus rhythm with esmolol appears to be better than with other agents such as verapamil.[95]

ANTICOAGULANTS.

Epidemiological observations suggest that the development of postoperative AF is associated with a marked increase in the risk of stroke (odds ratio 3.0) and prolonged hospitalization.[50] [51] [52] No consensus has been reached regarding anticoagulation recommendations in patients with postoperative AF. The risk of hemorrhage in the early postoperative period must be weighed against the risk of systemic thromboembolism.[96] When AF develops beyond the second postoperative

day, we generally advocate adherence to the guidelines established for nonsurgical patients and initiate anticoagulation (intravenous heparin followed by oral warfarin) in patients who have been in the arrhythmia for more than 48 hours, especially if the patient has a history of systemic embolism or if mitral valve disease or cardiomyopathy is present.[97]

Beyond control of the ventricular rate acutely, the two treatment strategies for management of postoperative AF are similar to those

Figure 60-8 Epicardial electrodes in patients undergoing cardiac surgery. The precise number and location of pacing wires may vary among institutions and also by the complexity of the operation (e.g., no atrial wires for routine coronary artery bypass surgery but both atrial and ventricular wires for valve surgery). In the example shown, the two atrial wires exit to the patient's right while the ventricular wires are the first two leads exiting to the patient's left; the subcutaneous ground wire is the one closest to the left anterior axillary line.

Figure 60-9 Recording of electrocardiographic leads II and III in a patient with atrial flutter. Panels *A* and *B* are not continuous tracings. The dots in *A* mark the onset of rapid atrial pacing at 350 beats/min with a pacing stimulator capable of high drive rates. The morphology of the atrial complexes changes dramatically such that by the end of the trace in *A,* the atrial complexes are positive in leads II and III. Panel *B* shows the termination of 30 seconds of atrial pacing at 350 beats/min. The circles represent the last paced atrial beat. With abrupt termination of the rapid atrial pacing, sinus rhythm appears. S = stimulus artifact. Time lines are at 1-second intervals. (From Waldo AL, MacLean WAH: Diagnosis and Treatment of Cardiac Arrhythmias Following Cardiac Surgery. Mt Kisco, NY, Futura, 1980.)

for nonsurgical patients: chronic anticoagulation while administering rate-controlling agents versus restoration of sinus rhythm and attempts at suppression of recurrence of AF. Because large-scale clinical trial data are not available to guide decision-making in this area, therapeutic approaches must be individualized.[96] Ibutilide, a class III antiarrhythmic agent, has been shown to be effective in the acute conversion of post-CABG AF when administered intravenously, albeit with a small risk (<2 percent) of torsades de pointes.[98] Procainamide is frequently used for the treatment of AF after open-heart surgery, although present evidence indicates that it has limited effectiveness in suppressing recurrence of AF.[99] Furthermore, any treatment decision formulated during hospitalization should be readdressed at the first postoperative visit (typically 4 to 6 weeks) to determine whether it is still a desirable course of action once the inflammation and metabolic alterations of the postoperative state have dissipated.

Patients with depressed left ventricular function or striking ventricular hypertrophy who experience troublesome dyspnea and/or hypotension when in AF postoperatively are suitable candidates for a trial of restoration of sinus rhythm.

Permanent suppressive antiarrhythmic therapy is often necessary in patients with rheumatic heart disease and a preoperative history of AF despite successful aortic or mitral valve surgery even if sinus rhythm is present during the early postoperative period.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA.

The reentrant forms of paroxysmal supraventricular tachycardia (PSVT)--atrioventricular nodal reentry tachycardia and atrioventricular reentry tachycardia--occur less frequently in postoperative patients than does AF or atrial flutter but, fortunately, retain their responsiveness to vagal maneuvers and pharmacotherapy designed to inhibit atrioventricular nodal conduction. The antiarrhythmic agent adenosine, an endogenous nucleoside, has a number of features that make it the drug of choice for treating PSVT in postoperative patients.[100] A rapid (2 seconds) intravenous bolus of 6 mg terminates about 60 percent of episodes of PSVT within 20

seconds; a subsequent bolus of 12 mg administered 1 to 2 minutes later terminates PSVT in virtually all patients who failed to respond to the lower dose. Because adenosine is rapidly transported into the cell or degraded enzymatically to inosine, the physiological effects of adenosine are dissipated in less than 5 minutes. Untoward reactions such as flushing, chest pain, or dyspnea, although common, are mild and short-lived.

PSVT may also be diagnosed by atrial recordings and terminated by burst atrial pacing or randomly delivered ventricular or atrial premature depolarizations that invade the reentrant circuit and interrupt the arrhythmia.

Ventricular Arrhythmias

VENTRICULAR PREMATURE DEPOLARIZATIONS.

Isolated ventricular premature depolarizations (VPDs) commonly occur after cardiac surgery. An increase in the density of VPDs may be seen in patients with a preoperative history of VPDs, or they may appear de novo in patients with no history of ventricular arrhythmias. Although a fall in arterial pressure may be associated with isolated VPDs, this decreased pressure is usually extremely brief and of no significant hemodynamic consequence to the patient unless prolonged periods of bigeminy occur.

Management.

We advocate a conservative approach focusing on prompt detection and correction of provocative factors, liberal use of beta blockers in patients with an ejection fraction greater than 30 percent, overdrive atrial or atrioventricular sequential pacing between 85 and 100 beats/min, and restriction of suppressive antiarrhythmic therapy to patients with a preoperative history of serious ventricular tachyarrhythmias.[52] If the decision is made to suppress VPDs in a patient without a history of symptomatic ventricular arrhythmias, the treatment period should be brief (6 to 24 hours) and the patient should not be automatically converted to treatment with an oral antiarrhythmic drug regimen without careful reconsideration of the indications for treatment.

VENTRICULAR TACHYCARDIA.

Many of the same arguments cited above for isolated VPDs can be applied to paroxysms of nonsustained VT. No definitive guidelines are available, but we believe that symptomatic episodes of nonsustained VT in the absence of correctable factors and attempts at overdrive atrial or atrioventricular sequential pacing are indications for antiarrhythmic therapy, especially if the episodes are associated with hemodynamic compromise. *Sustained VT* is a serious emergency that should be handled in an orderly approach. If the clinical situation permits, a 12-lead ECG should be obtained for future reference and confirmation of the diagnosis; simultaneous recording of surface ECG leads with electrograms from the epicardial wires may be helpful in establishing the mechanism of a wide complex tachycardia.

Attempts at acute conversion of the tachycardia include the following maneuvers in the sequence listed: thumpversion, burst ventricular pacing, and boluses of antiarrhythmic agents (lidocaine 100 mg, procainamide up to 500 to 1000 mg over a period of 20 minutes, amiodarone 75 to 150 mg infused over a 10-minute period, or bretylium 500 to 1000 mg over a period of 5 to 10 minutes). In urgent circumstances, synchronized direct-current cardioversion with a low-energy shock (25 to 50 watt-seconds) may be used. Unsynchronized shocks of 100 to 200 watt-seconds should be administered if the tachycardia rate is greater than 160 beats/min and/or has a sinusoidal waveform on ECG. After conversion, a search for correctable disorders should be undertaken, and if none is found, a continuous infusion of lidocaine (2 mg/min), procainamide (2 mg/min), amiodarone (1.0 mg/min for 6 hours followed by a maintenance infusion of 0.5 mg/min), or bretylium (1 to 2 mg/min) is started.

VENTRICULAR FIBRILLATION.

As in nonsurgical patients, ventricular fibrillation (VF) must be promptly treated with an unsynchronized direct-current shock. VF can often be reverted with shocks of 200 watt-seconds, provided that the intervention is performed promptly. It should be possible to defibrillate postoperative patients in the ICU expeditiously; therefore, the higher energies (360 to 400 watt-seconds) used in the "field" are probably unnecessary--at least initially. Because of the small number of patients experiencing unexpected sustained, hemodynamically compromising VT or VF, epidemiological data on provocative factors and the prognosis of these arrhythmias are difficult to evaluate.[52] [101] [102] Unexplained VT or VF occurring within 24 hours after CABG surgery is associated with very high in-hospital mortality, probably resulting from perioperative ischemia, infarction, and/or pump failure.[101] Episodes of VT or VF occurring more than 24 hours after bypass surgery have a slightly less ominous prognosis and may be due to reperfusion of previously ischemic zones, early postoperative occlusion of coronary bypass grafts, or transmembrane shift of electrolytes

during the process of recovery.[103] [104]

Risk stratification of patients experiencing VT or VF postoperatively should include assessment of left ventricular function, coronary arteriography if ischemia/infarction is suspected, and consideration of an electrophysiological study to establish the most appropriate course of therapy.[105] Because of the numerous metabolic fluxes taking place in the early postoperative period, electrophysiological study should, if possible, be postponed until at least 5 to 7 days following surgery.[52] Serious consideration should be given to use of an implantable cardioverter-defibrillator in patients without an identifiable reversible cause of their arrhythmia, particularly those with a depressed ejection fraction.

ATRIOVENTRICULAR JUNCTIONAL RHYTHMS.

Nonparoxysmal atrioventricular junctional rhythms (rate >45 beats/min) can be seen after mitral or aortic valve surgery. Trauma and tissue swelling from surgical debridement and suture placement are believed to be the provocative mechanisms. Such rhythms are typically transient (
48 hours) and easily treated with atrial or atrioventricular sequential pacing at a rate above that of the intrinsic junctional mechanism.[106]

Bradyarrhythmias

Sinus bradycardia or sinus arrest with emergence of a slow atrioventricular junction escape rhythm may be seen postoperatively when one or more of the following factors are present: advanced age, hypothermia, drug effects (diltiazem, beta blocker, digitalis, procainamide), preoperative sinus node dysfunction, intraoperative trauma to the sinus node, and postoperative elevation in vagal tone.[107] In addition to modifying the dose or discontinuing the use of offending drugs (such as those noted above), atrial pacing at 85 to 100 beats/min should be initiated to maintain adequate cardiac output and urine flow.

Although a new conduction defect may develop in up to 45 percent of patients following cardiac surgery, the majority are usually transient and related to the extensive use of cold cardioplegia, hypothermia, perioperative electrolyte shifts, or surgical trauma during valve repair/replacement or closure of septal defects.[108] [109]

MANAGEMENT.

The decision to insert a permanent pacemaker (see Chap. 24) after cardiac surgery should be based on the hemodynamic consequences of bradycardia in the individual patient rather than on a specific heart rate. Most new conduction defects resolve in the early postoperative period, but some persist for as long as 2 weeks. Few data are available to guide the decision about timing of implantation of a permanent pacemaker. We are willing to monitor a younger patient (<65 years) following CABG surgery with a temporary pacing system postoperatively to see whether a conduction defect resolves. However, we have a low threshold for implanting a permanent pacemaker following aortic or mitral valve surgery or if antiarrhythmic therapy or beta-blocker treatment is contemplated because these pharmacological measures might "stress" a diseased conduction system. We advocate early insertion of a permanent pacemaker in elderly patients with symptomatic

bradycardia because the recuperative process is facilitated, the period of relative immobilization and ECG monitoring is minimized, and hospital stay is shortened.[110] Finally, we are more aggressive about implantation of permanent pacemakers in patients with persistent advanced atrioventricular block than in to patients with isolated sinus bradycardia.

CARDIOVERSION.

Direct-current cardioversion should be used in postsurgical patients with the following additional considerations. The recent cardiotomy with resultant pericardial and mediastinal inflammation, the presence of chest tubes and/or pleural effusions, and elevated catecholamine levels after surgery may all contribute to higher energy requirements for reversion of arrhythmias such as AF than are commonly required in patients who have not recently undergone cardiac surgery. To achieve the maximum transcardiac spread of current after median sternotomy, the anterior paddle should be placed to the *right* of the sternum between the third and sixth intercostal space, and the other paddle should be positioned in the fourth to sixth intercostal space as far in the left axilla as possible or in a posterior location under the tip of the left scapula. Firm pressure is applied to the paddles to maintain contact with the chest wall as the discharge buttons are depressed.

Hemostatic Disturbances (See Chap. 62)

Multifactorial derangement of the hemostatic system develops in all patients who undergo cardiopulmonary bypass. These abnormalities are caused by exposure of the blood to artificial surfaces, hemodilution, and the effects of heparin[111] [112] [113] [114] [115] (Table 60-8) . Platelet dysfunction is the most significant hemostatic abnormality that occurs after cardiopulmonary bypass, although diminution of coagulation factor levels may assume greater significance in patients with preoperative deficiencies in hemostasis. Administration of the following drugs before surgery may predispose the patient to excessive bleeding: aspirin and other antiplatelet agents, nonsteroidal antiinflammatory agents, thrombolytic agents,[113] certain antibiotics (carbenicillin, ticarcillin, moxalactam, cefamandole, third-generation cephalosporins), dextran, amrinone, quinidine, cytotoxic agents, gold, phenylbutazone, and fish oils.[113]

MANAGEMENT.

The most obvious evidence of bleeding in a postoperative cardiac surgical patient is by means of chest tube drainage. "Acceptable" rates of bleeding are usually less than 100 ml/hr. In our institution, guidelines for returning to the operating room because of excessive bleeding include more than 500 ml/hr for 1 hour, more than 300 ml/hr for 3 hours, and 200 to 300 ml/hr for 5 hours. These guidelines may be tempered by correctable extenuating circumstances, such as uncontrolled hypertension postoperatively, failure to achieve normothermia, or an abnormal coagulation status that is being corrected. Emergency medical maneuvers that can be attempted after sending coagulation studies to the laboratory include the use of PEEP up to 10 cm H_2O for mediastinal tamponade, empirical "correction" of putative platelet dysfunction with desmopressin acetate (DDAVP, a synthetic analog of arginine vasopressin that increases plasma levels of von Willebrand factor) 0.3 mug/kg infused over a period of 15 to 30 minutes, and empirical administration of a small dose of protamine sulfate 25 to 50 mg because heparin may be liberated from the patient's fat stores as rewarming occurs.[116]

Once the coagulation profile returns, additional therapy in the form of platelet transfusions for a platelet count less than 100,000/mm^3 and fresh frozen plasma to correct an elevated prothrombin time can be prescribed. Aprotinin therapy (2×10^5 KIU loading bolus followed by infusion of 0.5×10^5 KIU/hr for 4 hours) is helpful in cases of excessive postoperative bleeding by virtue of its ability to inhibit fibrinolysis and replenish platelet glycoprotein Ib receptors and von Willebrand factor activity.[117] [117A] When monitoring bleeding from a chest tube, it is important to be alert to sudden cessation of hemorrhage, which may indicate that the chest tubes have clotted and the fluid is now draining into the mediastinum or the pleural spaces. Serial chest radiographs may be helpful while observing a patient during a bleeding episode. With correct medical management, less than 5 percent of patients need to return to the operating room for control of bleeding, preferaby within 3 to 4 hours of the original surgery, before hemodynamic destabilization occurs and large volumes of blood products are administered.

ANTITHROMBOTIC THERAPY IN CARDIAC SURGICAL PATIENTS.

A wide spectrum of patients recovering from cardiac surgery may require either short- or long-term antithrombotic therapy[118] (Table 60-9) . Furthermore the intensity of therapy will be dictated by the estimated risk of thromboembolism. Variables that may have an impact on the risk of thromboembolism include insertion of a prosthetic valve (mechanical more than bioprosthetic), valve location (mitral more than aortic), the presence of AF, size of the left atrium, history of thromboembolism, left atrial thrombi visualized at surgery, and ventricular wall motion abnormalities associated with mural thrombi.

TABLE 60-8 -- HEMOSTATIC DISTURBANCES FOLLOWING CARDIOPULMONARY BYPASS

ABNORMALITY	CAUSE
Exposure of blood to artificial surfaces	

1.Platelet dysfunction A. Prolonged bleeding time B. Decreased adhesiveness	1. Depletion of platelet alpha granules, reduced response to wounds, and increased plasma levels of platelet factor 4 and beta-thromboglobulin[111]
2. Inflammatory response	2. Activation of the complement, coagulation, fibrinolytic, and kallikrein cascades; activation of neutrophils with degranulation and protease enzyme release; oxygen free radical production; and synthesis of cytokines (tumor necrosis factor, interleukin-1, interleukin-6, interleukin-8)
Hemodilution	
1. Thrombocytopenia	1. Priming of extracorporeal bypass circuit with crystalloid solutions. Heparin-mediated immune thrombocytopenia may occur in about 5% of patients*
2. Coagulation factor depletion	2. Most coagulation factor levels are reduced by hemodilution by about 50%; factor V is reduced to 20-30% of normal and factor VIII is relatively unaffected. Factor levels usually return to normal within 12 hr after completion of cardiopulmonary bypass. Although plasminogen and fibrinogen levels are decreased by about 50%, fibrin degradation products usually do not appear in the plasma during bypass[113]
Heparinization	Thrombus formation is inhibited and excessive bleeding is avoided intraoperatively by maintaining the activated clotting time between 400 and 480 sec

*Note: reversal of heparin effects is accomplished with protamine sulfate. Vascular collapse has been reported in some patients during protamine treatment. To avoid the problem of heparin-induced thrombocytopenia and because heparin may not effectively inhibit all the thrombin generated during cardiopulmonary bypass ("heparin rebound"), novel antithrombins are being evaluated as alternatives to heparin during surgery.[114] [115]

TABLE 60-9 -- ANTICOAGULATION GUIDELINES FOR ANTITHROMBOTIC THERAPY IN CARDIAC SURGERY PATIENTS

SURGERY	ANTICOAGULANT	INR*
Mitral mechanical valve	Warfarin	2.5-3.5
Aortic mechanical valve	Warfarin	2.0-3.0
Tricuspid mechanical valve	Warfarin	2.5-3.0
Atrial fibrillation	Warfarin	2.0-2.5
Mitral tissue valve	Warfarin	2.0-3.0 for 6 wk
Mitral valve repair	Warfarin	2.0-2.0 for 6 wk
Tricuspid tissue valve	Warfarin	2.0-3.0 for 6 wk
Tricuspid repair	Warfarin	2.0-3.0 for 6 wk
LV thrombus	Warfarin	2.0-3.0 for 6 mo
LV aneurysm repair	Warfarin	2.0-3.0 for 6 wk
Aortic tissue valve	Aspirin (80 mg/d)	
Coronary artery bypass	ASA 325 mg/d, 81 mg/d if taking Coumadin	

ASA=acetylsalicylic acid (aspirin); LV=left ventricular.

*The target international normalized ratio is the midpoint of the range.

Infection

FEVER.

Despite its nonspecific nature, fever is the most common initial clinical sign of a postoperative infection.[119] It should be emphasized, however, that patients who experience a normal course of convalescence continue to show an elevated temperature for up to 6 days postoperatively.[120] In the absence of infection, such early fevers are believed to be caused by alterations in blood components after cardiopulmonary bypass. In addition to infectious causes, fevers that occur beyond 6 days may be due to drug reactions, phlebitis at the site of intravenous lines, atelectasis, pulmonary emboli, or the postpericardiotomy syndrome.

WOUND AND INCISION

Leg.

Infections of the leg wound are typically manifested by fever, induration, pain, erythema, local warmth, and drainage from the suture line. The usual infectious agents include *Staphylococcus, Streptococcus,* and aerobic gram-negative bacilli. Wound aspiration and Gram stain should be used to guide antibiotic treatment. More advanced cases require wound debridement and open drainage. Techniques of minimally invasive saphenous vein harvesting now make it possible to avoid a long leg incision, which decreases the risk of postoperative leg infection[120A] (Fig. 60-10) .

Recurrent bacterial cellulitis in the leg used for saphenous vein harvest may be a recalcitrant problem that appears months to years after surgery. Antibiotic courses directed against staphylococcal and streptococcal species for each individual occurrence may be insufficient, and a long-term course of antibiotic therapy may be needed. It is important to search for evidence of superficial fungal infections in the affected leg because persistent tinea pedis infection has been reported to cause recurrent lower extremity cellulitis.[121] If a fungal infection is identified, treatment with topical miconazole or clotrimazole should be given in addition to antibacterial therapy.

Mediastinitis.

Mediastinitis and sternal osteomyelitis are among the most serious complications of median sternotomy.[37] [122] If one excludes operations that occur after thoracic trauma, it is estimated that mediastinitis occurs in about 2 percent of patients who undergo median sternotomy.

Most cases of mediastinitis occur within 2 weeks after sternotomy. Important diagnostic features of patients in whom mediastinitis

Figure 60-10 Minimally invasive approaches to saphenous vein harvesting have significantly reduced incisional morbidity. Traditional harvesting requires long leg incisions (*A*), as compared with the less invasive videoscopic harvesting (*B*). A dissection cannula is introduced through a small incision (*C*), and branches are later divided (*D*) under videoscopic guidance.

develops early after cardiac surgery include persistent fever in excess of 101°F beyond the fourth postoperative day, a systemic toxic condition, leukocytosis,

bacteremia, and a purulent discharge from the sternal wound. Recognition of mediastinitis requires a high index of suspicion and a vigorous, repetitive search for evidence of sternal wound drainage in patients who are persistently febrile late into the first week after surgery and who have no other obvious focus of infection, such as pneumonia or urinary tract infection.[123] The diagnosis can be confirmed by needle aspiration from the subxiphoid approach followed by Gram's stain and culture.

Risk Factors and Diagnosis.

Risk factors for the development of mediastinitis include prolonged cardiopulmonary bypass time, excessive postoperative bleeding with reexploration for control of hemorrhage, and diminished cardiac output in the postoperative period. The incidence of mediastinitis is increased when both internal mammary arteries are mobilized bilaterally for use as bypass conduits.[124] Therefore, many surgeons prefer to use only the left internal mammary artery, particularly in elderly diabetic patients, who may already be predisposed to delayed sternal wound healing.

The spectrum of microorganisms that cause mediastinitis includes *Staphylococcus* (*aureus* and *epidermidis*) in about 50 percent of patients and a variety of gram-negative bacilli in about 40 percent of cases.[123] [124] [125] Mixed infections and fungal infections are rare. The organism isolated frequently is resistant to the prophylactic antibiotic used preoperatively, especially if the isolate includes a gram-negative bacillus or a beta-lactamase-producing *S. aureus.*

DIAGNOSIS OF STERNAL WOUND INFECTION.

Definitive diagnosis requires exploration of the wound and culture of suspicious areas. In the past, closed (debridement, reclosure, and antibiotic irrigation) and open (debridement, packing, closure by secondary intent) approaches were commonly used. To facilitate functional recovery, we now favor early plastic surgical flap techniques to allow for immediate primary closure with vascularized tissue.[126] [127] Regardless of the sternal closure strategy used, bacterial-specific intravenous antibiotics are typically administered for 6 weeks.

INFECTIVE ENDOCARDITIS (see Chap. 47)

It has been convincingly shown that perioperative antibiotic prophylaxis is of benefit in patients undergoing cardiac surgery.[128] Although the antibiotic regimen varies, in part related to local differences in microbiological flora and personal preference, it is directed against gram-positive cocci (the most frequent causative pathogens in infections after cardiac surgery) and usually contains a cephalosporin. The regimen used in our institution consists of 1 gm of cefazolin intravenously 30 minutes before the skin incision and then repeated at 8-hour intervals for 48 hours after surgery.

PROSTHETIC VALVE ENDOCARDITIS (see Chaps. 46 and 47) .

Prosthetic valve endocarditis is a rare, but extremely serious complication of cardiac surgery, frequently arising from nosocomial bacteremias.[129] [130] It is estimated to occur in only 2 to 4 percent of patients; about half of the cases are classified as "early" (<60 days from the date of surgery) and half as "late" (>60 days from the date of surgery).[129] [130] [131] Pooled data from several series indicate that the organism responsible for early prosthetic valve endocarditis includes a *Staphylococcus* species in about 50 percent of cases.[131] The remainder of early cases of prosthetic valve endocarditis are caused by gram-negative bacilli, diphtheroids, and fungi.

Management.

Features of prosthetic valve endocarditis that have been associated with increased mortality include invasive infection (i.e., extension into the myocardium), congestive heart failure resulting from dysfunction of the prosthesis, and the presence of antibiotic resistant, virulent microorganisms or a fungal organism.[131] Appropriate antibiotic therapy for prosthetic valve endocarditis is discussed in Chapter 47 .

VIRAL.

Viral infections that occur after cardiac surgery are almost exclusively the result of infectious complications of transfusion therapy and, with the exception of human immunodeficiency virus, primarily result in hepatitis. The incidence of viral infections after cardiac operations is decreasing as a result of a reduction in the number of transfusions of blood bank products (e.g., cell saver techniques and preoperative autologous blood donations) and improved screening techniques in contemporary blood bank practice. Cytomegalovirus infection is a febrile syndrome that typically occurs 1 month postoperatively. It is characterized by high-spiking fevers, abnormalities in liver function test results, and arthralgias. A self-limited illness, it is best treated with antipyretics and supportive fluid therapy.

FUNGAL.

Fungal infections that involve the heart are rare. They are typically seen in cases of fungemia and are usually fatal. Although the problem of fungemia is well described in immunocompromised hosts (e.g., heart transplant recipient), in an autopsy study of 60 patients with fungal infections of the heart, 25 percent of cases occurred in association with conventional valvular surgery.[132] About half of fungal infections of the heart are confined to the endocardium, and half involve both the endocardium and the myocardium. Extracardiac involvement is common, with spread of infection to the lungs, cerebrospinal fluid, urine, and skin. The most commonly encountered organisms, in descending order of frequency, are *Candida, Aspergillus,* and *Cryptococcus* species. Patients who appear to be at particular risk of fungal involvement of the heart are those who have received corticosteroids and long courses of antibiotic treatment postoperatively.

Peripheral Vascular Complications

Most adults who undergo cardiac surgery--especially coronary revascularization--have atherosclerosis of the peripheral vasculature (e.g., ileofemoral system) and may experience lower extremity ischemia after surgery because of low flow in the perioperative period with in situ thrombosis, embolism from the heart or aorta, or vascular compromise from an intraaortic balloon pump catheter. Management consists of anticoagulation and removal of indwelling catheters, if clinically feasible. Thrombectomy and even revascularization surgery of the lower extremities (e.g., femorofemoral, femoropopliteal, or axillofemoral bypass) may be required to salvage threatened limbs.

Asymptomatic deep venous thrombosis of the calf can develop before hospital discharge in about one-third to one-half of patients who receive saphenous vein bypass grafts. Occasionally, these thrombi propagate to the proximal leg veins; only rarely do they cause massive pulmonary embolism.[30] [133] The best strategy is rigorous perioperative prophylaxis against venous thromboembolism in all such patients. Low-molecular-weight heparin (e.g., enoxaparin 30 to 40 mg subcutaneously every 12 hours) appears to be efficacious.

Other Complications

PERICARDITIS (see Chap. 50) .

Postoperative tamponade is discussed on p. 55 . Pericardial friction rubs are frequently audible in the early postoperative period and are probably the result of mechanical irritation from the mediastinal chest tubes. They usually disappear by the second or third postoperative day and are asymptomatic because of the narcotic analgesics prescribed at that stage of recovery. Although pericardial rubs develop in some patients toward the end of the first postoperative week, they are usually benign, do not indicate a need for prolongation of hospitalization, and do not require treatment. A separate clinical syndrome that appears late in the first postoperative month is the *postpericardiotomy syndrome.*[134] The relationship between postpericardotomy syndrome and chronic constrictive pericarditis is not firmly established, but a number of patients with *postoperative constrictive pericarditis* have a history of postpericardiotomy syndrome.

RENAL FAILURE (see Chap. 72) .

All patients who undergo cardiac surgery experience a reduction in renal blood flow and the glomerular filtration rate (GFR) as a consequence of both anesthesia and cardiopulmonary bypass. Risk factors for the development of persistent renal failure after cardiac surgery include a preoperative history of renal dysfunction or left ventricular dysfunction, prolonged bypass time (>180 minutes), prolonged aortic cross-clamping (>60 minutes), perioperative hypotension, advanced age (>70 years), and the development of medical complications postoperatively.[135]

Most cases of acute renal failure after cardiac surgery result from renal ischemia that lowers the GFR directly (prerenal disease) or, if severe or prolonged, can induce acute tubular necrosis. Possible additional contributory factors include sepsis, nephrotoxic drugs, radiocontrast material injection, cholesterol plaque embolization in the renal circulation, increased urine free hemoglobin levels from hemolysis while undergoing cardiopulmonary bypass, and the effects of ACE inhibitors on glomerular capillary pressure.[136] The detrimental effects of ACE inhibitors are most likely to occur when renal perfusion pressure is low because of renal artery stenosis or

systemic hypotension caused by cardiac failure.

Urine output is variable in patients with postoperative acute renal failure. Anuria is uncommon and, if present, should raise the suspicion of urinary tract obstruction (e.g., occluded Foley catheter). More commonly, patients are either oliguric (<400 mg/d) or nonoliguric. Oliguric acute renal failure occurs less frequently than nonoliguric renal failure, usually reflects more severe renal injury, and is associated

with a greater probability of requiring dialysis during the acute phase.[136]

Differentiation Between Prerenal Azotemia and Acute Tubular Necrosis.

Important diagnostic studies in all patients with acute renal failure include urinalysis and estimation of pulmonary capillary wedge pressure and cardiac output by means of pulmonary artery catheterization. Prerenal azotemia should be suspected if the urine sodium level is less than 20 mEq/liter, the fractional excretion of sodium is less than 1 percent, and urine osmolality is greater than 500 mOsm/liter. Acute tubular necrosis should be suspected if the urine sodium level is greater than 40 mEq/liter, fractional excretion of sodium is greater than 2 percent, and urine osmolality is less than 350 mOsm/liter.[136]

Treatment.

Essential elements of therapy for both prerenal azotemia and acute tubular necrosis include optimization of intravascular fluid volume and cardiac output. The latter is best accomplished with vasodilators and inotropic agents rather than vasopressors to avoid further reductions in renal blood flow. Experimental studies suggest that several modalities may protect against the development of progressive renal failure in models of acute renal ischemic injury (e.g., renal artery clamping that simulates the effects of suprarenal aortic cross-clamping while undergoing cardiopulmonary bypass). Mannitol (which washes out obstructing casts), a loop diuretic (which decreases energy requirements in the thick ascending limb of the loop of Henle, thereby decreasing ischemic injury), and the combination of dopamine and atrial natriuretic peptide (but neither alone) have all been effective.[137]

It is prudent to undertake a trial of furosemide and mannitol (only if the patient can tolerate the volume load of the latter) within the first 12 to 24 hours after the development of oliguria. The aim of such therapy is to increase urine output. Because of the renal vasodilating effects of dopamine (2 to 3 mug/kg/min), patients with both oliguric and nonoliguric renal failure may experience an increase in urine output.[138]

If oliguria persists beyond 12 hours, a number of supportive measures must be initiated, including careful attention to electrolyte balance, specifically avoiding hyperkalemia; avoidance of excessive free water administration, which might lead to hyponatremia; correction of acidosis (adding bicarbonate to daily fluids); and adjustment of medication dosages for delayed excretion if the drug is cleared by renal mechanisms. Analysis should be carried out for pericarditis, refractory hyperkalemia, uremic encephalopathy, or colitis. Continuous arteriovenous hemofiltration can be used to remove excess fluid.

Cardiac Surgery in Patients with Chronic Renal Failure.

Patients with chronic renal failure who undergo surgery have an increased risk of exacerbation of renal dysfunction perioperatively. Deterioration in renal function may require temporary or even permanent hemodialysis, and these eventualities should be addressed with the patient and the cardiac surgical team preoperatively. Surgery can be safely performed in patients who are already maintained by hemodialysis, but careful coordination of the surgical and dialysis schedules is essential to minimize postoperative problems with fluid and electrolyte management.

GASTROINTESTINAL COMPLICATIONS.

Serious gastrointestinal complications after cardiac surgery [139] , [140] are rare (occurring in about 1 percent of patients) and can usually be handled by a conservative approach. Only about 0.5 percent of patients who undergo cardiac surgery require a general surgical operation for a gastrointestinal complication.[140] [141] Patients with circulatory compromise and those who require intraaortic balloon pump support are more likely to have gastrointestinal complications. Despite their relative rarity, gastrointestinal complications are associated with significant mortality (approaching 40 percent in some series), thus highlighting the need for careful monitoring and repeated physical examination in high-risk patients.[139] [140] Most complications occur within 7 days of surgery.

NEUROLOGICAL COMPLICATIONS.

Neurological complications after cardiac surgery are quite common, particularly in the elderly, if one is attentive to the subtle cognitive (short-term memory loss, lack of concentration) and psychological (depression, increased sense of dependency) changes seen early after surgery.[22] [142] [142A] A positive and supportive attitude on the part of the staff and enlistment of the aid of family members help minimize these problems. Although many patients return to their postoperative state by 4 to 6 weeks after surgery, about 10 percent continue to show deterioration in neuropsychological functioning over the next 6 months, especially if they are older than 65.[22] [142] More serious neurological complications such as stroke occur in 1 to 5 percent of patients but may be seen in as many as 10 percent of patients older than 65.[22]

Symptomatic visual defects may be seen after cardiac surgery and result from retinal emboli, occipital lobe infarction, or anterior ischemic optic neuropathy. Risk factors for cerebrovascular accident (CVA) or transient ischemic attack (TIA) after cardiac surgery include preoperative carotid bruit, previous CVA or TIA, postoperative AF, prolonged cardiopulmonary bypass (>2 hours), and preoperative left ventricular mural thrombus.[22] [143]

Neuropathies in the upper extremities have been reported after cardiac operations. A pattern of injury involving predominantly the ulnar nerve and medial antebrachial cutaneous nerve suggests that the lesion involves brachial plexus compression or a traction injury.[144] The average duration of symptoms after such an injury is 2 months, but some patients show a slower time course of improvement extending over 6 to 12 months.

REHABILITATION AND PREPARATION FOR DISCHARGE (see Chap. 39)

A coordinated, multidisciplinary cardiac exercise program is essential to overcome the physical deconditioning and psychosocial upheaval associated with cardiac surgery. Emphasis should be placed on early mobilization and progressively more patient self-care, including initiation of these measures in the ICU during the first 24 hours postoperatively. After transfer out of the ICU, the patient should be encouraged to engage in low-density (2 to 3 METS) isotonic activities such as walking and range-of-motion exercises.[145] The nursing staff should monitor the patient's progress while being alert to any undue accelaration in heart rate (>120 beats/min) or hemodynamically compromising arrhythmias.

Patients should also participate in an education program focusing on instructions regarding postoperative medications and initiation of secondary measures targeted at preventing graft occlusion and progression of atherosclerosis.[60] [146] [147] Because of the overwhelming evidence indicating that platelet inhibition is critical to prevention of graft occlusion, all patients undergoing bypass surgery should receive long-term therapy with aspirin unless contraindicated. Ticlopidine may be useful in aspirin-intolerant patients, but there is no evidence of significant benefit from the routine use of either dipyridamole or sulfinpyrazone. Fast-track discharge protocols are now standard, and uncomplicated patients are typically discharged on the fifth postoperative day.[148]

Chapter 61 - General Anesthesia and Noncardiac Surgery in Patients with Heart Disease

LEE GOLDMAN
JOSHUA ADLER

The cardiovascular system of patients undergoing general anesthesia and noncardiac surgical procedures is subject to numerous stresses owing to depression of myocardial contractility and respiration as well as fluctuations in temperature, arterial pressure, ventricular filling pressures, blood volume, and activity of the autonomic nervous system. Complications of anesthesia and operation, such as hemorrhage, infection, fever, pulmonary embolism, and myocardial infarction, impose additional burdens on the cardiovascular system. Patients who have cardiac disease and who are compensated preoperatively may be unable to meet these increased demands during the perioperative period, in which case arrhythmias, myocardial ischemia, and/or heart failure may develop.[1] [2] [3] As a consequence, a substantial proportion of all deaths in most series of noncardiac operations results from cardiovascular complications.

Because both the frequency and the seriousness of cardiovascular complications of general anesthesia and operation are considerably increased in patients with known cardiovascular disease, the magnitude of these risks must be appreciated to decide on the advisability of noncardiac surgery in cardiac patients. In addition, both the life expectancy and the quality of life of patients must be taken into account. For instance, a noncardiac surgical procedure with a high risk, directed to correct a disorder that is not life threatening, may be difficult to justify if the patient's cardiac condition precludes a survival period sufficient to allow the patient to reap the benefits of the operation. Obviously, the dangers and disability of the disease for which an operation is being proposed must also be balanced against the risk of the operation itself.

ANESTHESIA

Changes in cardiovascular function during general anesthesia are due to many factors, including direct effects of the anesthetic agent(s) and indirect effects mediated primarily through the autonomic nervous system. In addition, if respiration is inadequately maintained, the resulting hypoxemia, hypercarbia, and acidosis may further depress myocardial contractility and increase cardiac irritability. The interplay of these several variables may produce changes in arterial and central venous pressures, cardiac output, and rate and rhythm. To minimize the risk of operation in patients with a compromised cardiovascular system, it is essential to minimize these changes.[3]

The choice of the anesthetic approach and the specific anesthetic agents to be used should be made by a qualified anesthesiologist, commonly after careful evaluation of the patient's medical and cardiac condition and often after consultation with the surgeon and the internist or cardiologist. Different anesthesiologists may prefer different anesthetic techniques, and the anesthesiological literature clearly indicates that there is little, if any, correlation between the anesthetic route or agents and the likelihood of major clinical complications. Thus, the skill and experience of the anesthesiologist, including the ability to monitor hemodynamics and respond quickly, are far more important than the specific agent or technique that is used. Although the cardiological consultant should not expect to dictate the anesthetic approach, the quality of the consultation will be improved if the consultant appreciates the clinical pharmacology of the anesthetic agent.

General Anesthesia

The induction of general anesthesia is usually accomplished with intravenous anesthetics. The common agents used for the induction of anesthesia, barbiturates and benzodiazepines, lower systemic arterial pressure by about 20 to 30 percent in healthy patients but sometimes by a greater amount in hypertensive patients.[3] Barbiturates reduce blood pressure through depression of myocardial contractility and sympathetic tone. Benzodiazepines act primarily by venodilation and have a more modest effect on blood pressure. Ketamine, a phencyclidine derivative, stimulates the sympathetic nervous system and thus does not lower blood pressure but can increase myocardial oxygen demand. It is most often used in severely hypovolemic patients. During laryngoscopy and tracheal intubation, blood pressure can increase by 20 to 30 mm Hg.[3] Such increases can be avoided by adequate topical anesthesia because the hypertension appears to be caused by the laryngoscopy rather than by the passage of a tube into the trachea. Maintenance of general anesthesia can be achieved with inhalational or intravenous agents. In most cases, a combination of agents is used, so-called balanced anesthesia.

INHALATION AGENTS.

These agents enter the bloodstream by way of the alveoli and are excreted across the

alveoli essentially unchanged. The predominant hemodynamic effects of the commonly used inhalational agents (halothane, enflurane, and isoflurane) are depression of myocardial contractility and reduction in arterial blood pressure.[4] Nitrous oxide also decreases myocardial contractility but does not result in significant hypotension because of reflex vasoconstriction. Although the physiological and pharmacological properties of the inhalational agents differ slightly, no single agent has been shown to be appreciably safer in patients with cardiac disease.[5] [6] [7] [65A]

INTRAVENOUS ANESTHETICS.

Narcotics are the principal intravenous agents used for maintenance of general anesthesia. Most narcotics cause some degree of hypotension through venodilation, with little effect on myocardial contractility. The short-acting agents fentanyl, sufentanyl, and alfentanyl are less likely to cause hypotension than morphine.[4] Propofol is an attractive agent because of its very rapid onset and, particularly, offset of action. It may, however, cause moderate to severe hypotension principally due to venodilation. It is often used as a sedative agent in intensive care settings as well as a general anesthetic agent.

MUSCLE RELAXANTS.

Drugs used for muscle relaxation also may have cardiovascular effects. *Succinylcholine* can cause bradycardia, which can be reversed or prevented by administration of atropine. In patients anesthetized with halothane, *pancuronium* and *gallamine* cause an increase in heart rate, arterial pressure, and cardiac output, whereas *tubocurarine* and *metocurine* result in a fall in mean arterial pressure with mild elevations in heart rate and little, if any, change in cardiac output. *Vecuronium* has essentially no cardiovascular side effects.

Spinal and Epidural Anesthesia

Spinal and epidural anesthesia cause sympathetic denervation, which produces peripheral arteriodilation and venodilation. Systemic vascular resistance may be reduced by 10 to 15 percent. Venodilation may cause a marked reduction in right ventricular preload as a consequence of sympathetic denervation. Under these circumstances, right ventricular preload depends critically on the effects of gravity on the patient's position, as well as on the total blood volume.

In four randomized trials comparing general anesthesia with either spinal/epidural anesthesia or combined general plus spinal/epidural anesthesia, no differences in cardiac outcomes have been found.[8] [9] [10] [11] Furthermore, in an informal meta-analysis combining the data from these trials, still no difference was noted.[12] The choice of anesthetic technique should ultimately be left to the anesthesiologist.

REGIONAL AND LOCAL ANESTHESIA.

Cardiovascular effects from peripheral nerve blocks with local anesthetic agents are uncommon but can occasionally result from absorption of local anesthetic agents into the bloodstream. A major concern with local or regional anesthesia is whether the technique provides adequate anesthesia and analgesia for the planned procedure; the cardiological consultant should not underestimate the cardiovascular consequences of inadequate anesthesia.

Intraoperative Hemodynamics and Arrhythmias

During the operative procedure, it is not uncommon for systolic blood pressure to fall into the range of 95 to 105 mm Hg. Such blood pressure reductions are often brief and may respond to a lightening of the anesthesia, to a brisk fluid challenge, or to the use of intravenous sympathomimetic agents. Such blood pressure reductions are equally likely with general versus spinal/epidural anesthesia.[13] Any severe reduction in arterial pressure in patients with ischemic heart disease can reduce coronary flow and precipitate myocardial ischemia. In general, transient reductions in blood pressure are not associated with major cardiac complications. Marked or sustained reductions in blood pressure, such as a 33 percent reduction below the preoperative blood pressure lasting more than 10 minutes, have been associated with increased cardiac complication rates.[14] [15]

Positive-pressure ventilation during general anesthesia reduces the return of blood to the right side of the heart and tends to reduce ventricular preload. Fluid that is administered during positive-pressure ventilation does not increase preload to the extent that it would in patients who are ventilating spontaneously. When the positive-pressure ventilation of general anesthesia ceases, ventricular preload increases, often abruptly, and hypertension or pulmonary congestion may result. Analogous physiological changes can occur with the cessation of spinal or epidural anesthesia because the venodilation caused by these agents also reduces right ventricular preload.

Transient bradycardias, such as sinus bradycardia and junctional rhythm, can occur during periods of vagal stimulation. These bradyarrhythmias commonly respond to a lightening of the anesthesia or to the administration of atropine or beta$_1$ -adrenoceptor agonists such as isoproterenol or epinephrine. Tachyarrhythmias can result from hypovolemia or vasodilation as well as from sensitization of the myocardium to catecholamines that are circulating and/or released by sympathetic nerve endings in the heart.[16] Tachycardia is poorly tolerated by patients with mitral stenosis (see Chap. 46) and can cause myocardial ischemia in patients with coronary artery disease. Therapy with specific antiarrhythmic medications is usually indicated only when the arrhythmia causes circulatory compromise and does not respond to changes in the depth of anesthesia or to attention to problems such as hypoxemia, hypovolemia, hypotension, or potentially precipitating surgical manipulation.

Mild hypothermia frequently occurs during the intraoperative period. For most patients, there are few if any consequences from a transient decline in body temperature. In a study of patients undergoing vascular surgery, however, intraoperative hypothermia was associated with an increased risk of myocardial ischemia.[17] Furthermore, in a randomized trial comparing routine thermal care with supplemental warming during the intraoperative and early postoperative period in patients undergoing vascular surgery, postoperative cardiac morbidity was reduced in the warmed group.[18]

MONITORING.

In patients who have severe underlying heart disease and who are undergoing noncardiac surgery, it is mandatory to monitor cardiac function during anesthesia,[19] including cardiac rate and rhythm and directly recorded arterial blood pressure. A radial artery line permits not only monitoring of intraarterial pressure but also frequent sampling for determination of blood gas values. In the presence of peripheral vasoconstriction, indirect (cuff) blood pressure measurements may greatly underestimate true arterial pressure.

Multiple lead monitoring of cardiac rhythm and ST segments has become the standard of care in high-risk patients with coronary artery disease. Although intraoperative ischemia is less predictive of adverse cardiac outcomes than either preoperative or postoperative ischemia, prolonged episodes of intraoperative ischemia are associated with adverse cardiac events.[20]

The use of pulmonary artery (PA) catheters to measure pulmonary artery capillary wedge pressure and cardiac output is controversial. Many small studies have shown no reduction in adverse cardiac outcomes with the use of an intraoperative PA catheter in unselected high-risk patients undergoing vascular surgery.[21] [22] Nevertheless, in certain situations, a PA catheter may be helpful, such as in patients with severe left ventricular dysfunction, in patients who have severe aortic stenosis or unstable angina and who are undergoing high-risk surgery, and to monitor intracardiac fluid status closely.[23] [24] The decision to use an intraoperative PA catheter should be left to the anesthesiologist, but it is

appropriate for the cardiological consultant to recommend consideration of its use in very high-risk patients.

THE OPERATION

Just as consultant cardiologists must understand the pharmacological effects of anesthesia, they must also recognize the physiological effects of surgery, including the direct consequences of the operation and the expected responses to postoperative recuperation.

NATURE OF THE OPERATION.

A key element in perioperative risk assessment is an estimation of the baseline risk. This is the average risk of a particular procedure at a particular institution. This baseline risk may then be modified by the clinical characteristics of an individual patient. Among noncardiac surgical procedures, the highest cardiovascular complication rates are commonly associated with abdominal aortic aneurysm surgery,[25] which causes substantial myocardial stress because of aortic cross-clamping and major shifts in fluid and electrolytes. The risk of cardiac complications is also higher in other major abdominal and thoracic procedures than in procedures on the extremities, in large part because of the more difficult postoperative course.[26] Patients who undergo operation for aortic aneurysm, carotid arterial disease, or peripheral vascular disease often have substantial coronary artery disease as well, and the extent of the latter may be underestimated because of the limitations caused by the peripheral arterial disease. At the other end of the spectrum, ophthalmalogical surgery, upper endoscopy, and transurethral prostate resection can be safely performed even in patients with heart disease.[27] [28] The estimated risk of myocardial infarction or cardiac death due to various surgical procedures is shown in Table 61-1 .

DURATION.

The risk of cardiovascular mortality and morbidity is generally correlated with the duration of anesthesia, but this is principally because the longest operations are more often on the aorta or in the abdomen or chest than on the extremities. The risk of major cardiovascular complications does not appear to correlate with the duration of surgery after controlling for the type of surgery, unless the operation is prolonged because of intraoperative complications.

EMERGENCY OPERATION.

When an operation is carried out under emergency conditions, it is associated with greatly increased mortality in patients with cardiovascular disease. The risk of postoperative cardiac complications, including postoperative myocardial infarction or cardiac death, is increased anywhere from 2.5- to 4-fold in emergency compared

with elective surgery.[13] [25] [29] [30] Part of this increased risk is because patients undergoing emergency operations may often have poorly controlled or unappreciated general medical problems, such as fluid and electrolyte imbalance or hepatic dysfunction.[13] [25] However, emergency surgery appears to be an important correlate of postoperative complications, even after controlling for the underlying medical disease.[25] [29] [30]

ESTIMATION OF RISK.

A few patients have such compelling reasons for operation (e.g., leaking abdominal aortic aneurysm or perforated viscus) that estimation of operative risk is an academic exercise, because failure to operate almost certainly will result in the patient's death. The timing or even the performance of an operation is often elective, however, and under these circumstances estimation of operative risk is an important aspect of the medical consultant's role.

One convenient method to estimate surgical risk is to use multifactorial indices. The original index of Goldman and colleagues[29] and its modification[31] weighted several clinical factors based on their relative significance as predictors of adverse cardiac outcomes (Table 61-2) . Both indices have been validated in prospective series of general surgical patients[25] and in other studies.[32] [33] [34] [35] Because these indices were developed on general surgical patients, they tend to underestimate risk in patients undergoing vascular surgery and in patients with stable coronary artery disease.[36] Moreover, these indices were based on data from the 1970s and early 1980s; most patients undergoing surgery in 1999 had a low risk score, thus limiting the indices' ability to discriminate among patients.[31] [32]

A revised cardiac risk index has been developed using data from the 1990s.[37] In this study, Lee and colleagues identified six independent and relatively equally important predictors of postoperative adverse cardiac outcomes (see Table 61-2) . In this simple index, the number of predictors correlated with the risk of cardiac morbidity and mortality. When compared with the older indices and with the American Society of Anesthesiologists (ASA) class, the revised index was found to be superior.[37] Moreover, the revised index appears to predict risk accurately in vascular surgery,

TABLE 61-1 -- RISK OF MYOCARDIAL INFARCTION OR CARDIAC DEATH FOR NONCARDIAC PROCEDURES*

High risk (often >5%)	Aortic surgery
	Peripheral vascular surgery
	Emergent major operations, particularly in the elderly
	Anticipated prolonged surgical procedures associated with larger fluid shifts or blood loss
Intermediate risk (1-5%)	Intrathoracic and intraperitoneal surgery
	Carotid endarterectomy
	Head and neck surgery
	Orthopedic surgery
	Open prostate surgery
Low risk (generally <1%)	Endoscopic procedures
	Cataract surgery
	Superficial procedures and biopsies
	Transurethral prostate surgery

**Adapted from ACC/AHA Task Force Report: Guidelines for perioperative cardiovascular evaluation for noncardiac surgery. J Am Coll Cardiol 93:1278, 1996.*

with the exception of abdominal aortic aneurysm surgery. The optimal use of cardiac risk indices may be to modify a baseline risk such as that shown in Table 61-1 rather than to predict an absolute risk of complications.[38] [39] Furthermore, indices should generally serve as an adjunct to a thorough evaluation of specific cardiac conditions.

INFLUENCE OF SPECIFIC CARDIOVASCULAR DISORDERS

Ischemic Heart Disease

Assessment of Risk

CLINICAL.

Ischemic heart disease is a major determinant of perioperative morbidity and mortality. The incidence of perioperative myocardial infarction is increased 5- to 50-fold in patients who have previously suffered infarcts compared with patients who do not have a clinical history of coronary disease.

During the 1970s, several studies reported about a 30 percent risk of reinfarction or cardiac death when patients were operated on within 3 months of the previous myocardial infarction, about a 15 percent risk when the operation was performed 3 to 6 months after a prior infarction, and about a 5 percent risk when the operation was performed more than 6 months after the infarction.[13] Complication rates were subsequently reduced during the 1980s.[36] [40] [41] For example, Rao and colleagues[40] reported only a 6 percent reinfarction rate within 3 months after preoperative myocardial infarction and only a 2 percent reinfarction rate between 3 and 6 months after a myocardial infarction, and they then confirmed these low risks in a subsequent report.[41] The reduction in cardiac morbidity and mortality has been attributed to the use of perioperative monitoring and careful regulation of hemodynamic status, cardiac rhythm, oxygenation, electrolytes, and hematocrit.

Obviously, truly life-saving procedures must be performed almost regardless of the cardiac risk, and purely elective surgery should commonly be delayed for 6 months after infarction, when the cardiovascular risks will have returned to a stable, long-term baseline risk. The more difficult issue is in patients in whom the operation is not truly emergent but is also not purely elective--for example, a patient with severe symptomatic peripheral vascular disease

TABLE 61-2 -- MULTIFACTORIAL CARDIAC RISK INDICES

RISK FACTOR	POINTS	INTERPRETATION

or a patient with a potentially resectable malignant tumor. In such situations, one would like to delay operation sufficiently long for cardiac risk to be reduced but not wait a full 6 months. Because full healing of a myocardial infarction usually takes about 4 to 6 weeks, one rational approach is to evaluate the patient with post-myocardial infarction prognostic studies, such as a submaximal exercise tolerance test, and to use the patient's clinical and cardiological conditions as the guide for surgery sometime between 4 weeks and 3 months after the infarction.

A recent preoperative myocardial infarction increases a patient's relative risk of reinfarction with operation, but the absolute risk depends on various factors in addition to the timing of the infarction. Patients who have good exercise tolerance and left ventricular function after infarction and who can resume normal activity levels within 4 to 6 weeks after infarction should be able to undergo operation with relatively small absolute risks, even if their relative risk might be slightly lower if one could wait the full 6 months. By comparison, risks are likely to be substantially higher in patients who have postinfarction angina or who have evidence of ischemia on exercise electrocardiography, thallium scintigraphy, or dobutamine stress echocardiography.

When a patient with angina pectoris is evaluated, the patient's current (preoperative) exercise tolerance should be ascertained and an assessment made about whether the anginal pattern is stable or unstable (see Chap. 36) . In patients who can carry objects such as two grocery bags or a young child up a flight of stairs without stopping and without appreciable symptoms, most surgical procedures are generally well tolerated.[42] Physicians should avoid relying on the *frequency* of angina because patients who voluntarily reduce their activity level may also greatly reduce their symptoms. This phenomenon is especially true in patients whose surgical conditions, such as orthopedic disorders or peripheral vascular disease, limit ambulation.

NONINVASIVE TESTING FOR ISCHEMIA.

Exercise treadmill testing is an objective means for assessing exercise tolerance and is especially beneficial if the history is unreliable. Unfortunately, the limited sensitivity and specificity of standard electrocardiographic exercise tolerance testing limit the use of this test for diagnosing coronary artery disease (see Chap. 6) . In studies of patients undergoing vascular surgery, postoperative cardiac complications were significantly less common in patients who exercised to higher heart rates and cardiac workloads.[27] The prognostic value

of limited exercise tolerance has also been reported in persons older than 65[35] [43] in whom the inability to perform 2 minutes of bicycle exercise in a supine position and to raise the heart rate above 99 beats/min was an independent important predictor of cardiac complications in noncardiac surgery. Of note was that poor exercise capacity was an independent predictor of cardiac complications but that electrocardiographic changes with exercise were not.

In patients who are unable to exercise because of noncardiac disability (e.g., intermittent claudication or orthopedic abnormalities), dipyridamole thallium imaging, ambulatory ischemia monitoring, or stress echocardiography can be used to assess perioperative risk. Dipyridamole thallium imaging (see Chap. 9) has been successful in identifying high-risk patients among selected subgroups of patients who are referred for the test before undergoing vascular surgery, and it is especially appealing for patients who have abnormal resting electrocardiograms or are taking medications such as digoxin that make electrocardiographic monitoring unreliable for the detection of ischemia.

Among 1410 patients in the five largest series of such patients,[44] [45] [46] [47] [48] a reversible defect on thallium scintigraphy had a sensitivity of 85 percent for predicting postoperative cardiac complications and a specificity of 60 percent; the relative risk of cardiac complications in a patient with a reversible defect was 9.0. When dipyridamole thallium scintigraphy was used in *unselected* consecutive patients having abdominal aneurysm or major vascular surgery, it was *not* proved useful for predicting perioperative myocardial infarction, myocardial ischemia, or cardiac death.[49] [50] In the largest single series of 451 *consecutive* unselected patients, the presence of a reversible thallium defect had a sensitivity of just 36 percent, a specificity of 65 percent, and a relative risk of 1.0 (i.e., it was of no value whatsoever) for predicting major perioperative cardiac events.

Ambulatory electrocardiographic (Holter) recording can identify up to 90 percent of patients who will develop major postoperative ischemic complications.[51] Patients with asymptomatic preoperative ischemia or asymptomatic postoperative ischemia have as high as a 30 percent risk of developing a clinical event, including myocardial infarction, unstable angina, ischemic pulmonary edema, or cardiac death.[20] [51] [52] In contrast, asymptomatic intraoperative ischemia is less predictive.[20] [53] Asymptomatic postoperative ischemia, which is found in a substantial minority of patients with or at risk for atherosclerotic disease,[54] [55] commonly precedes a clinical event by an hour or more[52] [56] ; longer episodes of postoperative ischemia are associated with a higher risk of a major clinical event.[56] Patients with perioperative ischemia also have more late cardiac events well after surgery.[53] [57] The requirement for a near-normal resting electrocardiogram and a 24-hour testing period

generally makes this test less practical than either dipyridamole thallium scintigraphy or stress echocardiography.

Although some investigators have used radionuclide ventriculography to predict risk,[58] in other studies data from resting and/or exercise radionuclide ventriculography did not add important independent information for predicting overall perioperative cardiac risk.[35] [49] [59] [60] Similarly, routine transthoracic echocardiography adds little for the prediction of postoperative complications.[61]

Stress echocardiography after exercise or agents such as dipyridamole or dobutamine can be used to identify patients at markedly increased risk on the basis of the provocation of left ventricular wall motion abnormalities with stress.[62] [63] [64] [65] [65A] [66] [67] [68] [69] Poldermans and colleagues studied 300 consecutive unselected patients undergoing major vascular surgery with dobutamine stress echocardiography. Of 72 patients with a stress-induced new regional wall motion abnormality, 17 suffered a perioperative myocardial infarction or cardiac death. None of the 228 patients without a stress-induced wall motion abnormality suffered a cardiac complication.[65] Stress echocardiography appears to be at least as good as dipyridamole thallium scintigraphy or ambulatory ischemia monitoring for predicting complications.

Many studies have evaluated the extent to which specific clinical variables can be used to select patients for preoperative noninvasive ischemia testing. In patients undergoing vascular surgery, Eagle and colleagues found that age greater than 70 years, a history of ventricular arrythmias requiring treatment, angina, diabetes mellitus, and abnormal Q waves on the electrocardiogram were independent predictors of cardiac complications.[44] Patients with none of these variables were at low risk for complications, and those with three or more were at high risk regardless of the results of dipyridamole thallium scintigraphy. In the group with one or two of these variables, dipyridamole thallium scintigraphy accurately identified patients as either high or low risk. In a similar study, L'Italien and colleagues added a history of congestive heart failure as an independent predictor of adverse cardiac outcomes and found coronary revascularization within 5 years to have a protective effect.[70] Thallium scintigraphy added useful predictive information only to the group of patients found to be at intermediate risk on the basis of assessment using clinical variables.

Fewer data are available on dobutamine stress echocardiography. However, in patients with low-risk clinical variables, it appears that dobutamine echocardiography does not add appreciably to the clinical risk assessment. Unlike thallium scintigraphy, however, a normal dobutamine stress echocardiogram result in a patient with high-risk clinical variables may predict a low risk of perioperative complications.[65] Hypotension during dobutamine echocardiography predicts perioperative cardiac events.[65A] In conclusion, most data support the use of noninvasive ischemia testing in preoperative evaluation of patients found to be at intermediate risk on clinical assessment.

PRIOR CORONARY REVASCULARIZATION.

Patients who have undergone successful coronary revascularization can undergo major noncardiac surgical procedures with a low mortality rate,[71] except perhaps in the first 30 days postoperatively.[71A] An analysis of patients in the Coronary Artery Surgery Study registry[71] showed that total operative mortality was 2.4 percent in 458 patients who had significant coronary artery disease and underwent noncardiac operations without prior coronary artery bypass grafting (CABG). By comparison, operative mortality was 0.9 percent among 399 patients who had had a CABG procedure performed before noncardiac surgery. The mortality was higher in patients who had more severe left ventricular dysfunction or dyspnea on exertion and in patients who used nitrates, were older, and had diabetes. The risk of myocardial infarction, however, was not significantly different between the patients with and without preoperative CABG, and the cardiac death rates were only 0.4 percent and 1.3 percent, respectively, in the two groups. Subsequent studies have confirmed that prior CABG, particularly if within 5 years of subsequent noncardiac surgery, is associated with a decreased risk of perioperative cardiac death.[70]

Fewer data are available to evaluate the effects of preoperative percutaneous transluminal coronary angioplasty (PTCA). In three different series of high-risk patients who underwent PTCA before vascular surgery, the mortality with noncardiac surgery was less than 3 percent.[72] [73] [74]

APPROACH TO RISK ASSESSMENT.

A practical approach to patients with known ischemic heart disease or with specified high-risk characteristics[44] should use information from the history as well as diagnostic tests.[38] [39] [75] [76] [77] If the history reliably indicates that the patient has Canadian Cardiovascular Society class I or class II angina, the patient is able to raise the double product (the heart rate multiplied by the systolic blood pressure) above the range to be expected with general anesthesia and surgery and hence

Figure 61-1 Risk assessment in patients with ischemic heart disease.

should be able to withstand the stress of the procedure.[71] If the history is unreliable, exercise testing to assess physical function[35] [44] will aid in risk assessment. If the patient is unable to exercise because of noncardiac conditions, dipyridamole thallium imaging or stress echocardiography should be considered, particularly for patients believed to be at intermediate risk on clinical assessment. An approach to risk assessment in patients with ischemic heart disease is shown in Figure 61-1 .

Patients who have angina or who have had a myocardial infarction but who can exercise to class I or II level or have normal dipyridamole thallium imaging or stress echocardiography results can undergo most operations with acceptable risk, roughly a 4 to 5 percent risk of myocardial infarction and a 1 percent mortality. Patients who cannot perform class I or II activities or who have positive dipyridamole thallium or stress echocardiography results are likely to have a 5 to 25 percent risk of myocardial infarction and a 5 to 25 percent mortality. For any patient with an appropriate indication for noninvasive ischemia testing or coronary angiography independent of planned noncardiac surgery, such testing should generally precede surgery, particularly if the results may lead to a coronary revascularization procedure.

RISK REDUCTION STRATEGIES.

Medications.

All baseline preoperative cardiac medications should be continued up to and including the day of surgery and resumed promptly once the patient is eating. In three small studies, the institution of prophylactic beta-blocking agents immediately before surgery was associated with decreased intraoperative ischemia and, in one of these studies, a decreased risk of postoperative myocardial infarction.[78] [79] [80] A randomized controlled trial of prophylactic atenolol in patients with known coronary artery disease or at high risk for it demonstrated a significant reduction in both 6-month and 12-month mortality but no reduction in perioperative mortality or cardiac morbidity.[81] In a more recent study of prophylactic beta-adrenergic blockade, 112 high-risk patients were randomized to either preoperative bisoprolol or placebo before undergoing major vascular surgery. Oral bisoprolol, at a dose of 5 mg or 10 mg daily, was begun at least 7 days before surgery and continued until the 30th postoperative day. The combined incidence of perioperative cardiac death or nonfatal myocardial infarction was 34 percent in the placebo group compared with 3.4 percent in the bisoprolol group.[82] This difference was highly statistically significant. There is now sufficient evidence to recommend the routine use of prophylactic bisoprolol or atenolol in high-risk patients who are undergoing major surgery and are not already taking beta-blocking agents.[82A]

Nitrates have been shown in multiple studies to reduce intraoperative ischemia but have never demonstrated a reduction in adverse cardiac outcomes.[83] Prophylactic nitrates, most commonly intravenous nitroglycerin, should therefore be considered only for high-risk patients. Few data are available on the use of prophylactic calcium channel blocking agents during the perioperative period; thus, no firm recommendations can be made.

The alpha-adrenergic blockers may also be useful to reduce perioperative risk. Clonidine has been shown to reduce perioperative ischemia but has not demonstrated a reduction in cardiac morbidity.[84] [85] A newer agent, mivazerol, also appears to reduce ischemia and in a single study was associated with a decreased risk of myocardial infarction in patients undergoing vascular surgery.[86] [87] At the present time, however, beta-blocking agents are the preferred method to reduce risk in patients with ischemic heart disease.

Preoperative Cardiac Optimization.

In patients found to be at high risk because of poor cardiac functional status

or a positive result of a noninvasive ischemia test, one approach is to optimize the cardiac medications and then reevaluate cardiac status in a few weeks. Although not proved in clinical trials, an improvement in cardiac functional status or in the results of ischemia testing may be associated with a reduction in the risk of cardiac complications.

Intensive preoperative hemodynamic optimization has been advocated by some to reduce perioperative morbidity in high-risk patients. Three randomized controlled trials have demonstrated a reduction in perioperative morbidity,[23] [88] [89] and a fourth shows no difference,[90] with the use of immediate preoperative optimization of hemodynamic parameters. In these studies, patients were admitted to an intensive care setting where a PA catheter was placed. Intravenous fluid infusions, inotropic agents, and afterload-reducing agents were used to achieve goal values for the pulmonary capillary wedge pressure (usually 8 to 15 mm Hg) and oxygen delivery (usually 600 ml/min/m^2). Although goal values were achieved for most patients, the reduction in complication risk was independent of achieving the goal values. On the other hand, in other studies, when hemodynamics were optimized in medical and postoperative patients in an intensive care unit, there was no reduction in mortality or morbidity.[91] [92] Preoperative hemodynamic optimization of this type can be considered for high-risk patients undergoing high-risk operations.

CORONARY REVASCULARIZATION.

In patients who have an indication for coronary angiography and/or revascularization independent of planned noncardiac surgery, it is advisable to perform the cardiac procedures first. This is particularly important in high-risk patients. The use of prophylactic coronary revascularization, however, is controversial. No randomized controlled trials have evaluated the use of prophylactic coronary revascularization before noncardiac surgery. Two decision analyses attempted to define the precise role of prophylactic revascularization.[93] [94] Both concluded that routine revascularization is not warranted and that the subgroups most likely to benefit remain undefined. Patients found to be at low risk have roughly a 1 percent cardiac mortality with noncardiac surgery.[95] The mortality from CABG or PTCA ranges from 0.5 to 2 percent.[96] Therefore, prophylactic revascularization is not likely to reduce *total* mortality in low-risk patients.

In high-risk patients, prophylactic revascularization may be a reasonable strategy because such patients face a 5 to 25 percent mortality with noncardiac surgery.[44] Furthermore, if one considers potential long-term mortality reduction, prophylactic revascularization seems reasonable in certain groups. For example, high-risk patients undergoing vascular surgery, particularly those with diabetes mellitus, have significantly reduced long-term survival largely because of premature cardiac death and thus may be the most likely to benefit from prophylactic revascularization[97] , particularly surgical revascularization.[97A]

The risk of thrombosis is significant in patients soon after percutaneous coronary stent placement, particularly if anticoagulation is stopped too soon. Thus, noncardiac surgery should not immediately follow a stent procedure.

PREOPERATIVE TRANSFUSION.

No large randomized clinical trials have determined the optimal hemoglobin level before surgery or the appropriate threshold for transfusion. Most data suggest that perioperative morbidity and mortality increase as the preoperative hemoglobin level decreases.[98] [99] This relationship appears to be more pronounced in patients with cardiovascular disease.[98] At preoperative hemoglobin levels below 9.0 g/dl, the risk of mortality appears to increase sharply. Thus, in patients with cardiac disease, particularly ischemic heart disease, it is reasonable to consider preoperative blood transfusion when the hemoglobin level is less than 9 gm/dl. In general, however, the risks and benefits of transfusion should be individualized on the basis of the patient's comorbidities and the anticipated surgical blood loss. It is important to consider that the combined risk of transmission of human immunodeficiency virus, hepatitis C, or hepatitis B through transfusion of one unit of allogeneic blood is estimated to be 1 in 34,000.[100]

Hypertension (see Chap. 28)

Several studies have documented that patients with hypertension have higher risks of suffering major cardiac complications during or shortly after noncardiac operation than do patients who have always been normotensive. However, most of this increased risk is because of the ischemic heart disease, left ventricular dysfunction, renal failure, or other abnormalities that often occur in patients with hypertension. In patients with mild to moderate hypertension, diastolic pressures less than 110 mm Hg, and systolic blood pressure less than 200 mm Hg, and no evidence of serious end-organ damage, general anesthesia and major noncardiac surgery are generally well tolerated.[15] Hypertensive patients are, however, at higher risk for labile blood pressures and for hypertensive episodes during surgery and especially just after extubation. Thus, it is neither mandatory nor desirable to delay noncardiac operation for the weeks or months that may be required to achieve ideal blood pressure control in stable patients who have mild to moderate hypertension but who have no hypertensive end-organ damage.

Patients with severe hypertension in the immediate preoperative period are at increased risk for perioperative myocardial infarction and congestive heart failure.[15] In such patients, blood pressure should be controlled before surgery. Commonly used agents for this purpose include intravenous sodium nitroprusside and labetalol because they may be easily titrated. Although uncontrolled early studies suggested that the continuation of any hypertensive agents might increase the risk of perioperative hypotension, substantial subsequent data from more careful studies indicate that patients whose hypertension is well controlled do at least as well, if not better, if their medications are, in fact, continued up to the time of operation.[15]

Thiazide and other diuretics cause some degree of chronic volume depletion, and patients receiving these drugs may require more fluid administration early during the operative procedure.

Valvular Heart Disease (see Chap. 46)

Patients who have valvular heart disease and who are undergoing anesthesia and noncardiac operation are subject to many potential hazards: heart failure, infection, tachycardia, and embolization. As might be expected, patients with no or only mild limitation of activity (i.e., those in Class I or II) tolerate operation well and probably require little more than careful perioperative care and prophylaxis for infective endocarditis. Those with more serious impairment of cardiac reserve (i.e., those in Class III or IV) tolerate major noncardiac operations poorly, and their prognosis for surviving major surgery is distinctly worse.[13] [26]

Patients with symptomatic critical aortic stenosis[29] are at increased risk for sudden death or acute pulmonary edema during the perioperative period, if demands on cardiac output are suddenly increased or if atrial fibrillation and a rapid ventricular rate are precipitated by anesthesia or operation.

The risk associated with severe aortic stenosis may be most prominent when the valvular disease is not known to the surgical or anesthesia team before surgery.[101] It is therefore crucial to make the diagnosis of severe aortic stenosis before surgery to allow for appropriate preoperative and intraoperative treatment. In general, patients with symptomatic severe aortic stenosis should undergo corrective valve surgery or, when appropriate, valvuloplasty, before noncardiac surgery.[102] [103] On the other hand, in two series of patients with severe aortic stenosis, defined as an aortic valve area less than 1.0 cm^2 , and normal left ventricular function who underwent major noncardiac surgery, only 2 of 36 patients died during the perioperative period.[101] [104] This suggests that when preoperative correction of the valvular lesion is not feasible, surgery may be performed with an acceptable risk. In such cases, appropriate anesthetic care may involve invasive hemodynamic monitoring and anesthetic agents or techniques that minimize reductions in preload.

In patients with mitral stenosis, control of heart rate and, particularly, avoidance of atrial fibrillation with a rapid ventricular response are important to prevent perioperative congestive heart failure.[27] In patients with severe mitral stenosis, corrective valve surgery or valvuloplasty should precede noncardiac surgery.

Perioperative cardiac morbidity in patients with aortic or mitral regurgitation appears to be largely related to the associated congestive

---

heart failure. Therefore, preoperative control of heart failure is crucial. This should include the use of diuretic agents and afterload-reducing agents.

HYPERTROPHIC CARDIOMYOPATHY (see Chap. 48) .

Patients with hypertrophic cardiomyopathy are intolerant of hypovolemia, which may lead to both a reduction in the elevated preload necessary to maintain cardiac output and an increase in the obstruction to left ventricular outflow. Similarly, decreases in afterload may also increase dynamic outflow obstruction. With careful perioperative, intraoperative, and postoperative care, however, the risk of major cardiac complications in such patients is small. In the two largest series of noncardiac

operations in patients with hypertrophic cardiomyopathy, no deaths and only two myocardial infarctions ensued after a total of 133 operations. Reversible cardiac complications were common, however. Arrhythmias occured in more than 20 percent of patients, congestive heart failure in 16 percent, and hypotension requiring vasopressor therapy in 14 percent.[105] [106] It has previously been suggested that spinal anesthesia may be relatively contraindicated in patients with hypertrophic obstructive cardiomyopathy because of its tendency to reduce systemic vascular resistance and increase venous pooling and thereby increase the severity of obstruction to outflow.[105] However, Haering and colleagues[106] did not find spinal anesthesia to be associated with an increase in cardiac complications. Hemodynamic monitoring is not routinely required but may be helpful when these patients undergo major aortic, abdominal, or thoracic procedures.

PROSTHETIC HEART VALVES.

Most patients with mechanical prosthetic heart valves receive anticoagulants on a long-term basis to prevent thromboembolic complications (see Chap. 46) . If these medications are continued through the period of noncardiac operation, hematoma formation and persistent postoperative bleeding can ensue. Anticoagulants can be temporarily discontinued during the perioperative period with minimal risk of thrombosis. In one study,[107] no thromboembolic complications occurred in 159 patients who had prosthetic valves and were undergoing 180 noncardiac operations when warfarin was discontinued an average of 2.9 days preoperatively and resumed 2.7 days postoperatively.[107] Using a similar approach. Katholi and associates did not observe thromboembolic complications in 25 noncardiac operations on patients with prosthetic aortic valves[108] ; however, two such complications occurred in the 10 patients with mitral valve prostheses when anticoagulants were discontinued for noncardiac operations, although these patients had Kay-Shiley caged-disc valves, which are associated with a somewhat higher risk of thromboembolic complications. Using a decision analytical approach, Kearon and Hirsh concluded that perioperative heparinization with either intravenous standard heparin or subcutaneous low-molecular-weight heparin in patients with mechanical heart valves leads to a substantial increase in major bleeding risk and only a modest reduction in thromboembolic risk.[109] They recommended discontinuation of warfarin 4 days before surgery and resumption as soon as possible after surgery. Because it takes 4 days on average for the International Normalized Ratio (INR) to drop below 1.5 in patients with a baseline INR of 2.0 to 3.0, the number of days with normal anticoagulation is usually only 2 or 3 using this approach.[109] In certain patients, the risk of perioperative thromboembolism may be particularly high, such as in those with a caged-disc valve or those who have had a recent embolic event. In such patients, perioperative heparinization may be justified. Warfarin should be discontinued 4 days before surgery and heparin (intravenous standard heparin or subcutaneous low-molecular-weight heparin) begun once the INR has dropped below 1.5. Heparin is then stopped 6 hours before surgery and resumed at least 12 hours after surgery if considered safe by the surgeon. Analyses indicate that these various anticoagulation regimens are cost-effective, provided that they do not result in lengthening the hospitalization.[110] Even 1 day of additional hospitalization is relatively costly, and the daily risk of thromboembolic complications is low. Thus, perioperative anticoagulation management should focus on regimens that provide reasonable protection from thromboembolic disease but that permit patients to be discharged when the surgical condition itself permits.[110]

Endocarditis Prophylaxis (see Chap. 47)

Numerous surgical procedures are associated with the development of transient bacteremia with organisms that may cause endocarditis.[111] However, the risk of developing endocarditis after surgery is low,[111] [112] and a reduction in risk with the use of prophylactic antibiotics has not been demonstrated in controlled clinical trials. Nevertheless, because the risks associated with prophylactic antibiotics are low and the potential morbidity of endocarditis is high, antibiotic prophylaxis is recommended for patients with moderate- or high-risk structural cardiac lesions undergoing procedures with a high risk of bacteremia.

Congenital Heart Disease (see Chap. 44)

Depending on the nature of the malformation, patients with congenital heart disease may be subject to one or more potentially serious complications, such as infection, bleeding, hypoxemia, hypotension, and paradoxical embolization during general anesthesia and operation. As is the case for patients with valvular heart disease, patients who have congenital heart disease and who are to undergo a surgical procedure require prophylaxis to prevent infective endocarditis.

Patients with cyanotic congenital heart disease tolerate systemic hypotension poorly because this increases the right-to-left shunt and the severity of hypoxemia. In one large series, induction was commonly accomplished using ketamine or fentanyl to avoid hypotension, and anesthesia was maintained with morphine and nitrous oxide or with large doses of fentanyl with or without nitrous oxide. With use of careful anesthetic techniques, the risk of major anesthetic complications is extremely low even in very ill and cyanotic patients.[113] However, spinal anesthesia, which causes peripheral arterial vasodilation and reduces venous return, can have deleterious hemodynamic effects in patients with cyanotic congenital heart disease. Infusion of a vasoconstrictor such as phenylephrine may occasionally be required to raise systemic vascular resistance and thereby decrease the magnitude of the right-to-left shunt. Because patients with right-to-left shunts are subject to the risk of paradoxical emboli, including air emboli, meticulous techniques with regard to intravenous solutions and injections are mandatory to prevent such complications.

Congestive Heart Failure (see Chaps. 17 and 18)

Congestive heart failure is a major determinant of perioperative risk, irrespective of the nature of the underlying cardiac disorder. Mortality with noncardiac surgery increases with worsening cardiac class[13] [42] and with the presence of pulmonary congestion,[13] [25] especially when a third heart sound is noted. [29] The perioperative mortality rate appears to depend more on a patient's condition at the time of operation than on the most severe depression of cardiovascular status the patient has ever experienced. Patients with well-controlled congestive heart failure have an increased risk of developing postoperative pulmonary edema but little excess mortality.[49] When heart failure is not well controlled, as evidenced by the presence of an S_3 gallop, rales on lung examination, or pulmonary edema on chest radiograph, the risk of death may be as high as 15 percent.[13] It is therefore advisable to control heart failure preoperatively with the use of diuretics and afterload-reducing agents. In such patients, it is important to avoid overdiuresis in the immediate preoperative period because the risk of severe intraoperative hypotension is increased in intravascularly volume-depleted patients. It is therefore desirable, if possible, to stabilize a patient's condition by treating heart failure for approximately 1 week rather than for only 1 or 2 days before the contemplated operation. Perioperative cardiogenic pulmonary edema develops in about 2 percent of patients who are older than 40 years and are undergoing

major noncardiac surgery without prior congestive heart failure, in about 6 percent of patients whose heart failure is well controlled, and in about 16 percent of patients whose heart failure persists on physical examination or chest radiograph before surgery.[13]

Digitalis is one of the most common causes of iatrogenic complications in hospitalized patients, and it may be associated with a higher risk of intraoperative bradyarrhythmias.[13] Therefore, preoperative digitalization is *not* recommended except in patients whose congestive heart failure is sufficiently severe that they would normally meet the criteria for long-term digitalization.

Arrhythmias (see Chap. 25)

Arrhythmias may be a manifestation of the severity of underlying left ventricular dysfunction and of coronary artery disease and hence are frequently markers for the likelihood of perioperative cardiac complications. Because patients who have ventricular premature complexes but no evidence of underlying heart disease on detailed examination have an apparently normal cardiac prognosis, ventricular premature complexes in the *absence* of underlying heart disease should not be considered a risk factor for cardiac complications with noncardiac surgery.

Although it would be ideal for arrhythmias to be well controlled preoperatively, the risks associated with arrhythmias appear to be related more to the underlying cardiac disease than to the arrhythmias per se. Furthermore, the frequency of preoperative ventricular premature complexes or nonsustained ventricular tachycardia in patients with known structural heart disease does not appear to correlate with adverse cardiac outcomes.[114] Therefore, no current evidence shows that asymptomatic ventricular premature complexes or episodes of nonsustained ventricular tachycardia require aggressive preoperative control or prophylactic intraoperative suppression. Similarly, in patients with well-controlled atrial fibrillation, cardioversion need not be carried out specifically because of planned noncardiac surgery if such a management option would not otherwise be appropriate. Careful rhythm monitoring during surgery and in the immediate postoperative period would be prudent.

Patients who are most at risk for the development of postoperative supraventricular tachyarrhythmias include elderly patients undergoing pulmonary surgery, patients with subcritical valvular stenoses, and patients with prior histories of supraventricular tachyarrhythmias. Although previous data suggested that digitalis may reduce the risk of development of postoperative supraventricular tachycardia and decrease the ventricular rate when it does occur,[13] the use of prophylactic digitalis has not been formally studied. Given the effectiveness of beta-adrenergic blocking agents, calcium channel antagonists, and adenosine for the treatment of supraventricular arrhythmias, it may be most prudent simply to treat the arrhythmia when it occurs rather than use prophylactic digitalis.

Several studies have shown that pretreatment with amiodarone or sotalol reduces the incidence of postoperative atrial fibrillation after CABG or cardiac valve surgery.[115] [116] [117] [118] In a randomized controlled trial of 85 patients, the use of prophylactic sotalol begun 24 to 48 hours before cardiac surgery and continued for 4 days was associated with a 12 percent incidence of postoperative atrial fibrillation, compared with 38 percent in the placebo group.[118] Similarly, intravenous amiodarone administered immediately after cardiac surgery was associated with a 35 percent incidence of atrial fibrillation, compared with 47 percent for placebo.[115]

Such results are promising and justify consideration of prophylactic therapy in patients at risk for developing atrial fibrillation after cardiac surgery. It is not known whether prophylactic therapy with amiodarone or sotalol is effective for noncardiac surgery; therefore, it is not currently recommended for routine use.

CONDUCTION DEFECTS.

Patients with *complete heart block* must respond to the demands for an increased cardiac output by augmenting stroke volume, but this compensatory response is prevented in many patients by a concurrent impairment of cardiac contractility. In addition, most anesthetic agents depress myocardial contractility and/or produce peripheral vasodilatation. Furthermore, anesthesia can cause further depression of the automaticity, and therefore the ventricular rate, of patients with heart block. Thus, patients with untreated complete heart block may be unable to meet the increased demands placed on the cardiovascular system by anesthesia and operation, and a permanent or temporary pacemaker should be inserted before the use of general anesthesia, even in asymptomatic patients (see Chaps. 24 and 25) .

Another problem is presented by patients with *chronic bifascicular block* (see Chap. 25) . A significant fraction of patients developing this abnormality in the course of an acute myocardial infarction progress to complete heart block, often accompanied by sudden severe hemodynamic compromise. Progression from bifascicular to complete heart block has not been documented during the perioperative period in patients without a previous history of third-degree heart block. Prophylactic pacemaker placement for such patients or for patients with first-degree atrioventricular (AV) block or type I second-degree AV block (Wenckebach) is not recommended, although a pacemaker should always be available in the operating room for emergency placement.[27] However, in patients who have bifascicular block and type II second-degree AV block and who have a history of unexplained syncope or transient third-degree AV block, the risk of development of complete heart block is much higher, and a temporary pacemaker should be inserted preoperatively.

In general, a prophylactic *temporary pacemaker* should be inserted before noncardiac operations only if the patient meets the indications for permanent pacemaker insertion and the operation should not be delayed for the time required for a permanent pacemaker insertion, or if the operative course is likely to be complicated by transient bacteremia. In such situations, a temporary pacemaker should be placed initially, and the permanent pacemaker can be inserted after the operation.

PATIENTS WITH A PERMANENT PACEMAKER OR DEFIBRILLATOR (seeChap. 24) .

When a patient with a permanent pacemaker or defibrillator in situ is about to undergo operation, the device should be carefully evaluated to ensure that it is functioning properly preoperatively. Demand pacemakers and defibrillators are sensitive to electromagnetic interference, such as that produced by the electrocautery, which may result in failure to pace or provoke defibrillator discharge. The danger of this potentially hazardous interaction can be reduced by placing the indifferent plate of the cautery unit as far as possible from the lead and pacemaker pulse generator, and the electrocautery should be used in brief bursts rather than continuously. Also, a magnet should be available in the operating room to convert the pacemaker from the demand to the fixed-rate mode. Defibrillators should have sensing inactivated preoperatively to prevent the device from sensing electrocautery as ventricular fibrillation and delivering a shock. Because the cautery may also interfere with the electrocardiographic monitor and render results temporarily uninterpretable, arterial pressure should be monitored directly when the cautery is being used.

GENERAL MEDICAL PROBLEMS.

Patients with heart disease and with a general medical status complicated by diabetes, renal insufficiency, hepatic abnormalities, hypoxemia, or electrolyte abnormalities have a higher risk of cardiac complications, presumably because these nonmedical conditions exacerbate the stress placed on the heart by the operation.[13] [25] [29] Morbidity is also higher in markedly obese patients[118A] because obesity is often associated with abnormal cardiorespiratory function, metabolic function, and hemostasis. Every effort should be made to correct any of these noncardiac problems before

operation, and the potential long-term benefits of surgery must also be interpreted in light of the patient's general prognosis.

POSTOPERATIVE COMPLICATIONS

MYOCARDIAL INFARCTION.

Transient intraoperative ischemia does not appear to be a major correlate of postoperative ischemic events in patients undergoing noncardiac surgery,[20] [53] but most clinical postoperative ischemic events are preceded by asymptomatic episodes of postoperative ischemia that can be detected by ambulatory ischemic monitoring.[20] [52] [53] [54] [56] Although series from before 1980 showed a peak in the risk of myocardial infarction on about the third postoperative day, more recent series show that a combination of frequent electrocardiograms and cardiac enzymes detects many non-Q-wave infarctions in the first 24 hours postoperatively.[34] [51] [119] [120] [121] Although care must be taken in interpreting cardiac enzymes in the perioperative period,[120] it may be that supply-demand imbalances cause an early peak in non-Q-wave postoperative infarctions, whereas the hypercoagulable postoperative state leads to a later (3 to 5 days postoperatively) peak in Q wave infarctions. For both types of infarction, postoperative stresses include general surgical complications, hypoxia and other pulmonary complications, fluid and electrolyte abnormalities, and the stresses of modern postoperative ambulation protocols. Substantial data indicate that prophylactic anticoagulation with low-dose heparin reduces the risk of postoperative venous thromboembolic complications,[122] and such therapy is routinely indicated in most cardiac patients who undergo noncardiac operations. In fact, such anticoagulation regimens may permit a more gradual postoperative ambulation protocol in cardiac patients and hence possibly lower the incidence of postoperative myocardial infarction.

The diagnosis of postoperative myocardial infarction can be difficult. Roughtly 50 percent of patients who have postoperative myocardial infarctions are pain free.[13] [95] Other signs such as hypotension, hypertension, arrhythmias, or altered mental status may often be the only clue to the presence of myocardial ischemia or infarction. In patients with signs or symptoms of myocardial ischemia or infarction, measurement of serum cardiac enzyme levels may be helpful. Elevated troponin I levels (>1.0 ng/ml) may be somewhat more specific for myocardial ischemia or infarctions than are elevations in CK-MB isoenzymes.[121] [123]

HYPERTENSION.

Postoperative hypertension is most likely to occur soon after the cessation of positive-pressure ventilation or in the recovery room, and it is more common after carotid endarterectomy and major abdominal vascular procedures.[15]

Common precipitants include fluid overload after cessation of positive-pressure ventilation, hypoxemia, anxiety, and pain. The principal therapeutic approaches should therefore concentrate on ensuring adequate oxygenation, pain control, and fluid control. In general, supplemental oxygen, morphine, and diuretics are the mainstays of the treatment of postoperative hypertension. Nitroprusside and labetalol (see Chap. 29) are the preferred medications for more severe hypertension. Intravenous hydralazine in small doses is effective for treating postoperative hypertension, but it has the potential of precipitating supraventricular tachyarrhythmias.

CONGESTIVE HEART FAILURE.

Although postoperative heart failure can be precipitated by myocardial infarction or ischemia, a substantial proportion of the cases are directly caused by excess fluid administration. Heart failure tends to occur soon after cessation of positive-pressure ventilation and again at about 24 to 48 hours after operation, when the fluid that was given in the perioperative period is mobilized from the extravascular sites. Diuretics, often given intravenously and occasionally supplemented with afterload-reducing agents, are usually sufficient therapy for postoperative congestive heart failure.

POSTOPERATIVE ARRHYTHMIAS.

Arrhythmias are common after operation and are often a manifestation of a noncardiac complication, such as bleeding, infection, or an acid-base or electrolyte imbalance occurring in a patient with heart disease. Management of such arrhythmias often requires recognition and correction of extracardiac factors.

A new postoperative supraventricular tachyarrhythmia should prompt a search for remediable medical problems. Direct antiarrhythmic therapy is often unnecessary and is usually secondary in importance to correction of the underlying cause of the arrhythmia.

Sinus tachycardia is the most common rhythm disturbance in postoperative patients. Many noncardiac etiological factors have been identified, including pain, hypovolemia, hypervolemia, fever, anemia, hypoxemia, pulmonary emboli, anxiety, infection, hypotension, and electrolyte abnormalities (especially hypokalemia). These noncardiac factors are much more common causes of sinus tachycardia in postoperative cardiac patients than is either myocardial infarction or heart failure.

Sinus tachycardia not caused by congestive heart failure does not slow with cardiac glycosides.

Atrial fibrillation is also a common postoperative arrhythmia. Atrial dilatation, which lowers the threshold for development of this arrhythmia, can result from heart failure, mitral valve disease, and/or hypervolemia. Noncardiac precipitants include pneumonia, atelectasis, and pulmonary emboli. Initially, postoperative patients with atrial fibrillation should be treated with a beta-blocking agent, calcium channel antagonist, or digitalis. Cardioversion is usually delayed until the precipitating factors have been eliminated, because patients who undergo cardioversion before clearing of the atelectasis or pneumonia frequently have reversion to atrial fibrillation, whereas patients whose pulmonary problem or congestive heart failure is adequately treated often have spontaneous reversion to sinus rhythm.

In the case of coronary artery or cardiac valve surgery, postoperative atrial fibrillation is very common, occurring in up to 40 percent of patients,[124] and is associated with thromboembolic complications and prolonged hospital stays. Unlike the noncardiac surgery setting, most cases of postoperative atrial fibrillation do not appear to be associated with reversible noncardiac conditions. Therefore, early cardioversion can be beneficial. In one study, intravenous ibutilide was shown to be effective and safe for the treatment of postoperative atrial fibrillation following cardiac surgery.[125] It is not known whether ibutilide is as useful in the noncardiac surgery setting; however, these data suggest that when urgent cardioversion is indicated after noncardiac surgery, ibutilide should be considered.

Atrial flutter is often poorly tolerated because of the rapid ventricular rate and the difficult pharmacological management. Cardioversion is the treatment of choice.

IMPLICATIONS OF POSTOPERATIVE COMPLICATIONS FOR LONG-TERM MANAGEMENT.

When a patient develops a perioperative myocardial infarction, the evaluation and the recuperative process generally should be analogous to when a myocardial infarction occurs in other patients (see Chap. 35) . Because postoperative congestive heart failure is commonly precipitated by iatrogenic fluid overload, the patient commonly does not need long-term therapy for congestive heart failure. Similarly, perioperative arrhythmias are often precipitated by specific stimuli, and patients with a postoperative arrhythmia should not automatically be consigned to long-term antiarrhythmic therapy. In patients who develop either postoperative congestive heart failure or arrhythmias, it is often appropriate to discontinue new cardiac

therapies several days before discharge and to observe patients to see whether long-term therapy is indicated.

THE ROLE OF THE MEDICAL CONSULTANT

The physician called on to evaluate the status of a patient with suspected or overt cardiac disease before elective or emergency noncardiac surgery first must determine whether cardiovascular disease is present and, if it is, must identify those factors that can increase the risk of operation. It may be necessary to invest considerable time and effort to prepare patients for operation. In addition, patients must be carefully monitored after operation to detect and manage the cardiac problems that frequently complicate the postoperative period.

PREPARATION OF PATIENTS FOR ANESTHESIA AND OPERATION.

Careful preparation of cardiac patients for operation may diminish the frequency and seriousness of intraoperative and postoperative complications. The medical consultant should, after appropriate discussion with the surgeon, be prepared to urge postponement or cancellation of an elective operation or to insist on sufficient time to institute any measures that are necessary to minimize risk. The consultant should attempt to be brief and to the point and to provide a limited number of explicit, relevant suggestions. The cardiological consultant should work closely with the anesthesiologist and the surgeon so that their talents may be combined to maximize the likelihood of a favorable outcome.

GUIDELINES
SUMMARY OF GUIDELINES FOR REDUCING CARDIAC RISK WITH NONCARDIAC SURGERY

Thomas M. Lee

Guidelines on the assessment and management of perioperative risk of coronary artery disease in noncardiac surgery were published by the American College of Physicians (ACP) in 1997[1] and an American College of Cardiology/American Heart Association (ACC/AHA) task force in 1996.[2] These guidelines preceded research demonstrating the beneficial impact of beta blockers on high-risk patients undergoing noncardiac surgery,[3] [4] as well as the publication of the Revised Cardiac Risk Index.[5]

Both the ACP and the ACC/AHA guidelines emphasize the importance of using clinical data to stratify patients according to their risk of major cardiac complications. The ACP guidelines recommend use of a modification[6] of the Cardiac Risk Index of Goldman and colleagues.[7] Compared with this modification and other algorithms available when these guidelines were developed, the revised cardiac risk index[5] is more accurate and identifies a larger percentage of patients as having intermediate or high risk. Thus, this new index may be incorporated into future guidelines.

Low-risk patients may proceed directly to surgery, whereas special risk-reducing strategies (e.g., coronary angiography and revascularization) may be appropriate for very high-risk patients (Table 61-G-1) . Among patients undergoing vascular surgery, both guidelines also recommend focusing use of noninvasive testing for further risk stratification on those with intermediate clinical risk. The ACP guidelines differ from the ACC/AHA guidelines by recommending against noninvasive testing in nonvascular patients with an intermediate risk determined by clinical evaluation.

These recommendations may be influenced in future revisions by randomized trial data demonstrating marked reductions in perioperative risk associated with treatment with bisoprolol in a population of patients who had abnormal results of stress echocardiography examinations and who underwent major vascular surgery.[3] These findings raise the possibility that an appropriate strategy may be to use beta blockers for intermediate- and high-risk patients rather than use noninvasive testing or coronary angiography to identify patients for revascularization. No prospective data show that testing or revascularization strategies can improve overall outcomes for patients undergoing noncardiac surgery.

TABLE 61--G-1 -- ACC/AHA GUIDELINES FOR MANAGEMENT OF CARDIAC RISK IN NONCARDIAC SURGERY

Issue	Class I	Class II	Class III
Recommendations for preoperative noninvasive evaluation of left ventricular function	Patients with current or poorly controlled CHF	Patients with prior CHF and patients with dyspnea of unknown cause	As a routine test of left ventricular function in patients without prior CHF
Perioperative therapy with beta blockers*	Beta blockers required in the recent past to control symptoms of angina or patients with symptomatic arrhythmias or hypertension	Preoperative assessment identifies untreated hypertension, known coronary disease, or major factors for coronary disease	Contraindication to beta blockade
Recommendations for intraoperative nitroglycerin	High-risk patients previously on nitroglycerin who have active signs of myocardial ischemia without hypotension	As a prophylactic agent for high-risk patients to prevent myocardial ischemia and cardiac morbidity, particularly in those who have required nitrate therapy to control angina	Patients with signs of hypovolemia or hypotension
Intraoperative use of pulmonary artery catheters	Patients at risk for major hemodynamic disturbances that are most easily detected by a pulmonary artery catheter who are undergoing a procedure that is likely to cause these hemodynamic changes in a setting with experience in interpreting the results (e.g., suprarenal aortic aneurysm repair in a patient with angina)	Either the patient's condition or the surgical procedure (but not both) places the patient at risk for hemodynamic disturbances (e.g., total hip replacement in a patient with chronic renal insufficiency)	No risk of hemodynamic disturbances

CHF=congestive heart failure; Class I=Appropriate indication; Class II=equivocal indication; Class III=contraindicated. For definitions, see p. 1714.

Part VIII - CARDIOVASCULAR DISEASE AND DISORDERS OF OTHER ORGAN SYSTEMS

Chapter 62 - Hemostasis, Thrombosis, Fibrinolysis, and Cardiovascular Disease

ANDREW I. SCHAFER
NADIR M. ALI GLENN N. LEVINE

BASIC MECHANISMS OF HEMOSTASIS AND THROMBOSIS

The human hemostatic system has evolved as a remarkably orchestrated scheme of linked activities designed to preserve the integrity of blood circulation. Hemostasis is regulated to promote blood fluidity under normal circumstances. It is also prepared to clot blood with speed and precision at sites of vascular damage to arrest blood flow and prevent exsanguination whenever and wherever the integrity of the circulation is disrupted. Finally, hemostasis has the capability to restore blood flow and perfusion upon subsequent healing of a damaged vessel. The major components of the hemostatic system include (1) the vessel wall itself, (2) plasma proteins (the coagulation and fibrinolytic factors), and (3) platelets (and probably other formed elements of blood, such as monocytes and red cells). These constituents function virtually inseparably (Fig. 62-1) . Although they are discussed in this chapter individually, it is important to recognize the interdependence of the actions of the vessel wall, plasma clotting factors, and platelets.

Figure 62-1 Interactions between the major components of the hemostatic system: the vessel wall, plasma proteins (clotting and fibrinolytic factors), and platelets.

Vascular Endothelium

A monolayer of endothelial cells lines the intimal surface of the entire circulatory tree, thereby representing the only stationary cell type that components of blood ever come in contact with under normal circumstances. The endothelial surface of the adult human is enormous: It is composed of about 1 to 6×10^{13} cells, weighs approximately 1 kg, and covers a surface area equivalent to about six tennis courts.[1] [2] Yet, as recently as the first half of the 20th century, endothelial cells were viewed simply as barriers of blood flow, acting "merely in a negative manner," "similarly to a layer of paraffin or oil."[3] Today, we recognize that endothelium is a dynamic organ with complex metabolic capabilities, including the ability to control vascular permeability, the flow of biologically active molecules and nutrients, cell-cell and cell-matrix interactions within the vessel wall, blood flow and vascular tone, interactions of blood cells, the inflammatory response, and angiogenesis.

Endothelium is also an ideal regulator of hemostasis.[4] [5] It is endowed with a remarkable repertoire of activities that permit it to rapidly transform from a potent antithrombotic to a prothrombotic surface wherever the need arises. Indeed, attempts to reproduce these properties in clinical settings such as cardiovascular prostheses, extracorporeal circuits, and bypass grafts by pharmacological or even gene transfer methods have proven suboptimal, leading to more recent approaches to tissue engineering of vessels.[6]

Normal, quiescent endothelium constitutively displays a potent antithrombotic (thromboresistant) surface to blood (Fig. 62-2) . It expresses anticoagulant, profibrinolytic, and platelet inhibitory properties. Whenever endothelium is activated or perturbed, however, it is rapidly transformed to a prothrombotic surface that actually promotes coagulation, inhibits fibrinolysis, and activates platelets. These are not entirely uniform phenomena, however. Throughout the circulatory

Figure 62-2 Balance of antithrombotic and prothrombotic properties of vascular endothelium. In general, antithrombotic properties dominate in quiescent endothelium under normal physiological conditions. In contrast, prothrombotic properties are expressed whenever endothelium is perturbed or activated. GAGs=glycosaminoglycans; AT III=antithrombin III; TFPI=tissue factor pathway inhibitor; t-PA=tissue-type plasminogen activator; u-PA=urokinase-type plasminogen activator; PAI=plasminogen activator inhibitor; TAFI=thrombin-activatable fibrinolysis inhibitor; vWF=von Willebrand factor; PAF=platelet-activating factor.

tree, even within a single organ, there is marked heterogeneity in the phenotype of endothelial cells.[7] [8] [9] [10] [11] With respect to hemostasis, for example, endothelial cells from different tissues are heterogeneous in their expression of von Willebrand factor, plasminogen activators, and tissue factor.[1] [12] [13] This endothelial heterogeneity is determined by both genetic and environmental factors. Exposure to different microenvironmental stimuli, including variable hemodynamic forces and cellular and humoral mediators, contributes significantly to the heterogeneity of endothelial phenotypes that develops throughout the circulation.[14]

The specific antithrombotic and prothrombotic properties of endothelial cells that are shown in Figure 62-2 are described in more detail in the following sections. The hemostatic conversion of the vessel wall is triggered by mechanical damage or by perturbation and activation of the vascular cells by agents such as cytokines, endotoxin, hypoxia, and hemodynamic forces.

Similarly, as illustrated in Figure 62-3 , a delicate balance exists in the capability of endothelial cells to modulate vascular tone. An important physiological vasodilator released by endothelial cells is nitric oxide (NO), a simple diatomic gas synthesized from the terminal guanidino nitrogen atoms of L-arginine by the action of a group of enzymes known as nitric oxide synthases (NOSs).[15] [16] [17] [18] [159A] [173A] The major isoform of NOS present in endothelial cells, eNOS, is constitutively active and is further activated by stimuli that increase intracellular calcium, including several receptor-dependent agonists (e.g., thrombin) and hemodynamic forces (shear stress

and cyclic stretch).[19] NO acts as a potent vasodilator as well as an inhibitor of platelet adhesion and platelet aggregation by stimulating soluble guanylate cyclase and thereby elevating intracellular levels of cyclic guanosine monophosphate in vascular smooth muscle cells and platelets. Prostaglandin I_2 (PGI_2 , prostacyclin) is a major endothelium-derived oxygenation product of arachidonic acid, synthesized by the sequential actions of cyclooxygenase (COX) and prostacyclin synthase.[4] [20] [21] Prostacyclin, like NO, is both a vasodilator and inhibitor of platelet aggregation (but not adhesion), exerting these actions by stimulating adenylate cyclase and thereby elevating intracellular cyclic adenosine monophosphate (AMP) in target vascular smooth muscle and platelets. Endothelium-derived hyperpolarizing factor (EDHF)[21] [22] [23] and carbon monoxide (CO), a byproduct of heme metabolism to biliverdin by heme oxygenases,[24] are also direct vasodilators elaborated by endothelial cells. Endothelial ecto-adenosine diphosphatase (ADPase), recently identified as CD39,[25] is a membrane-associated platelet inhibitor but may also indirectly promote vasodilation by generating adenosine.[5] These vasodilator properties of endothelium are counterbalanced by endothelium-derived vasoconstrictors, including platelet-activating

factor,[26] [27] endothelin-1,[28] [29] [30] and thromboxane A_2 (TXA_2).[31]

In many cases, endothelium-derived vasodilators are also platelet inhibitors and, conversely, endothelium-derived vasoconstrictors can also be platelet activators. The net effect of vasodilation and inhibition of platelet function is to promote blood fluidity, whereas the net effect of vasoconstriction and platelet activation is to promote hemostasis. Thus, as indicated in Figures 62-2 and 62-3 , blood fluidity and hemostasis can be exquisitely regulated by the balance of antithrombotic/prothrombotic and vasodilatory/vasoconstrictor properties of endothelial cells, which are often coordinately modulated by their relative states of quiescence and activation.[5]

Coagulation

Plasma coagulation proteins ("clotting factors") normally circulate in plasma in their biologically inactive zymogen (or proenzyme) forms. When the thromboresistant nature of the vascular system is altered, by either mechanical injury or inflammatory and other systemic stimuli, (e.g., coronary plaque rupture in patients who develop unstable angina), the coagulation system is activated. If the physiological antithrombotic defenses can be overwhelmed, the result will be the formation of hemostatic thrombi composed of platelets and fibrin. In cases where activation of the coagulation system is triggered by focal vascular injury, the occlusive hemostatic thrombus will be precisely localized at and limited to the site of damage.

The sequence of coagulation protein reactions that culminate in the formation of fibrin was originally described as a "waterfall" or a "cascade" (Fig. 62-4) . The coagulation cascade is a highly coordinated and regulated series of linked enzymatic reactions that involves the sequential activation of plasma zymogens to serine proteases. Each protease then catalyzes the subsequent zymogen-protease transition by cleavage of peptide bonds. This creates a biochemical amplifier in which a small initiating stimulus rapidly generates high levels of the end product fibrin.[32] [33] [34] Our understanding of the coagulation cascade has been refined with the recognition that it actually involves a series of linked enzymatic multiprotein complexes, each consisting of a serine protease, one or more cofactor proteins, divalent cations, and a cellular surface (e.g., platelet membranes) on which these components can be assembled.[34]

Two pathways of blood coagulation have been recognized: the so-called intrinsic or contact activation pathway and the so-called extrinsic or tissue factor pathway. These two pathways of activation of the coagulation cascade converge to form a "common" pathway, which leads to the generation of the pivotal coagulation enzyme thrombin. As illustrated in Figure 62-4 , thrombin not only catalyzes the conversion of fibrinogen to fibrin but also serves an important role in sustaining the cascade by feedback activation of coagulation factors at several strategic sites.

INTRINSIC PATHWAY.

This pathway of coagulation is triggered by the autoactivation of factor XII to its active serine protease form (factor XIIa) on "negatively charged" surfaces, optimally in the presence of two other contact activation proteins, prekallikrein and high-molecular-weight kininogen.[35] The physiological negatively charged surface for contact activation of factor XII and the intrinsic pathway of coagulation is really the cell membrane, which serves as a foundation for the assembly and activation of these proteins.[36] Factor XIIa converts the zymogen factor XI to its corresponding serine protease, factor XIa. Factor XIa, in turn, then serves as an activator of factor IX to IXa. The final step in the intrinsic pathway is the activation of the plasma zymogen factor X to factor Xa by factor IXa, a reaction that requires the activated form of the plasma cofactor, factor VIIIa. Factor VIIIa is generated by thrombin-induced limited proteolysis of factor VIII.

In vivo, however, coagulation is probably not initiated primarily by this intrinsic pathway. The most compelling support of this is the

Figure 62-4 The coagulation cascade. This scheme emphasizes recent understanding of the importance of the tissue factor pathway in initiating clotting in vivo, the interactions between pathways, and the pivotal role of thrombin in sustaining the cascade by feedback activation of coagulation factors. TF=tissue factor; PK=prekallikrein; HMWK=high-molecular-weight kininogen; PL=phospholipid; PT=prothrombin; Th=thrombin. (Modified from Schafer AI: The primary and secondary hypercoagulable states. *In* Schafer AI [ed]: Molecular Mechanisms of Hypercoagulable States. Austin, TX, Landes Bioscience, 1997, pp 1-48.)

clinical observation that individuals with inherited deficiencies of any of the contact activation factors (factor XII, prekallikrein, high-molecular-weight kininogen) do not have a bleeding tendency. Thus, it has been argued that this system has little to do with the initiation of hemostasis.[36] In fact, these proteins may play important roles in other physiological systems, such as vasoregulation and as antithrombotic and profibrinolytic agents.[37] In contrast, individuals with deficiencies of factors XI, IX, or VIII do have clinical bleeding tendencies; and, therefore, these proteins in the intrinsic pathway do appear to play important roles in hemostasis. The participation of factor XI in hemostasis is therefore probably not dependent on its activation by factor XIIa but rather on its positive feedback activation by thrombin. Thus, this positive feedback loop (see Fig. 62-4) would permit factor XIa to function in the propagation and amplification, rather than in the initiation, of the coagulation cascade.

EXTRINSIC PATHWAY.

Coagulation in vivo is probably initiated predominantly through the extrinsic pathway. The immediate trigger is the injury-induced expression of the integral membrane glycoprotein tissue factor[38] [39] [40] on the surfaces of activated endothelial cells and circulating blood cells (particularly leukocytes), cells that normally do not express tissue factor activity on their surfaces.[41] Alternatively, vascular damage can expose blood to tissue factor that is constitutively expressed on the surfaces of subendothelial cellular components of the vessel wall, such as smooth muscle cells and fibroblasts. The serine protease

factor VIIa (activated factor VII) circulates in blood at trace levels[42] but possesses very poor enzymatic activity in its free form. Exposure of blood to cell surface tissue factor activates coagulation by binding this free factor VIIa. The tissue factor/factor VIIa complex then acts as a bimolecular enzyme to rapidly autocatalyze the conversion of factor VII to VIIa, thereby generating more tissue factor/factor VIIa complexes and amplifying this initial hemostatic response.[43] Factor Xa and thrombin can also induce factor VII activation (see Fig. 62-4) ; in fact, these two enzymes may be kinetically preferred over the tissue factor/factor VIIa complex as physiological activators of factor VII.[44] The final reaction in the extrinsic pathway is the activation of factor X to factor Xa. This can be catalyzed directly by the tissue factor/factor VIIa bimolecular enzyme complex. Alternatively, the complex can indirectly activate factor X by initially converting factor IX to factor IXa (providing communication between the extrinsic and intrinsic pathways of coagulation), which then activates factor X. This indirect route of factor X activation is probably the one that is favored kinetically.

COMMON PATHWAY.

Factor Xa, which can be formed through the actions of either the tissue factor/factor VIIa complex or factor IXa (with factor VIIIa as a cofactor), initiates the common pathway of coagulation by converting the inactive plasma zymogen prothrombin to thrombin, the pivotal protease of the coagulation system. The essential cofactor for this reaction is factor Va, a plasma protein that shares about 30 percent sequence identity to the other plasma coagulation cofactor, factor VIIIa. Like the homologous factor VIIIa, factor Va is produced by thrombininduced limited proteolysis of factor V. As noted earlier and further described later, thrombin is a multifunctional enzyme, but its major role in the common pathway is to convert soluble plasma fibrinogen to an insoluble fibrin matrix.[45] Fibrin polymerization involves an orderly process of intermolecular associations.[46] Thrombin also activates factor XIII (fibrin-stabilizing factor) to factor XIIIa, a transglutaminase that covalently cross-links and thereby stabilizes the fibrin clot.[46] [47]

The coagulation cascade that culminates in fibrin formation would occur extremely inefficiently and slowly in fluid phase plasma. However, the assembly of these

clotting factors on activated cell membrane surfaces greatly accelerates their reaction rates and also serves to localize blood clotting to sites of vascular injury.[32] [34] [38] In addition, proteases in the coagulation factor complexes assembled on cell surfaces are sequestered from inactivation by their physiological antithrombotic regulators described later, further enhancing the efficiency of membrane-dependent reactions. The critical cell membrane components on which these coagulation reactions proceed are acidic phospholipids. These phospholipid species are not normally exposed on resting cell membrane surfaces. However, when platelets, monocytes, and endothelial cells are activated by vascular injury or inflammatory stimuli, the procoagulant head groups of the membrane anionic phospholipids become translocated to the surfaces of these cells, making them available to support and promote the plasma coagulation reactions.[48] [49]

PROTHROMBINASE COMPLEXES.

Major membrane phospholipid-associated enzyme complexes in the coagulation cascade include the "Xase" (or tenase) and "prothrombinase" complexes (Fig. 62-5) . Each complex consists of a serine protease enzyme, its zymogen substrate, and its cofactor assembled in association with each other on the membrane surface. The "extrinsic Xase" complex consists of the tissue factor/factor VIIa enzyme complex and its zymogen substrates, factor IX and factor X. The "intrinsic Xase" complex consists of factor IXa as the enzyme, factor X as its substrate, and factor VIIIa as the cofactor. The "prothrombinase complex" consists of factor Xa as the enzyme, prothrombin (factor II) as its substrate, and factor Va as the cofactor. Factor IXa generated by the "extrinsic Xase" complex becomes the enzyme of the "intrinsic Xase" com

Figure 62-5 Schematic representation of the phospholipid membrane-associated enzyme complexes of coagulation. Each vitamin K-dependent serine protease (factors VIIa, IXa, and Xa and alpha-thrombin [IIa]) is shown in association with its cofactor protein (tissue factor [TF], factors VIIIa and Va, and thrombomodulin [TM]) and zymogen substrate(s) (factors IX and X, prothrombin [II] and protein C [C]) on the membrane surface. The cofactor proteins, factor VIIIa and factor Va, are characterized by a two-domain structure and consist of heavy (H) and light (L) chains that are bridged together by Ca^{2+} ions. Both domains are required for cofactor-membrane association and cofactor-protease binding. (Modified from Jenny NS, Mann KG: Coagulation cascade: An overview. *In* Loscalzo J, Schafer AI [eds]: Thrombosis and Hemorrhage. 2nd ed. Baltimore, Williams & Wilkins, 1998, pp 3-27.)

plex. Factor Xa generated by either the "extrinsic Xase" or the "intrinsic Xase" complex becomes the enzyme of the "prothrombinase" complex. These successive reaction complexes of coagulation most likely occur by diffusion of products along the same cell membrane surface.[34]

The final enzyme product, thrombin, is detached from cell membranes and out into the blood to serve its multiple purposes. A major terminating reaction, also shown in Figure 62-5 , involves membrane assembly of the "protein Case" complex in which free thrombin (factor IIa) binds to the integral membrane protein, thrombomodulin, which serves as the site for activation of protein C, a major antithrombotic protein discussed later in the chapter.

Anticoagulant (Antithrombotic) Mechanisms

Several physiological antithrombotic mechanisms act in concert to prevent clotting under normal circumstances. Optimal activity of each of the anticoagulant systems depends on the integrity of vascular endothelium. Thus, these physiological mechanisms operate to preserve blood fluidity in the intact circulation and also to limit blood clotting to specific focal sites of vascular injury.[50]

Endothelial PGI_2 , nitric oxide, ADPase, and carbon monoxide are physiological platelet inhibitory mediators (see Fig. 62-2). Other anticoagulant systems are designed to limit fibrin accumulation. Several of these mechanisms, including antithrombin, the protein C/protein S/thrombomodulin system and tissue factor pathway inhibitor (TFPI), act at different sites in the coagulation cascade to dampen fibrin accumulation. Fibrin that forms despite these anticoagulant defenses is then degraded by the fibrinolytic system. The sites of action of the major physiological antithrombotic pathways are shown in Figure 62-6.

ANTITHROMBIN.

Antithrombin (or antithrombin III) is the major plasma protease inhibitor of thrombin and the other clotting factors in the intrinsic and common pathways of coagulation. It is a single-chain glycoprotein that is synthesized primarily in the liver and belongs to the serine protease inhibitor ("serpin") family of proteins.[51] [52] Antithrombin neutralizes thrombin and other activated coagulation factors by forming a complex between the active site of the enzyme and the reactive center (Arg393 and Ser394) of antithrombin. The rate of formation of these inactivating complexes increases by a factor of several thousand in the presence of heparin. This is the major anticoagulant mechanism of action of heparin (see later). Heparin and heparan sulfate proteoglycans are actually present as endogenous components of the vessel wall. Thus, antithrombin inactivation of thrombin and other activated clotting factors probably occurs physiologically on vascular surfaces, where heparins are present to catalyze these reactions, rather than in fluid phase plasma. Inherited quantitative or qualitative deficiencies of antithrombin lead to a lifelong predisposition to venous thromboembolism.[11] , [32] , [50] , [53]

PROTEIN C/PROTEIN S/THROMBOMODULIN.

Protein C is another plasma glycoprotein synthesized by the liver, which becomes an anticoagulant when it is activated by thrombin through cleavage of an Arg169-Leu170 bond in its heavy chain.[54] [55] The thrombin-induced activation of protein C occurs physiologically on thrombomodulin, a transmembrane proteoglycan binding site for thrombin on endothelial cell surfaces.[56] [57] Thrombomodulin thus serves an antithrombotic function both by binding and thereby removing thrombin from the circulation and also by promoting generation by thrombus of anticoagulantly active protein C. Activated protein C acts as an anticoagulant by cleaving multiple bonds and thereby destroying the membrane-bound activated forms of coagulation factors V (Va)

Figure 62-6 Sites of action of the four major physiological antithrombotic pathways: antithrombin (AT); protein C/protein S (PC/PS); tissue factor pathway inhibitor (TFPI); and the fibrinolytic system, consisting of plasminogen, plasminogen activator (PA), and plasmin (Pl). (From Schafer AI: The primary and secondary hypercoagulable states. *In* Schafer AI [ed]: Molecular Mechanisms of Hypercoagulable States. Austin, TX, Landes Bioscience, 1997, pp 1-48.)

and VIII (VIIIa). This reaction is accelerated by a cofactor, protein S. Like protein C, protein S is a glycoprotein that undergoes vitamin K-dependent posttranslational carboxylations to form gamma-carboxyglutamic acid ("Gla") residues that allow it to bind to negatively charged phospholipid surfaces. Protein S acts as a cofactor by increasing the affinity of activated protein C for phospholipids in the formation of the membrane-bound protein Case complex (see Fig. 62-5) . Quantitative or qualitative deficiencies of protein C or protein S, or resistance to the action of activated protein C by a specific mutation at its target cleavage site in factor Va (factor V Leiden), lead to hypercoagulable states.[11] [32] [50] [53]

TISSUE FACTOR PATHWAY INHIBITOR.

TFPI is a plasma protease inhibitor that regulates the tissue factor-induced extrinsic pathway of coagulation.[58] Unlike other coagulation inhibitors, which are members of the serpin family, TFPI is a multivalent Kunitz-type serine protease inhibitor. This structure permits TFPI to exert dual inhibitory actions against both tissue factor/factor VIIa (mediated by its Kunitz-1 domain binding to factor VIIa), as shown in Figure 62-6, as well as factor Xa (mediated by its Kunitz-2 binding to factor Xa). Circulating plasma TFPI is bound to lipoproteins. TFPI can also be released by heparin from endothelial cells, where it is bound to glycosaminoglycans, and from platelets.

THE FIBRINOLYTIC SYSTEM.

Any thrombin that escapes the inhibitory effects of the physiological anticoagulant systems described earlier is available to convert fibrinogen to

fibrin. In response, the endogenous fibrinolytic system is then activated to dispose of intravascular fibrin and thereby maintain or reestablish the patency of the circulation. Just as thrombin is the key protease enzyme of the coagulation system, plasmin is the major protease enzyme of the fibrinolytic system, acting to digest fibrin to fibrin degradation products. The general scheme of fibrinolysis and its control is shown in Figure 62-7 .

Plasminogen, the inactive zymogen form of plasmin, is synthesized primarily in the liver and circulates in plasma in high (micromolar) concentrations. It is a single-chain glycoprotein, which has significant sequence homology with apolipoprotein (a). Elevated plasma levels of lipoprotein (a) are associated with atherosclerotic cardiovascular risk.[59] Indeed, one possible atherogenic mechanism for lipoprotein (a) might be to inhibit fibrinolysis by competing with plasminogen for plasmin generation.

Plasminogen Activators.

These cleave the Arg560-Val561 bond of plasminogen to generate the active enzyme plasmin, a two-chain molecule that derives its heavy chain (or A chain) from the amino-terminal region and its light chain (or B chain) from the carboxy-terminal region of plasminogen. The enzyme-active site of plasmin is localized in the B chain, whereas the A chain contains lysine-binding sites. The lysine-binding sites of plasmin (and plasminogen) permit it to bind to fibrin, so that physiological fibrinolysis is "fibrin specific." Plasmin is a serine protease the actions of which are not limited to fibrinolysis; plasmin also plays important roles in tissue remodeling, wound healing, angiogenesis, and cell migration.[60]

The major physiological plasminogen activators that convert plasminogen to plasmin are tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA). Both are serine proteases that are released by endothelial cells into plasma in trace concentrations. Plasmin can convert t-PA from its single-chain form to a two-chain molecule, in which the heavy and light chains are disulfide bonded. Both the single-chain and two-chain forms of t-PA are catalytically active to convert plasminogen to plasmin. In contrast, single-chain u-PA (scu-PA) has little enzyme activity and must be converted to its disulfide bonded, two-chain active form by hydrolysis of a Lys158-Ile159 bond. t-PA and u-PA are released from endothelial cells by a variety of humoral factors (e.g., growth factors, hormones, and cytokines), as well as hemodynamic forces, but many of these stimuli also induce the release of plasminogen activator inhibitors.

Both plasminogen (through its lysine-binding sites) and t-PA possess specific affinity for fibrin and thereby bind selectively to clots. In the absence of fibrin, t-PA activates

Figure 62-7 Scheme of the fibrinolytic system and its control.

plasminogen to plasmin relatively slowly. Fibrin provides a surface for the sequential binding of t-PA and plasminogen. The assembly of a ternary complex, consisting of fibrin, plasminogen, and t-PA, promotes the localized interaction between plasminogen and t-PA and thereby greatly accelerates the rate of plasminogen activation to plasmin. Moreover, partial degradation of fibrin by plasmin exposes new plasminogen and t-PA binding sites in carboxy-terminus lysine residues of fibrin fragments to enhance further these reactions. Thus, early fibrin digestion by plasmin further accelerates fibrinolysis, thereby amplifying the process. This creates a highly efficient mechanism to generate plasmin focally on the fibrin clot, which then becomes plasmin's substrate for digestion to fibrin degradation products. Thus, the fibrin surface itself is an important regulator of its own degradation by providing binding sites for fibrinolytic proteins.

In addition to its interactions with fibrin, components of the fibrinolytic system are also efficiently assembled on cell surfaces, similar to the coagulation system, to localize and kinetically optimize the generation of plasmin.[61] [62] Specific binding sites for plasminogen and t-PA are present on the surfaces of endothelial cells, identified with annexin II, and other cell surfaces[63] to catalyze plasminogen activation. The presence of u-PA receptors (u-PAR) has also been identified on endothelial cells and other cell types.

The capacity of endothelial cells to synthesize and release plasminogen activators and then to bind these and other components of the fibrinolytic system provides a powerful paracrine mechanism to concentrate and activate fibrinolysis in proximity to intravascular thrombi contiguous to sites of endothelial damage. At the same time, receptors for the fibrinolytic proteins are also present on the surfaces of other cell types, including platelets and leukocytes that accumulate within thrombi.[64]

Plasmin cleaves fibrin at different rates at different sites of the fibrin molecule. This orderly process leads to the generation of characteristic fibrin fragments during the process of fibrinolysis. At the end of this sequential proteolysis, the D and E domains of fibrin are liberated. The sites of plasmin cleavage of fibrin are the same as those in fibrinogen. However, when plasmin acts on covalently cross-linked fibrin, D-dimers are released; hence, D-dimers can be measured in plasma as a relatively specific test of fibrin (rather than fibrinogen) degradation. Fibrin(ogen) degradation products may have potent anticoagulant and antiplatelet actions, thereby further contributing to the net antithrombotic effects of fibrinolysis.

Fibrinolytic Inhibitors.

As shown in Figure 62-7 , physiological regulation of fibrinolysis occurs primarily at two levels: (1) Plasminogen activator inhibitors (PAIs), specifically PAI-1 and PAI-2, inhibit the physiological plasminogen activators, and (2) alpha$_2$ -antiplasmin inhibits plasmin. PAI-1 is the primary inhibitor of t-PA and u-PA in plasma.[65] [66] This serine protease inhibitor is a single-chain glycoprotein derived from endothelial cells and other cell types. PAI-1 inhibits t-PA by the formation of a complex between the active site of t-PA and the "bait" residues (Arg346-Met347) of PAI-1.[67]

PAI-2, which also belongs to the serpin superfamily, was originally identified in trophoblastic epithelium and hence is referred to as placental-type PAI.[68] Particularly elevated plasma levels of PAI-2 are found in pregnant women. Alpha$_2$ -antiplasmin is a single-chain glycoprotein serpin that is synthesized predominantly by the liver. It is the main inhibitor of plasmin in human plasma, forming a 1:1 stoichiometric complex with plasmin that inactivates the enzyme.[67] Alpha$_2$ -macroglobulin also inhibits plasmin, but at a much slower rate than alpha$_2$ -antiplasmin; therefore, alpha$_2$ -macroglobulin is of questionable importance in the physiological regulation of fibrinolysis.

Platelets

Platelets are cytoplasmic fragments that are released into blood from bone marrow megakaryocytes and circulate with an average life span of 7 to 10 days.[69] These terminal cell fragments are anucleate and therefore possess minimal capacity to synthesize new protein.

Figure 62-8 Sequence of events in platelet activation. *A,* Under normal conditions, a monolayer of endothelial cells lines the intimal surface of the circulatory tree, releasing platelet-inhibitory mediators such as PGI_2 (prostacyclin) and nitric oxide (NO). *B,* At a site of vascular injury, endothelium is lost and platelets undergo "adhesion" (platelet-vessel wall interactions) to subendothelial structures that are now exposed (e.g., collagen). *C,* Adherent platelets are activated, and release granule constituents (e.g., ADP, fibrinogen, von Willebrand factor) and thromboxane A_2 (TXA_2). *D,* Substances released from activated platelets recruit additional platelets from the circulation to the site of injury and mediate the process of platelet "aggregation" (platelet-platelet interactions), resulting in the formation of an occlusive platelet plug.

The antithrombotic properties of intact vascular endothelium include potent platelet inhibitors (see Fig. 62-2 and Fig. 62-8 *A*). These inhibitors include PGI_2 , NO, and CO, which are labile molecules that are released by endothelial cells and act locally as autocoids, and ADPase, an ectonucleotidase of endothelial membranes that breaks down platelet-activating ADP.

ADHESION.

On vascular intimal injury, the antiplatelet properties of endothelium are diminished locally, while previously cryptic, thrombogenic subendothelial substances (e.g., collagen) become exposed to flowing blood. Circulating platelets recognize sites of vascular disruption and undergo the process of adhesion to the site of injury (see Fig. 62-8 *B*). Adhesion results in the formation of a monolayer of platelets that are attached to the denuded vascular intimal surface. Platelet adhesion (i.e., platelet-vessel wall interaction) is mediated primarily by von Willebrand factor (vWF), a multimeric protein consisting of a wide spectrum of polymerized subunits that create a mature protein with a molecular mass that ranges from about 550 to more than 10,000 kDa, one of the largest soluble proteins in plasma.[70] [71] vWF is synthesized by both endothelial cells and megakaryocytes, where it is stored in Weibel-Palade bodies and alpha granules, respectively, before its regulated secretion. Released vWF is present in both plasma and in the extracellular matrix of the subendothelial vessel wall, to which the platelets are anchored. The large vWF multimers serve as the primary "molecular glue" to attach platelets to a damaged vessel wall with sufficient strength to withstand the high levels of shear stress that would tend to detach them with the flow of blood. The receptor for vWF on the platelet surface is localized in membrane glycoprotein (Gp) Ib, part of the platelet membrane Gp Ib/IX-V complex.[72] [73] Higher levels of shear stress on the arterial side of the circulation promote the interaction between vWF and platelet membrane Gp Ib, probably

through subtle shear-induced changes in the vWF molecule and/or its platelet receptor.[74] Platelet adhesion is also facilitated by direct binding to subendothelial collagen by means of specific platelet membrane collagen receptors.[75] [76] [77]

ACTIVATION.

Adherent platelets then become activated[78] (Fig. 62-8 *C*). The platelet activation process results from the combined actions of several agonists that bind to their respective membrane receptors on adherent platelets and transmit platelet-activating intracellular signals. These platelet stimuli include humoral mediators in plasma (e.g., epinephrine, thrombin), mediators released from activated cells (e.g., ADP, serotonin), and vessel wall extracellular matrix constituents that come in contact with adherent platelets (e.g., collagen, vWF). Several of these stimuli can synergistically activate platelets[79] [80] and may also act in concert with shear forces to which platelets are simultaneously exposed.[81] Activated platelets undergo the release reaction, during which they secrete prepackaged constituents of their cytoplasmic granules: ADP, adenosine triphosphate, and serotonin from the dense granules; soluble adhesive proteins (fibrinogen, vWF, thrombospondin, fibronectin); growth factors (including platelet-derived growth factor, transforming growth factor-alpha and transforming growth factor-beta); and procoagulants (platelet factor 4, factor V) from the alpha granules.[82] Simultaneously, activated platelets synthesize *de novo* and release the potent platelet activator and vasoconstrictor TXA_2 . TXA_2 is the major cyclooxygenase product of arachidonic acid metabolism in platelets. As described later in the section on antiplatelet agents, aspirin inhibits cyclooxygenase and thereby blocks TXA_2 synthesis in platelets.

TXA_2 acts in concert with several of the substances released from granules to induce the activation of additional platelets in the microenvironment of the developing thrombus.[83] [84]

AGGREGATION.

The products of the platelet release reaction, including secreted granule constituents and TXA_2 , mediate the final phase of platelet activation, the process of aggregation (see Fig. 62-8 *D*). During platelet aggregation (platelet-platelet interaction) additional platelets are recruited from the circulation to the site of vascular injury, leading to the formation of an occlusive platelet thrombus. As discussed earlier, the platelet plug is anchored and stabilized by the fibrin mesh that develops simultaneously as the product of the coagulation cascade. At lower shear levels (e.g., in the venous circulation), the "molecular glue" that mediates aggregation is fibrinogen, which can be derived either from plasma or from the alpha-granule releasate of activated platelets. At higher shear levels (e.g., in arteries), vWF itself, which is also the ligand that mediates platelet adhesion, can substitute for fibrinogen as the ligand of aggregation.[74] Fibrinogen or vWF binds to specific platelet membrane receptors that are located in the Gp IIb/IIIa integrin complex.[85] [86] Integrins are widely distributed on the surfaces of adherent eukaryotic cells. All receptors in the integrin superfamily contain an alpha and a beta subunit. Individual integrins can often bind to more than one ligand; thus, platelet Gp IIb/IIIa can recognize both fibrinogen and vWF, as well as some other adhesive proteins.

The Gp IIb/IIIa complex is the most abundant receptor on the platelet surface. Its alpha subunit (Gp IIb) is expressed specifically on platelets, but its $beta_3$ subunit (Gp IIIa) is shared by other integrins, including receptors on vascular cells. The heterodimeric, ligand-binding Gp IIb/IIIa complexes are not normally exposed in their active forms on the surfaces of quiescent circulating platelets. However, platelet activation converts Gp IIb/IIIa into competent receptors by means of specific signal transduction pathways,[86] [87] enabling Gp IIb/IIIa to bind to fibrinogen and vWF. The binding of these adhesive proteins requires that they contain the specific tripeptide sequence Arg-Gly-Asp (RGD). Recognition of fibrinogen and other ligands by the active Gp IIb/IIIa complex involves the RGD tripeptide sequence (located at positions 95-97 and 572-574 of each of the two A-alpha chains of fibrinogen). When two activated platelets with functional Gp IIb/IIIa receptors each bind the same fibrinogen molecule, a fibrinogen bridge is created between the two platelets (Fig. 62-9). Because the surface of each platelet has about 50,000 Gp IIb/IIIa fibrinogen binding sites, numerous activated platelets recruited to the site of vascular injury can rapidly form an occlusive aggregate by means of a dense network of intercellular fibrinogen bridges.[88] In addition to its RGD sequences, the gamma chains of fibrinogen also contain a 12-amino acid residue (dodecapeptide HHLGGAKQAGDV) that also has the ability to bind to the platelet Gp IIb/IIIa receptor. These events of ligand binding to activated platelet membrane Gp IIb/IIIa receptors, which mediate the process of platelet aggregation, have served as targets for antiplatelet therapy with Gp IIb/IIIa antagonists.

Central Role of Thrombin

Thrombin plays a pivotal role in coordinating, integrating, and regulating hemostasis. Depending on the circumstances, it can either promote or prevent blood clotting. This multifaceted effect of thrombin has been referred to as the "thrombin paradox."[89] The balance of prothrombotic and antithrombotic activities of thrombin is determined by at least two variables: (1) the concentration of free thrombin in blood and (2) the presence or absence of endothelial cells at thrombin's site of action.

When free thrombin is available in blood at high concentrations, particularly at a site of vascular injury where

Figure 62-9 Linkage of two activated platelets by fibrinogen, which binds to its receptors in the platelet Gp IIb/IIIa complex by means of tripeptide RGD (arginine-glycine-aspartic acid) sequences located on the alpha chains of dimeric fibrinogen. The high density of Gp IIb/IIIa complexes on the surfaces of activated platelets permits the rapid formation of a network of fibrinogen bridges, leading to platelet aggregation at the site of vascular injury. (In regions of high shear stress, such as in diseased coronary arteries, von Willebrand factor may replace fibrinogen as the primary aggregating ligand. Like fibrinogen, the von Willebrand factor molecule has RGD sequences that mediate this process.) The result of platelet aggregation is the formation of an occlusive platelet thrombus. (From Schafer AI: Antiplatelet therapy with glycoprotein IIb/IIIa receptor inhibitors and other novel agents. Tex Heart Inst J 24:90-96, 1997.)

the antithrombotic influence of endothelium is lost, thrombin is a potent inducer of clotting (Fig. 62-10) . This enzyme catalyzes several coagulation factor activation reactions that lead to fibrin formation, factor XIII activation to promote fibrin cross-linking, and activation and aggregation of platelets. In fact, under these procoagulant conditions, reciprocal, interdependent, and mutually self-amplifying interaction occurs between thrombin generation and platelet activation. Membranes of activated platelets facilitate thrombin generation by providing a surface for the assembly of coagulation factors and cofactors (Fig. 62-11 and described earlier). Conversely, thrombin is a potent activator of platelets, stimulating the availability of additional activated platelet surface for further thrombin generation. Thus, this reciprocal interaction between thrombin and platelets promotes and amplifies the formation of a tightly focused hemostatic plug composed of platelets and fibrin.

At lower concentrations of thrombin and in the presence of intact endothelium, the antithrombotic effects of thrombin predominate (see Fig. 62-10) . Low levels of thrombin stimulate increased levels of the endogenous circulating anticoagulant, activated protein C.[90] Accordingly, as shown in Figure 62-12 , a J curve describes the relationship between the thrombotic potential of blood and free thrombin concentration.[89] Furthermore, in the presence of normal endothelial cells in the intact circulation (see Fig. 62-10) , endothelial thrombomodulin removes free thrombin from blood and low concentrations of thrombin stimulate t-PA release and the release of antiplatelet PGI_2 and NO from endothelial cells. Thus, thrombin plays a central role in modulating the state of blood coagulability, depending on its free concentration in blood and the presence or absence of intact endothelial cells at its site of action.

Figure 62-10 Central role of thrombin in modulating the state of blood coagulability, depending on the presence or absence of intact endothelial cells (EC) at its site of action. In the presence of intact EC *(lower part of figure),* free thrombin is removed from the circulation by EC thrombomodulin and the antithrombotic effects of thrombin predominate: activation of protein C, release of tissue-type plasminogen activator (t-PA), and release of platelet-inhibitory nitric oxide (NO) and prostaglandin I_2 (PGI_2) by intact EC. In the absence of intact EC *(upper part of figure),* free thrombin is available in blood at higher concentrations and its prothrombotic effects predominate: activation of coagulation factors, fibrin formation and cross-linking, and activation of platelets (PLTS). PAI-1=plasminogen activator inhibitor-1.

Figure 62-11 Reciprocal interaction between thrombin generation and platelet activation. Membranes of activated platelets facilitate thrombin generation by providing a surface for assembly of coagulation factors. Conversely, thrombin is a potent activator of platelets, thus acting to promote and amplify activation of the coagulation system. This reciprocal interaction results in the accelerated and tightly focused formation of a hemostatic plug composed of platelets and fibrin. (From Schafer AI: The primary and secondary hypercoagulable states. *In* Schafer AI [ed]: Molecular Mechanisms of Hypercoagulable States. Austin, TX, Landes Bioscience, 1997, pp 1-48.)

Figure 62-12 The thrombin paradox. At low concentrations of thrombin, protein C is activated and elevated activated protein C exhibits antithrombotic activity. At increasingly higher levels of thrombin, the procoagulant properties of thrombin become dominant and prothrombotic potential is markedly increased. (Adapted from Griffin JH: The thrombin paradox. Nature 378:337-338, 1995.)

ANTITHROMBOTIC DRUGS

Heparin

Because its onset of action is practically immediate when administered parenterally, heparin is the anticoagulant of choice when rapid anticoagulation is required.[91] Commercial preparations of unfractionated heparin consist of a heterogenous mixture of glycosaminoglycans, with molecular weights ranging from 3000 to 30,000.[91] [92] However, only about one third of the molecules in these products are anticoagulantly active. Heparin exerts its anticoagulant effect by interacting with antithrombin III (AT), as shown in Figure 62-13 (Figure Not Available) . A specific pentasaccharide sequence in heparin accounts for its ability to bind with high affinity to lysine sites on AT. In the absence of heparin, AT binds to and neutralizes thrombin and other activated clotting factors (see earlier) slowly; however, heparin-bound AT undergoes a conformational change that dramatically accelerates its ability to bind to and neutralize these factors. In these reactions, arginine reactive centers in AT bind to the enzyme active center serines of thrombin and other serine protease coagulation factors, thereby inhibiting their activities. Heparin then dissociates from these complexes and can be reused to bind to other AT molecules. Heparin thus acts as a true catalyst in accelerating the neutralization of thrombin and other activated clotting factors by AT.[93] Fibrin-bound thrombin is relatively protected from inactivation by the heparin/AT complex.

Heparin is poorly absorbed from the gastrointestinal tract and therefore must be administered parenterally. The complex pharmacokinetics of unfractionated heparin are due to its nonspecific binding to many plasma proteins (including some acute-phase reactants) and to vascular and blood cells. Provided that the doses used are adequate, the efficacy and safety of heparin are comparable when administered by continuous intravenous infusion or by subcutaneous injection.[94] Intermittent intravenous injections of heparin are associated with more bleeding complications than is continuous intravenous infusion.

HEPARIN MONITORING.

Because of unfractionated heparin's often unpredictable pharmacokinetics and its narrow therapeutic range, therapy with this agent requires laboratory monitoring for proper dosing.[95] This is conventionally performed with the activated partial thromboplastin time (aPTT), a test that is sensitive to the inhibitory effects of heparin on thrombin, factor Xa, and factor IXa. For the treatment of deep venous thrombosis or pulmonary embolism, heparin is usually initiated with an intravenous bolus of 5000 U, followed by continuous intravenous infusion of 30,000 to 35,000 U/24 hours that is subsequently adjusted to maintain the aPTT at one and one-half to two and one-half times the control value. To standardize and optimize management with intravenous heparin, dosage-adjustment nomograms (which can be adapted into preprinted order sheets) and computer algorithms have been used. Weight-adjusted nomograms for heparin treatment of unstable angina have been published.[96] Heparin can also be monitored by heparin levels using protamine titration (therapeutic range: 0.2 to 0.4 U/ml), or by antifactor Xa levels (therapeutic range: 0.3 to 0.6 U/ml), but these assays are more expensive and not available in all hospital laboratories. The aPTT is sensitive over a heparin range of 0.1 to 1.0 U/ml. Because the aPTT becomes immeasurably prolonged at heparin concentrations of more than 1.0 U/ml, this test is unsuitable for monitoring heparin dosage during percutaneous coronary interventions (angioplasty and stenting) and during cardiac bypass surgery, in which patients require higher levels of anticoagulation with heparin. In these procedures, heparin can be monitored by the activated clotting time, because this test provides a graded response to heparin concentrations in the range of 1 to 5 U/ml.[91]

Low-dose subcutaneous unfractionated heparin has also been used to prevent (rather than treat) venous thromboembolism in high risk patients. Doses of 5000 U every 8 or 12 hours generally do not prolong the aPTT and therefore do not require monitoring in this setting.

COMPLICATIONS.

The major complication of heparin is bleeding. Factors that predispose to increased bleeding risk include advanced age, serious concurrent illness, heavy consumption of alcohol, concomitant use of aspirin, and renal failure.[92] Due to its relatively short half-life, simple discontinuation of heparin is usually adequate to control bleeding complications. Protamine sulfate can be used in emergency situations with serious bleeding. Protamine, a strongly basic protein, practically instantaneously neutralizes heparin, which is highly negatively charged.

Two distinct types of thrombocytopenia are associated with heparin therapy. The more common form, which may occur in up to 15 percent of patients receiving therapeutic doses of heparin, is a benign and self-limited side effect. This dose-dependent, non-immune-mediated type of thrombocytopenia rarely causes severe reductions in the platelet count or clinical complications and usually does not require discontinuation of heparin. In contrast, the rarer, immune form of heparin-induced thrombocytopenia (HIT) can, paradoxically, cause serious, limb- and life-threatening arterial as well as venous thrombosis. The mechanism in these cases is the interaction of antibody (usually IgG) with a complex of heparin and platelet factor 4 (PF4) on the surfaces of platelets from which PF4 is released upon activation.[97] [98] This complex results in the activation of platelets through their FcgammaIIa receptors and their intravascular aggregation, which may cause apparently paradoxical thrombosis in the presence of thrombocytopenia. In HIT, the platelet count decreases, often precipitously, characteristically 5 to 10 days after starting heparin.

Figure 62-13 (Figure Not Available) Mechanism of heparin action. (Modified from Rosenberg RD: Hemorrhagic disorders: I. Protein interactions in the clotting mechanism. *In* Beck WS [ed]: Hematology. 5th ed. Cambridge, MIT Press, 1991, pp 507-542.)

The decline in platelet count in HIT is usually moderate, with a typical nadir of 50,000 to 60,000/mm[3] . However, HIT can cause severe thrombocytopenia even in the absence of thrombosis; and, conversely, heparin-induced thrombosis can actually occur with a normal platelet count. Immune-mediated HIT is not heparin dose dependent and can develop with low-dose heparin or even with heparin flushes or the use of heparin-bonded catheters. There is no single, definitive laboratory test to ascertain the diagnosis of HIT. Laboratory testing for HIT can involve functional assays in which the heparin-induced activation of platelets in vitro is tested by aggregation, serotonin release, or platelet activation markers.[98] Alternatively, enzyme immunoassays of antibody-heparin-PF4 complexes can be used to test for HIT.[99]

When HIT is suspected, any source or route of heparin being administered to the patient must be discontinued immediately. Because many such patients need continued anticoagulation for the underlying problem that required heparin, alternative treatment may include danaparoid, a mixture of low-molecular-weight anticoagulant glycosaminoglycans with relatively weak cross-reactivity with HIT sera,[100] or a direct thrombin inhibitor such as hirudin[101] or argatroban, a small-molecule synthetic antithrombin.[102] Low-molecular-weight heparins (LMWH) should not be substituted for heparin because they have stronger cross-reactivity with HIT sera.[98] [103]

Other side effects of heparin include cumulative dose-dependent osteoporosis, skin necrosis, alopecia, hypersensitivity reactions, and hypoaldosteronism.[92] Heparin is the anticoagulant of choice during pregnancy; unlike warfarin, it does not cross the placenta and is not teratogenic.

Low-Molecular-Weight Heparins

Low-molecular-weight heparins are manufactured from standard, unfractionated heparin by chemical or enzymatic depolymerization that yields fragments about one-third the size of unfractionated heparin.[104] [105] [106] An important mechanism of action of LMWH that presumably provides them with therapeutic and safety advantages over unfractionated heparin is their ability to inhibit and neutralize factor Xa relatively selectively. Inhibition of thrombin requires that heparin bind to both AT and thrombin, thereby forming a ternary complex (Fig. 62-14) .[104] Ternary complex formation requires that heparin contain at least 18 saccharide residues, including the high-affinity pentasaccharide sequence that binds to AT. In contrast, inhibition of factor Xa requires that heparin bind only to AT; hence, only the pentasaccharide sequence of heparin is needed for this simpler reaction. Most heparin chains in LMWH preparations have less than 18 saccharide units and therefore are of insufficient length to bind to both AT and thrombin. However, the shorter heparin fragments in LMWH are able to catalyze the inhibition of factor Xa by AT, provided that they contain the essential pentasaccharide sequence. Thus, the effects of LMWH in the coagulation cascade are restricted to relatively selective inactivation of factor Xa, while standard (unfractionated) heparin has equivalent inhibitory activity against factor Xa and thrombin.

LMWH has been considered theoretically superior to standard heparin in several additional ways.[106] [106A] First, unlike unfractionated heparin, it can inhibit platelet-bound factor Xa and therefore should be a more effective anticoagulant. Second, LMWH binds less readily to plasma proteins (including acute phase reactants)

and vascular and blood cells, and LMWH is more resistant to neutralization by platelet factor 4; this produces a longer plasma half-life, more predictable bioavailability, and more favorable pharmacokinetics than standard heparin. Third, LMWH has less pronounced effects on platelet function and vascular integrity, properties that presumably contribute to its lower risk of bleeding complications than standard heparin. The longer plasma half-life and more predictable anticoagulant response of LMWH preparations allow their administration as fixed-dose, once-daily or twice-daily subcutaneous injections, without need for laboratory monitoring. The convenience of use of LMWH has been extended to outpatient management of patients with uncomplicated acute venous thromboembolism, a situation that previously required continuous intravenous heparin infusion in the hospital.[105] Although several LMWH preparations have been approved for use in North America and Europe, they are prepared by different depolymerization methods and have somewhat different molecular compositions, pharmacological properties, and anticoagulant profiles.[107] Therefore, caution should be exercised in the interchangeability of these LMWH products.

Many (though not all) studies have shown that LMWH

Figure 62-14 Mechanisms of inhibitory action of unfractionated heparin (heparin) and low-molecular-weight heparin (LMWH) on thrombin and factor Xa. Both unfractionated heparin and LMWH bind to antithrombin (AT) through a high-affinity pentasaccharide sequence (5) that both types of heparin contain. Inhibition of thrombin *(left side of figure)* requires formation of a ternary complex of heparin with both antithrombin (AT) and thrombin. Unfractionated heparins have sufficient length (
18 saccharide residues, including the pentasaccharide sequence) to accomplish this, but LMWHs do not. In contrast, inhibition of factor Xa *(right side of figure)* requires that heparin bind only to AT, which unfractionated heparin and LMWH can catalyze equally effectively through their common pentasaccharide sequences. Thus, LMWH (but not unfractionated heparin) inactivates factor Xa selectively relative to thrombin.

Figure 62-15 Activation and inhibitors of coagulation. New anticoagulants act by inhibiting the tissue factor pathway (initiation), thrombin generation, and thrombin activity. (Modified from Hirsh J, Weitz JI: New antithrombotic agents. Lancet 353:1431-1436, 1999.)

are associated with a lower incidence of major bleeding complications than standard, unfractionated heparin. Furthermore, the frequency of immune-mediated HIT is much lower with LMWH.[108] Osteoporosis also occurs less often with long-term administration of LMWH than with standard heparin.[109]

OTHER GLYCOSAMINOGLYCAN-DERIVED DRUGS (NEW HEPARINS)

Heparan sulfate, dermatan sulfate, and proteoglycans are endogenous heparin-like molecules with antithrombotic activity.[110] Several of these endogenous glycosaminoglycans have been developed as clinical anticoagulants.[111] , [112]

Danaparoid (Orgaran, formerly ORG 10172) is a mixture of low-molecular-weight anticoagulant glycosaminoglycans, predominantly heparan sulfate (84 percent) and dermatan sulfate (12 percent).[98] , [113] It preferentially inhibits factor Xa and has a lesser degree of antithrombin activity. Bioavailability of danaparoid is essentially 100 percent by subcutaneous dosing, and twice-daily administration is required when using this route. Rapid full anticoagulation is better achieved by an initial intravenous bolus.[114] Danaparoid is a weak anticoagulant as measured by the prothrombin time (PT) and aPTT tests. Therefore, laboratory monitoring of danaparoid can only be performed using anti-factor Xa levels. However, in view of the predictable dose-dependent anticoagulant response to danaparoid, laboratory monitoring is not required in most patients. Because danaparoid is excreted largely unchanged into the urine, dose reduction and laboratory monitoring are required in patients with renal failure. A disadvantage of danaparoid is the inability of protamine sulfate to neutralize its activity.

Dermatan sulfate, a naturally occurring glycosaminoglycan, catalyzes the inactivation of thrombin by heparin cofactor II. Like direct thrombin inhibitors (see later), and unlike standard and low-molecular-weight heparins, dermatan sulfate can inactivate fibrin-bound thrombin.[115]

Pentasaccharide, representing the high-affinity heparin binding site for antithrombin, and its synthetic analogs (SR90107A/ORG31540, SANORG 32701) selectively catalyze the inactivation of factor Xa by antithrombin without inhibiting thrombin (Fig. 62-15) .[116] Definitive clinical trials will be required to demonstrate the superiority of these and other heparin mimetics obtained by chemical synthesis.[117]

Warfarin

Warfarin (Coumadin) is the most frequently used oral anticoagulant.[118] Oral anticoagulants, which are derivatives of coumarins, exert their anticoagulant actions as vitamin K antagonists. As shown in Figure 62-16 , [119] the reduced form of vitamin K, vitamin KH_2 , is normally required as a cofactor for the gamma-carboxylation of glutamic acid residues in coagulation factors II (prothrombin), VII, IX, and X. This posttranslational modification of these clotting factors is necessary for them to function physiologically in the coagulation cascade by allowing them to bind to and form calcium-dependent complexes on cellular phospholipid surfaces. Oral anticoagulants block the reductase enzymes that are required to recycle vitamin K epoxide to vitamin KH_2 after the gamma-carboxylation reaction, thereby depleting the active vitamin K cofactor.

Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract and circulates bound to albumin with a mean plasma half-life of approximately 40 hours.[104] [120] Numerous drugs alter the anticoagulant response to warfarin by pharmacokinetic or pharmacodynamic interactions. Drugs such as phenylbutazone, erythromycin, fluconazole, cimetidine, amiodarone, clofibrate, isoniazid, and propranolol increase warfarin levels, whereas drugs such as cholestyramine, barbiturates, rifampin, and sucralfate decrease warfarin levels. Dietary variations in vitamin K likewise alter warfarin's anticoagulant effects; high vitamin K intake in the diet (including nutritional supplements and vitamin preparations) reduces the anticoagulant response to warfarin. Conversely, liver disease, malabsorption, and hypermetabolic states enhance the anticoagulant effect of warfarin.

MONITORING.

Oral anticoagulant therapy requires laboratory monitoring with the PT test. Commercially available thromboplastin reagents that are used in the PT assay vary considerably in their clotting ability. This problem previously created major variability in the PT values reported by different laboratories. To standardize PT reporting, the international normalized ratio (INR) is now used. The INR corrects for differences in the thromboplastin reagents used by different laboratories. The optimal therapeutic range of warfarin dose for the prevention of venous thromboembolism and for the prevention of systemic embolism from atrial fibrillation and tissue heart valves targets an INR of 2.0 to 3.0. Higher intensity anticoagulation (INR 2.5 to 3.5) is required in patients with mechanical prosthetic heart valves.

Figure 62-16 Vitamin K cycle and its inhibition by warfarin. Warfarin inhibits vitamin K epoxide reductase and vitamin K quinone reductase and so blocks the conversion of vitamin K epoxide to vitamin KH_2 . Vitamin KH_2 is a cofactor for the carboxylation of inactive proenzymes (factors II, VII, IX, and X) to their active forms. (From Furie B, Furie BC: Molecular basis of vitamin K-dependent gamma-carboxylation. Blood 75:1753-1762, 1990.)

"Loading doses" of warfarin should not be employed in initiating oral anticoagulation. Although warfarin has a rapid onset of action, its optimal antithrombotic effect requires several days. The activity of all four of the vitamin K-dependent clotting factors must be inhibited to achieve clinically effective anticoagulation. The effects of warfarin require depletion of circulating clotting factors that are already gamma-carboxylated and hence biologically active when warfarin is started. The vitamin K-dependent clotting factors have different half-lives, with factor VII having the shortest. Therefore, the initial increase in the INR is predominantly due to a decrease in functional factor VII. A large "loading dose" of warfarin (i.e., 10 mg or more per day) will thus create a selective, severe factor VII deficiency state, with its attendant bleeding risk, while still failing to provide antithrombotic effect. In addition, a precipitous reduction in the plasma level of protein C, a vitamin K-dependent anticoagulant (rather than clotting) factor, which has the shortest half-life of all vitamin K-dependent proteins, can lead to a transient paradoxical hypercoagulable state during the first 36 hours of warfarin therapy (see later).[121] [122] Therefore, the initial dose of warfarin should approximate the chronic maintenance dose that is anticipated, generally in the range of 4 to 6 mg/d in most adults.[120]

COMPLICATIONS.

Skin necrosis is a very rare complication that occurs within the first few days of starting warfarin therapy and tends to occur in patients with underlying inherited protein C or protein S deficiency. As noted earlier, it is likely to be related to the initial precipitous decrease in protein C levels (especially in individuals who may already have a congenitally low level of protein C). This leads to a transient prothrombotic imbalance, particularly with the use of large loading doses of warfarin. Warfarin should be avoided in pregnancy because of its potential to cause embryopathy and peripartum neonatal and maternal bleeding complications.

As with heparin, bleeding complications are the most frequent adverse effects of warfarin. For an individual patient, the cumulative risk of bleeding complications is directly related to the intensity and duration of anticoagulant therapy.[123] Major bleeding on warfarin occurs at a rate of 5 to 7 percent per year.[124] As noted earlier, the INR can vary despite a stable, chronic dose of warfarin as a function of changes in other medications or diet. When the INR exceeds the therapeutic range, discontinuing or reducing the dose of warfarin is usually sufficient; stopping warfarin generally normalizes the INR within about 3 days. If more rapid reversal of warfarin effect is required because of extreme elevations of the INR or clinical bleeding, vitamin K can be administered orally or parenterally. However, particularly when vitamin K is given at higher doses, a transient resistance to re-anticoagulation with warfarin may be encountered subsequently. Emergency reversal of warfarin effect can be rapidly achieved by infusion of fresh frozen plasma (usually starting with 2 to 4 units). Algorithms for the management of elevated INR with or without bleeding have been proposed.[120] [125]

Thrombin Inhibitors and Other Specific Coagulation Inhibitors

New anticoagulants have been developed that specifically target inactivation of thrombin, factor Xa, factor IXa, and the factor VIIa/tissue factor complex, as well as inactivation of factors VIIIa and Va by enhancement of the protein C anticoagulant pathway.[116] The sites of action of these anticoagulants are shown in Figure 62-15. Except for the direct thrombin inhibitors, most of these agents have yet to be evaluated in phase 3 trials.

THROMBIN INHIBITORS

Direct thrombin inhibitors inactivate both free (fluid-phase) thrombin and fibrin-bound thrombin. In this respect, these agents differ from heparin and its low-molecular-weight derivatives, which require complex formation with antithrombin III and are thus weak inhibitors of clot-bound thrombin.[126] [127] [128] The thrombin molecule has distinct functional domains. The "active site" of thrombin is the catalytic site that possesses serine protease activity. "Exosite 1" of thrombin serves to dock substrates in the proper orientation and is the binding site for fibrin(ogen).[129] Direct thrombin inhibitors interact with one or both of these sites. Hirudin and bivalirudin are more specific for thrombin than active-site inhibitors because they are bivalent, binding to thrombin at both the active site and exosite 1. In contrast, low-molecular-weight thrombin inhibitors such as argatroban and efegatran bind to only the active site of thrombin. Because the active site of thrombin is structurally similar to other serine proteases, these active-site inhibitors are less selective for thrombin than the bivalent inhibitors.[116] [128]

Hirudin (desirudin) is the prototype of the direct thrombin inhibitors. It is a 65-amino acid polypeptide that was originally isolated from the saliva of *Hirudo medicinalis*, the medicinal leech. Hirudin is now produced by recombinant DNA technology. It binds tightly to thrombin, forming a slowly reversible, 1:1 stoichiometric complex. In this complex, the amino-terminal of hirudin binds to the active site and its carboxy-terminal binds to exosite 1 of thrombin.

Bivalirudin (formerly Hirulog) is a synthetic 20-amino acid polypeptide. It is composed of a peptide sequence (D-Phe-Pro-Arg-Pro) that is directed at the active site of thrombin, linked to a dodecapeptide analog of the exosite 1-binding carboxy-terminal of hirudin.[130] Thus, like hirudin, bivalirudin interacts bivalently with both the active site and exosite 1 of thrombin, forming a 1:1 stoichiometric complex. However, once bound, thrombin cleaves the Arg-Pro bond and thereby removes the active site binding part of bivalirudin, leaving only a low-affinity, weaker inhibitory interaction with thrombin. Consequently, the potent thrombin inhibitory effect of bivalirudin is short lived, conferring on it a potential safety advantage.

Hirudin, bivalirudin, and other direct thrombin inhibitors have theoretical advantages over heparin. First, as noted earlier, they can inactivate clot-bound thrombin. Second, unlike heparin, they do not bind to plasma proteins. Therefore, they have the pharmacokinetic advantage of a more predictable anticoagulant response. This should permit their administration without laboratory monitoring. However, the narrow therapeutic window for hirudin makes its monitoring necessary and may prove to be a significant limitation. In clinical trials of hirudin, used in conjunction with thrombolytic therapy in patients with acute myocardial infarction, concentrations of hirudin were selected that produced a prolongation of the aPTT similar to that achieved with heparin. The excessive bleeding observed with hirudin in these trials suggests that hirudin causes more bleeding than heparin when these agents are used in doses that prolong the aPTT to the same extent,[131] and it points out the potential pitfalls of extrapolating from the experience of heparin when choosing a laboratory test to monitor a new antithrombotic agent.[126] The better benefit-to-risk profile of bivalirudin appears to permit its administration in weight-adjusted doses without laboratory monitoring.[130]

Several low-molecular-weight direct thrombin inhibitors have been developed. These less-specific agents target only the active site of thrombin. Argatroban is the prototype of the noncovalent class of these active site inhibitors, which also includes napsagatran, inogatran, and melagatran. Efegatran and boroarginine derivatives are reversible-covalent active site inhibitors of thrombin. They serve as pseudosubstrates for thrombin, which are cleaved by thrombin to form a covalent enzyme-inhibitor adduct.[130]

OTHER SPECIFIC COAGULATION INHIBITORS

Inhibitors of factor Xa (see Fig. 62-15) [128] [132] include tick anticoagulant peptide (TAP) and antistatin. Both are potent and specific factor Xa inhibitors that are available in recombinant forms. DX-9065[133] is a synthetic, low-molecular-weight, reversible factor Xa inhibitor that has oral bioavailability. Experimental agents that are inhibitors of factor IXa include a monoclonal antibody and an active site-blocked factor IXa.[134] Specific inhibitors of the tissue factor pathway under study include a soluble mutant form of tissue factor that has decreased cofactor function for factor VIIa-induced activation of factor X[135] ; active-site-blocked factor VIIa (VIIai), which competes with factor VII for tissue factor binding; NAPc2, a small, nematode-derived anticoagulant protein that binds to factor X and inhibits factor VIIa within the factor VII/tissue factor complex[136] ; and recombinant TFPI.[137] Protein C activators that have been studied as therapeutic anticoagulants include plasma and recombinant forms of protein C and recombinant soluble thrombomodulin.[116]

Thrombolytic (Fibrinolytic) Drugs

The fibrinolytic system has been described previously and is illustrated in Figure 62-7 (see p. 2104). The common mechanism of action of currently available thrombolytic (fibrinolytic) agents, including streptokinase, urokinase, alteplase (recombinant tissue-type plasminogen activator [rt-PA]), and anistreplase (anisoylated plasminogen streptokinase activator complex [APSAC]), involves the conversion of the inactive plasma zymogen, plasminogen, to the active fibrinolytic enzyme, plasmin.[138] Plasmin has relatively weak substrate specificity and can degrade not only fibrin but any protein that has an arginyl-lysyl bond available for enzymatic attack, including fibrinogen. Because indiscriminate plasmin lysis of both fibrin and fibrinogen can produce a systemic state of fibrin(ogen)olysis (or "systemic lytic state"), which might cause a serious systemic bleeding tendency, attempts have been made to develop thrombolytic agents that generate plasmin preferentially at the fibrin surface in a preformed thrombus ("fibrin specific agents"). Plasmin associated with fibrin is protected from rapid inhibition by $alpha_2$ -antiplasmin (see earlier) and can thereby effectively degrade the fibrin of a clot.[139] Thus, the biochemical strategy was to develop fibrinolytic agents that bind to fibrin and thereby produce only fibrin-bound plasmin from fibrin-bound plasminogen.

Streptokinase and urokinase induce a systemic lytic state, with extensive systemic activation of the fibrinolytic system, deplete $alpha_2$ -antiplasmin, and degrade circulating fibrinogen. In contrast, the physiological plasminogen activators t-PA and scu-PA, as well as staphylokinase, activate plasminogen preferentially at the fibrin surface.[140] The promise of a marked reduction in the risk of hemorrhage with "second generation" fibrin-specific agents has not been fulfilled in large clinical trials, however. This may be due to the inability of plasmin to discriminate between fibrin in pathological thrombi, which is the desired target, and fibrin in physiological hemostatic plugs, the lysis of which will induce bleeding.

Streptokinase

Streptokinase is isolated from hemolytic streptococci and is produced from bacterial cultures. The mechanism of activation of plasminogen by streptokinase is unique among plasminogen activators in that streptokinase itself possesses no enzymatic activity.[141] Streptokinase forms a complex with plasminogen, and it is the streptokinase-plasminogen complex that actually possesses enzymatic activity toward plasminogen. The streptokinase-plasminogen complexes are thereby converted to streptokinase-plasmin complexes, and the enzyme active sites in the streptokinase-plasmin complexes are the same as those in plasmin. The

streptokinase-plasmin(ogen) complexes activate circulating and fibrin-bound plasminogen relatively indiscriminately, producing a systemic lytic state.

Because of its bacterial source, streptokinase is antigenic. Most individuals have preexisting antibodies resulting from previous streptococcal infection. The administration of streptokinase stimulates the rapid formation of high titers of neutralizing antistreptokinase antibodies, which are sufficient to neutralize standard doses of streptokinase. Although antibody titers may return to near-baseline levels as early as 2 years after a single dose,[142] once streptokinase has been used then subsequent thrombolytic treatment should be with an immunologically unrelated agent because of the uncertain efficacy of repeated treatment.[140] Streptokinase causes transient hypotension in many patients and significant allergic reactions in some, including a serum sickness-type syndrome, fever, rash, and bronchospasm.[143]

Anisoylated Plasminogen/Streptokinase Activator Complex

Although the streptokinase/plasmin complex possesses high plasmin-generating efficiency, it is rapidly inactivated in

plasma by protease inhibitors. This limitation led to the synthesis of anisoylated plasminogen-streptokinase activator complex (APSAC; anistreplase), in which streptokinase is noncovalently associated with plasminogen and the enzyme active site of plasminogen is protected by the covalent addition of a *p*-anisoyl group. APSAC retains the fibrin-binding properties of the streptokinase-plasminogen complex, but it is enzymatically inert. Therefore, when injected intravenously, APSAC circulates to the site of fibrin deposition. APSAC cannot be inactivated by plasma $alpha_2$ -antiplasmin because its enzyme active site is inaccessible. Deacylation of fibrin-bound APSAC then uncovers the catalytic center, which converts plasminogen to plasmin. APSAC thereby permits fibrin-targeted thrombolysis.

Compared with streptokinase, APSAC has greater stability in plasma (fibrinolytic half-life of 12 to 18 minutes vs. 40 to 60 minutes), and can be administered rapidly as a single intravenous bolus without hypotension. Like streptokinase, the bacterial origin of APSAC causes immunological complications. Some individuals with preexisting antistreptococcal antibodies demonstrate a blunted fibrinolytic response to APSAC, and high titers of neutralizing antibodies following a single treatment persist for months.[144] As with streptokinase, APSAC can also cause allergic reactions in a small percentage of patients.

Urokinase

Urokinase, or two-chain urokinase-type plasminogen activator (tcu-PA), is a trypsin-like serine protease composed of two polypeptide chains with molecular masses of 20 and 34 kDa, respectively, linked by a disulfide bridge. Urokinase is produced from cultures of human fetal kidney cells. It directly activates plasminogen to plasmin, leading to relatively nonspecific degradation of fibrin, fibrinogen and other plasma proteins, depletion of circulating $alpha_2$ -antiplasmin, and a systemic lytic state. Urokinase is not antigenic and does not cause allergic reactions.[138]

Single-Chain Urokinase-Type Plasminogen Activator

Single-chain urokinase-type plasminogen activator (scu-PA; prourokinase) is a naturally occurring 54 kDa protein that is the zymogenic precursor of urokinase; scu-PA is converted to proteolytically active urokinase (two-chain u-PA) by means of limited hydrolysis by plasmin and kallikrein. In plasma, scu-PA is mostly inactive. Although scu-PA does not directly bind to fibrin, it induces plasminogen activation in the presence of fibrin, leading to relative fibrin-specific plasminogen activation. Urokinase-type plasminogen activator receptors (u-PAR) on endothelial cells and leukocytes may also modulate scu-PA fibrinolytic activity. Plasmin generation is enhanced by binding of scu-PA to u-PAR.[141] [145]

Tissue-Type Plasminogen Activator

Tissue-type plasminogen activator (t-PA) is a naturally occurring molecule released from vascular endothelial cells. For therapeutic thrombolysis, it is produced commercially by recombinant DNA technology (rt-PA; alteplase) and, as a "second-generation" agent, it is relatively fibrin specific.

t-PA is a single-chain serine protease composed of 527 amino acids with a molecular mass of 68 kDa. It activates plasminogen directly and follows Michaelis-Menten kinetics.[141] The efficiency of plasminogen activation by t-PA is significantly enhanced in the presence of fibrin. The basis for the relative fibrin specificity of t-PA action is described previously in the section on the fibrinolytic system. Briefly, fibrin provides a surface for the sequential binding of enzyme (t-PA) and substrate (plasminogen). The assembly of this ternary complex thereby promotes the activation of plasminogen to plasmin that is efficiently localized to the fibrin clot; fibrin then becomes the substrate for lysis by the plasmin that is generated on its surface.

t-PA is converted by plasmin to a disulfide-linked two-chain form by hydrolysis of the Arg 275--Ile276 bond; alteplase consists mainly of the single-chain form of t-PA. Both the single-chain and two-chain forms of t-PA are cleared from plasma according to a two-compartment model, with initial half-lives of 3 to 6 minutes and terminal half-lives of 40 to 50 minutes. The currently preferred dosage regimen of fibrin-selective alteplase for coronary thrombolysis consists of weight-adjusted, accelerated ("front-loaded") administration. The front-loaded administration of alteplase achieves a mean steady-state plasma concentration during the initial 30 minutes that is 45 percent higher than that achieved with standard infusion, although it does not alter the plasma half-life.[141] [146]

VARIANTS, CHIMERAS, AND CONJUGATES OF PLASMINOGEN ACTIVATORS

These thrombolytic agents have been engineered to favorably alter the pharmacokinetic and functional properties of currently used drugs. They are designed to have prolonged half-lives, improved enzymatic efficiency, enhanced local concentrations in the clot by altered binding to fibrin and stimulation by fibrin, and resistance to plasma protease inhibitors.[140] [141] [147] Several of these agents have begun to undergo clinical trial.[148]

Reteplase (r-PA) is a single-chain nonglycosylated deletion variant of t-PA, containing only the kringle-2 and serine protease domains. This deletion mutant has a prolonged half-life and, therefore, can be administered by bolus injection.[149] A mutant of rt-PA, TNK-rt-PA, contains amino acid substitutions at three sites: threonine (T) at position 103 is replaced by asparagine; asparagine (N) at position 117 is replaced by glutamine; and four amino acids, lysine (K), histidine, arginine, and arginine, are replaced by alanine-alanine-alanine-alanine at positions 296 through 299. TNK-rt-PA is characterized by a prolonged half-life, improved fibrin specificity, and increased resistance to inhibition by PAI-1.[150] Another third-generation agent that is a modification of wild-type t-PA is lanoteplase (n-PA), which has an even longer half-life than TNK-rt-PA and can be administered by single-bolus, weight-adjusted injection.[151] Prolonged half-lives have also been obtained by substitution or deletion of one or more selected amino acids in the finger or epidermal growth factor domains of t-PA.[140] [147] One of these t-PA variants is E6010, in which Cys is replaced by Ser at position 84; it possesses a half-life of 23 minutes or more after a single intravenous bolus. The t-PA of saliva from the vampire bat *Desmodus rotundus* (bat-PA) has potent and relatively fibrin-specific thrombolytic properties.[152] [153] Different molecular forms of bat-PA have been purified, characterized, cloned, and expressed.

Antibody targeting of thrombolytic agents is a potentially powerful approach to localizing the actions of these drugs to specific components of different types of thrombi (e.g., directed at platelet antigens in arterial thrombi, or thrombin in recently formed thrombi). This can be achieved by conjugating plasminogen activators with monoclonal antibodies that are specific, for example, for fibrin but do not cross react with fibrinogen.[154] These bifunctional molecules are engineered to contain both a highly specific antigen-binding site that concentrates the drug at the clot and an effector site that promotes thrombolysis.

STAPHYLOKINASE

Staphylokinase [155] [156] [157] is isolated from *Staphylococcus* species. Like streptokinase, it forms a 1:1 stoichiometric complex with plasminogen. Unlike the streptokinase-plasminogen complex, however, the staphylokinase-plasminogen complex is enzymatically inactive; it must be converted to staphylokinase-plasmin to become a potent plasminogen activator. Also unlike streptokinase-plasmin(ogen), the staphylokinase-plasmin complex is rapidly neutralized in the circulation by $alpha_2$ -antiplasmin. After inhibition by $alpha_2$ -antiplasmin, staphylokinase is released from the complex and is recycled to bind other plasminogen molecules. The relative fibrin selectivity of staphylokinase resides in the ability of fibrin to largely (> 100-fold) protect it from inhibition by $alpha_2$ -antiplasmin. As a bacterial plasminogen activator, staphylokinase is an antigenic thrombolytic agent that induces antibody formation and resistance to repeated administration.

Antiplatelet Agents

The sequence of events involved in the process of platelet activation is described in detail in the previous section on platelets and is summarized in Figures 62-8 (p.

2105) and 62-17 . Inhibition of platelet function can be targeted at any

Figure 62-17 Sequence of events in platelet activation, with potential targets for antiplatelet therapy. *A,* Platelet adhesion to the injured vascular intimal surface is mediated by von Willebrand factor (vWF) binding to its receptor on platelet membrane Gp Ib. *B,* Adherent platelets are also anchored to the damaged vessel wall by binding of subendothelial collagen (COL) to its platelet surface COL receptors. Other platelet stimuli in blood, including thrombin (THR) and epinephrine (EPI), bind to their respective receptors. *C,* In response to these different stimuli, adherent platelets are activated and release thromboxane A_2 (TXA_2) and adenosine diphosphate (ADP), which bind to their own respective platelet receptors and amplify the activation process. AA=arachidonic acid; PGG_2 and PGH_2 =labile prostaglandin endoperoxides. *D,* Platelet aggregation is mediated by fibrinogen (FIB) binding to its receptors on adjoining platelets, forming fibrinogen bridges. The FIB receptor is formed by the complexing of Gp IIb/IIIa in the membrane of activated platelets. (Modified from Schafer AI: Antiplatelet therapy with glycoprotein IIb/IIIa receptor inhibitors and other novel agents. Tex Heart Inst J 24:90-96, 1997.)

one of these activation steps. Platelet blockade would be expected to be most effective if it is directed at either the initial (adhesion) (see Fig. 62-17 *A*) or final (aggregation) (see Fig. 62-17 *D*) points in the sequence. Antiplatelet agents targeted at any one of the intermediate events should be less potent, because platelet adhesion is followed by the binding of several specific agonists to their respective receptors and the activation of several simultaneous intracellular pathways (e.g., ADP release, TXA_2 synthesis) that act in concert to induce the final step of platelet aggregation. Therefore, pharmacological interruption of only one of these intermediate steps (e.g., with aspirin, antithrombins, ticlopidine, clopidogrel) may permit platelet activation through alternative, uninhibited pathways. Agents that block the interaction of vWF with its platelet membrane Gp Ib receptor should inhibit adhesion (see Fig. 62-17 *A*) as well as the subsequent downstream cascade of platelet activation events, including secretion of mitogens into the vessel wall and platelet aggregation.[158] Therapeutic approaches to inhibit adhesion could involve anti-vWF or anti-Gp Ib monoclonal antibodies or agents that interfere with vWF-platelet Gp-Ib binding. These strategies have yet to be translated to clinical practice, however. In contrast, considerable clinical evidence has now validated various powerful therapeutic strategies to block the final step of platelet aggregation that is mediated by the interaction of fibrinogen (or vWF) with its platelet Gp IIb/IIIa receptors (see Fig. 62-17 *D*).

Aspirin

Aspirin (acetylsalicylic acid), which has been used medicinally since antiquity and has been demonstrated to have antithrombotic efficacy for almost 50 years, has stood the test of time as an effective, inexpensive, and relatively safe drug for the prevention of various thrombotic and vascular disorders, particularly in the arterial circulation where platelets are the predominant participants in the thrombotic process.[159] [159A] Until recently, aspirin has been essentially the only available, clinically effective antiplatelet drug. However, there are several clinical settings in which aspirin

Figure 62-18 Aspirin (acetylsalicylic acid) inhibition of cyclooxygenase (prostaglandin-G/H synthase). Aspirin acetylates serine at position 529 of cyclooxygenase, rendering the enzyme inactive. Acetylated cyclooxygenase does not function to catalyze the oxygenation of arachidonic acid to prostaglandin G_2 . Aspirin thereby blocks the formation of thromboxane A_2 (in platelets) and prostacyclin (in vascular cells). (From Loscalzo J, Schafer AI: Anticoagulants, antiplatelet agents, and fibrinolytics. *In* Loscalzo J, Creager MA, Dzau MV [eds]: Vascular Medicine: A Textbook of Vascular Biology and Diseases. Philadelphia: Lippincott Williams & Wilkins, 1996.)

fails to provide full (or even partial) antithrombotic benefit.[160]

Aspirin is readily absorbed from the stomach and upper small intestine and is then hydrolyzed to release free acetyl groups. As shown in Figure 62-18, this moiety acetylate serine residues at position 529 of cyclooxygenase (COX; prostaglandin G/H synthase), which leads to irreversible inactivation of the enzyme.[161] [162] Inactive, acetylated COX is unable to function to catalyze the oxygenation of arachidonic acid to prostaglandin G_2 . Aspirin thereby blocks the formation of TXA_2 , a potent mediator of platelet aggregation and vasoconstrictor. Because anucleate platelets are essentially unable to synthesize new, unacetylated COX, aspirin blocks the function of platelets exposed to it for their remaining lifetime (normally 7 to 10 days) in the circulation. This accounts for the lengthy therapeutic effect of aspirin despite its plasma half-life of only 20 minutes.

The inhibitory effects of aspirin on platelet TXA_2 production and ex vivo aggregation are rapid, with maximal effects achieved within 15 to 30 minutes of oral administration of a dose as low as 81 mg.[163] A single oral dose of 100 mg of aspirin almost completely suppresses platelet TXA_2 synthesis in both normal individuals and in patients with cardiovascular disease. Daily administration of only 30 to 50 mg of aspirin exerts a cumulative effect and likewise results in almost complete inhibition of platelet TXA_2 production within 7 to 10 days.[159] These aspirin effects on platelet TXA_2 formation generally correlate well with inhibition of ex vivo platelet aggregability and prolongation of the skin bleeding time. Although platelet function remains impaired for 4 to 7 days after a single dose of aspirin, reflecting the life span of irreversibly inhibited platelets, the prolonged bleeding time generally returns to normal within 24 to 48 hours of aspirin ingestion: This discrepancy is due to the release from bone marrow into the circulation of a sufficient cohort of uninhibited platelets after the elimination of aspirin from blood to restore normal in vivo hemostasis (bleeding time) even before complete normalization of ex vivo platelet function.

Aspirin also inhibits COX in vascular endothelial cells, leading to suppression of platelet inhibitory and vasodilatory endothelium-derived PGI_2 ; this would be expected to offset the antiplatelet effects of aspirin. Attempts to design "platelet selective" aspirin regimens have not translated to clinical feasibility. Nevertheless, there is ample evidence that the antithrombotic effects of aspirin predominate in vivo, possibly due to mechanisms in addition to platelet TXA_2 inhibition.[161]

NON-ASPIRIN NONSTEROIDAL ANTIINFLAMMATORY DRUGS (NSAIDS)

Non-aspirin NSAIDs likewise inhibit COX. Unlike aspirin, however, these other NSAIDs are reversible inhibitors of the enzyme; and, therefore, their durations of TXA_2 and platelet inhibitory action are dependent on the clearance of the drugs from the circulation.[164] Thus, there is considerable variability in the extent and duration of the effects of various NSAIDs on ex vivo platelet aggregation and bleeding time prolongation.[164] Non-aspirin NSAIDs reversibly inhibit COX by preventing its arachidonic acid substrate from gaining access to the active site of the enzyme.[165] Interaction of NSAIDs with COX may prevent acetylation of the enzyme by aspirin. This suggests that the concomitant administration of non-aspirin NSAIDs may actually antagonize the

effects of aspirin on COX by competitive interaction, and consequently blunt aspirin's antiplatelet efficacy.[166]

The constitutive isoform of COX, COX-1, is the one that is present in platelets and produces TXA_2 . Aspirin and the traditional NSAIDs are nonselective inhibitors of both COX-1 and COX-2. The newer COX-2-specific inhibitors are designed to maximize the antiinflammatory effects that are mediated by the COX-2 isoform, while minimizing the common side effects (e.g., bleeding) that are attributed to the COX-1 isoform. Therefore, the antiplatelet potency of the new COX-2 inhibitors is several orders of magnitude lower than that of aspirin and the standard NSAIDs[167] [168] and generally cannot be assumed to afford antithrombotic protection.[169]

OTHER THROMBOXANE INHIBITORS

Figure 62-17 *C* illustrates other opportunities to interrupt platelet TXA_2 synthesis and/or action in addition to COX blockade. The reduced incidence of atherosclerotic cardiovascular disease in Greenland Eskimos has been attributed, at least in part, to their diets rich in fish oils containing omega-3 polyunsaturated fatty acids. A major omega-3 fatty acid in fish oils is eicosapentaenoic acid (EPA), which incorporates into cell membrane phospholipids and competes with arachidonic acid as substrate for COX. The product of EPA oxygenation is TXA_3 , an eicosanoid that is devoid of the potent platelet activating and vasoconstrictor actions of arachidonic acid-derived TXA_2 . Large and often unpalatable doses (> 10 gm EPA daily) of medicinal fish oils are required to simulate changes in platelet membrane fatty acid content attained with Eskimo diets and thereby produce antiplatelet actions.[158] Thromboxane synthase inhibitors (e.g., dazoxiben) and TXA_2 receptors antagonists, as well as dual thromboxane synthase/TXA_2 receptor inhibitors (e.g. ridogrel), have been developed but have generally not been found to be superior to aspirin in limited clinical

trials.[158] [170]

Ticlopidine and Clopidogrel

Ticlopidine (Ticlid) and clopidogrel (Plavix) are structurally related thienopyridine derivatives. They produce their antiplatelet effects by inhibiting the ADP-dependent pathway of platelet activation.[171] After oral administration, both drugs apparently require modification to active forms. They exert a permanent effect on a platelet protein(s),[162] which is the ADP receptor itself or a platelet membrane component closely related to the ADP receptor. As ADP receptor blockers, these drugs inhibit ADP-induced platelet aggregation (see Fig. 62-17 *C*).

Presumably because they must be converted to an active form in vivo, ticlopidine and clopidogrel have a relatively slow onset of antiplatelet action, which may make them less than optimal agents in clinical settings where rapid effect is desired (e.g., unstable angina). Full platelet inhibitory effect is achieved only 3 to 5 days after oral administration of ticlopidine, and the bleeding time does not become maximally prolonged until 5 to 6 days after starting treatment. Regimens involving bolus administration of these thienopyridines may accelerate their antiplatelet effects. The effect of ticlopidine on platelets persists for 4 to 8 days after discontinuation of the drug, reflecting the circulating lifetime of platelets and consistent with an irreversible antiplatelet effect.

Severe neutropenia, which is usually reversible with discontinuation of the drug, has been noted in up to 1 percent of patients on ticlopidine. The risk of this adverse effect is much lower (about 0.1 percent) with clopidogrel. (See also Chapter 67.) In addition, thrombotic thrombocytopenic purpura (TTP), a serious and sometimes fatal disorder, is a rare complication of therapy with ticlopidine. TTP typically occurs within 2 to 8 weeks of initiation of ticlopidine[172] and has been noted in 0.02 percent of patients receiving ticlopidine after coronary stenting.[173] [173A] More recently, TTP has also been reported after the initiation of clopidogrel therapy, often within the first two weeks of treatment.[173A] Other side effects, including gastrointestinal symptoms, pruritus, urticaria, and bleeding, also appear to occur less often with clopidogrel than with ticlopidine.[171]

Dipyridamole

The mechanism of antiplatelet action of dipyridamole is unclear. Although this drug has been previously demonstrated to stimulate PGI_2 synthesis, potentiate the platelet inhibitory effects of PGI_2 , raise platelet cyclic AMP levels by inhibiting phosphodiesterase, and block uptake of adenosine into vascular and blood cells, these potential antiplatelet actions generally do not occur at therapeutically achievable drug concentrations.[158] Unlike aspirin, dipyridamole does not prolong the bleeding time or inhibit ex vivo platelet aggregation at therapeutic doses. Although numerous clinical trials have failed to demonstrate antithrombotic efficacy of dipyridamole when it is used alone in any clinical setting, it may enhance the effect of warfarin in preventing systemic embolization from mechanical heart valve prostheses and add to the beneficial effect of aspirin in preventing the progression of peripheral occlusive arterial disease or, when used in a sustained release preparation, in the secondary prevention of ischemic stroke.[174]

Glycoprotein IIb/IIIa Antagonists

Regardless of the stimulus for their activation, the aggregation of platelets is finally regulated through their membrane binding sites for fibrinogen in the Gp IIb/IIIa receptor complex (see Fig. 62-17 *D*). This provides the rationale for pharmacological intervention directed against the platelet Gp IIb/IIIa complex.[175] [176] The role of the platelet Gp IIb/IIIa complex in platelet activation is discussed in more detail earlier in the section on platelets. Because Gp IIb/IIIa antagonists do not block TXA_2 production by activated platelets, [177] concomitant use of aspirin may enhance their antithrombotic efficacy.

Platelet Gp IIb/IIIa antagonists generally belong to one of the following classes: (1) monoclonal antibody against Gp IIb/IIIa; (2) peptide (peptidomimetic) antagonists, many of which contain the RGD sequence that can compete with fibrinogen for its Gp IIb/IIIa binding site; and (3) nonpeptide (nonpeptide-mimetic) antagonists of Gp IIb/IIIa. Three drugs currently available for coronary intervention or acute coronary syndromes represent the prototypes for these groups: Abciximab (c7E3 Fab, ReoPro) is a monoclonal antibody, eptifibatide (Integrilin) is a peptide antagonist, and tirofiban (Aggrastat) is a nonpeptide mimetic. These agents are approved for intravenous administration, but numerous oral Gp IIb/IIIa antagonists are currently under development and in phase II trials for chronic antiplatelet therapy.[175] [178] [179] Although the mechanism of action of these agents (i.e., inhibition of ligand binding to the receptor) is similar, it should not be assumed that they react at the same site within the receptor or that the consequences of their binding to Gp IIb/IIIa are identical.[179] Monoclonal antibody has a relatively extended duration of antiplatelet action, whereas the peptides and nonpeptide mimetics have a shorter elimination half-life.

Abciximab is the Fab fragment of a monoclonal antibody to Gp IIb/IIIa that has been humanized (mouse/human chimera) to reduce immunogenicity.[180] Abciximab is not specific to platelet Gp IIb/IIIa: It cross reacts with the related integrin, $alpha_v$ -$beta_3$, the vitronectin receptor that is present on vascular cells. This cross reactivity was originally considered to be of potential therapeutic benefit in the prevention of coronary restenosis and inhibition of thrombin generation.[181] [182] Abciximab is presently administered as an intravenous bolus followed by infusion for 12 to 24 hours for coronary interventions.[175] Because abciximab is derived from an antibody, concern has been raised about repeat administration. However, initial data indicate that readministration is safe and efficacious and that the same indications for first-time use can apply to subsequent readministration.[183]

Eptifibatide is a synthetic cyclic heptapeptide that contains a modified lysine-glycine-aspartic acid (KGD), rather than RGD, sequence that recognizes the binding site of platelet Gp IIb/IIIa[184] (see Fig. 62-9) . The rationale for eptifibatide is that the substitution of a single lysine (K) for

arginine (R) makes this agent specific for the platelet Gp IIb/IIIa integrin. Whether this is an advantageous or disadvantageous property (see earlier) has yet to be definitely determined. Eptifibatide is administered by bolus intravenous injection followed by infusion for up to 72 hours in acute coronary syndromes.[175] Patients who undergo coronary interventions are usually continued on eptifibatide infusion for 18 to 24 hours after intervention. Eptifibatide is not immunogenic and is safe for repeated administration.[185]

Tirofiban (Aggrastat) is a nonpeptide mimetic. In contrast to the RGD (or KGD) peptidomimetics, which inhibit platelet aggregation by binding competitively to the RGD recognition site of Gp IIb/IIIa, the nonpeptides mimic the geometric, stereotactic, and charge characteristics of the RGD sequence.[88]

The clinical development of oral Gp IIb/IIIa antagonists has proven to be challenging.[88A] A major problem has been the question of optimal inhibition and monitoring of platelet function. Although 80 percent Gp IIb/IIIa blockade has been found to be effective and relatively safe with brief intravenous administration of the currently available agents in a controlled hospital environment, appropriate dosing of oral agents for chronic therapy remains problematic. Interindividual variability of response to chronic inhibition may be caused by genetic polymorphism of the Gp IIb/IIIa complex. Rapid, simple laboratory monitoring of Gp IIb/IIIa antagonist therapy will be required,[186] [187] and "therapeutic range" of inhibition of platelet function may have to be established for long-term administration. Chronic oral Gp IIb/IIIa blockade with certain agents may also be complicated by a paradoxical prothrombotic effect due to partial agonist effects at certain doses.[188]

COMPLICATIONS.

Bleeding complications with currently approved intravenous platelet Gp IIb/IIIa antagonists have primarily involved vascular access puncture sites in patients undergoing percutaneous intervention. Reduction and weight-adjustment in adjunctive heparin dosing in patients undergoing coronary interventions have reduced the incidence of these bleeding problems. No increase in intracerebral hemorrhage has been observed with the Gp IIb/IIIa antagonists. Therefore, the need for platelet transfusion to treat life-threatening bleeding is extremely rare, particularly with the short-acting agents eptifibatide and tirofiban.[175] Severe thrombocytopenia (platelet count <20,000/mul) occurs in 0.1 to 0.5 percent of patients treated with the intravenous agents, and the incidence appears to be slightly higher with abciximab.[175] [179] There may be more than one mechanism for thrombocytopenia: A precipitous decrease in platelet count may occur within 1 to 2 hours of initial exposure, or there may be a significant decline several days after initiation of therapy.

ANTITHROMBOTIC AND THROMBOLYTIC THERAPY IN CARDIOVASCULAR DISEASE

Primary Prevention of Ischemic Heart Disease

Three major trials have now evaluated the potential benefits of aspirin and/or warfarin in the primary prevention of ischemic heart disease. Two trials, the United States Physicians' Health Study[189] and the British Doctors' Trial,[190] compared aspirin therapy with placebo. The ultimate design of the Thrombosis Prevention Trial was a 2×2 factorial design comparing warfarin with placebo and comparing aspirin with placebo.[191]

ASPIRIN.

In the Physicians Health Study, over 22,000 healthy male physicians were treated with either aspirin (325 mg every other day) or placebo for 5 years. Although treatment with aspirin reduced the risk of a first myocardial infarction by 44 percent, the absolute risks of myocardial infarction in both aspirin and placebo groups were low (0.2 percent/year and 0.4 percent/year, respectively). This reduction in myocardial infarction risk was manifest only in those 50 years of age or older, and hemorrhagic stroke and gastrointestinal bleeding tended to occur more frequently in those treated with aspirin. There was no difference in the incidence of cardiovascular mortality, the primary study endpoint.

In the British Doctors' Trial,[190] 5139 male physicians were randomized to take either aspirin (500 mg daily in most cases) or to avoid aspirin. After 6 years of therapy, there was no difference in the rates of myocardial infarction or cardiovascular death. Disabling strokes were more common in those treated with aspirin. When the Physicians' Health Study and the British Doctors' Trial are considered together, aspirin therapy resulted in a 32 percent reduction in nonfatal myocardial infarction and a 13 percent reduction in any vascular event, although there was no difference in total cardiovascular death and there was a trend toward increased risk of nonfatal stroke.[192]

In one arm of the Thrombosis Prevention Trial,[191] approximately 4000 men aged 45 to 69 years at high risk for the development of ischemic heart disease were randomized to either aspirin (75 mg daily of controlled-release formulation) or placebo. Aspirin therapy reduced the incidence of nonfatal myocardial infarction by 32 percent, corresponding to an absolute reduction of 2.3 events/1000 person-years. There was no reduction in fatal myocardial infarction. Overall stroke rates were similar, although there tended to be more hemorrhagic strokes in those treated with aspirin.

The previous three trials enrolled only men, and as of yet there are no randomized data examining aspirin therapy in women for primary prevention. The results of three prospective observational studies and one case-control study of aspirin in women have yielded conflicting results.[193] Two studies showed a reduced incidence of myocardial infarction, one showed no effect on ischemic heart disease, and one showed no effect on acute myocardial infarction but an increased risk of overall ischemic heart disease. The ongoing Women's Health Study, in which 40,000 women are randomized to either aspirin (100 mg every other day) or placebo, should yield important information on the role of aspirin for primary prevention of ischemic cardiac events in women.

WARFARIN.

In the other arm of the Thrombosis Prevention Trial design, patients were treated with either warfarin (target INR 1.5) or placebo. Warfarin therapy reduced the incidence of nonfatal myocardial infarction by 10 percent, fatal myocardial infarction by 39 percent, and the combined endpoint of ischemic cardiac events by 21 percent. There tended to be more hemorrhagic and all-cause strokes, as well as a greater incidence of aortic aneurysm rupture, in those treated with warfarin. The all-cause mortality rate was reduced by warfarin therapy by a statistically significant 17 percent.

In patients who received both warfarin and aspirin therapy, nonfatal and fatal myocardial infarctions were reduced 35 percent and 29 percent, respectively, when compared with placebo therapy. This reduction was, however, accompanied by an increase in hemorrhagic and fatal strokes. Of note, approximately half of all patients in the Thrombosis Prevention Trial had withdrawn from treatment by the time the study was completed. Figure 62-19 displays the results of the Thrombosis Prevention Trial for the four treatment groups (placebo, aspirin alone, warfarin alone, aspirin plus warfarin).

RECOMMENDATIONS.

Although aspirin therapy does appear to reduce the incidence of nonfatal myocardial infarction in men, the absolute reduction is extremely modest (two to five events per 1000 subjects per year), has only been shown to be of benefit in those at least 45 to 50 years old, and may be accompanied by a small increased risk of hemorrhagic stroke. Therefore, it is difficult to recommend the widespread use of aspirin for the primary prevention of myocardial infarction. Aspirin therapy may have some modest benefit in selected higher risk patients older than 45 to 50 years. The utility of aspirin in the primary prevention of myocardial infarction in women is at present unresolved, and recommendations regarding its use must await the results of the Women's Health Initiative.

Figure 62-19 Cumulative proportion of men in the four treatment groups (WA=warfarin+aspirin; W=warfarin; A=aspirin; P=placebo) with fatal or nonfatal myocardial infarction (All IHD), fatal myocardial infarction (Fatal IHD), or nonfatal myocardial infarction (Nonfatal IHD). (From Medical Research Council's General Practice Research Framework: Thrombosis prevention trial: Randomized trial of low-intensity oral anticoagulation with warfarin and low-dose aspirin in the primary prevention of ischemic heart disease in men at increased risk. Lancet 351:238, 1998.)

Warfarin therapy in high-risk male subjects does lead to a reduction in the risk of myocardial infarction and overall mortality. However, as with aspirin therapy, the absolute reductions are modest (three ischemic cardiac events and one death per 1000 men per year) and this benefit appears to be accompanied by a small risk of serious adverse events. Combination warfarin and aspirin therapy may lead to the greatest reduction in ischemic cardiac events, but it may also be accompanied by an increased risk of hemorrhagic and fatal stroke. Furthermore, as suggested by the results of the Thrombosis Prevention Trial, many patients will discontinue treatment over time, owing to bleeding or other factors. The modest benefits in absolute terms of warfarin or combination therapy must therefore be balanced by physicians and patients against the small but real risks of bleeding and the inconveniences of anticoagulation monitoring.

Secondary Prevention of Ischemic Heart Disease (See also Chap. 37)

ANTIPLATELET AGENTS FOR SECONDARY PREVENTION.

The fissuring of atherosclerotic plaque with subsequent platelet deposition and activation of the coagulation cascade are key events in the pathogenesis of acute coronary syndromes. Thus, antiplatelet agents and anticoagulants are useful therapeutic strategies for prevention of vascular events in patients with stable or unstable angina as well as post-myocardial infarction.[194] [195] [196] [197] [198] [199] [200]

The 1994 Antiplatelet Trialists' Collaboration is a meta-analysis of the effect of prolonged antiplatelet therapy on prevention of vascular events including myocardial infarction, stroke, and cardiovascular death.[201] This overview included over 70,000 high-risk patients with known atherosclerotic disease. Among these categories, about 20,000 patients were post-myocardial infarction, 10,000 were post stroke or transient ischemic attack (TIA), 4000 had unstable angina, and 16,000 were in the other vascular disease categories (e.g., stable angina, percutaneous transluminal coronary angioplasty). The absolute reduction of vascular events for every 1000 patients treated was 40 events in patients with myocardial infarction treated for 2 years, 40 events in patients with previous strokes treated for 3 years, 50 events in patients with unstable angina treated for 6 months, and 20 events in patients belonging to the other vascular disease categories treated for 1 year (Fig. 62-20). This benefit was separately statistically significant in middle-aged and older patients, men and women, hypertensive and normotensive patients, and diabetic and nondiabetic patients. Doses of aspirin in the range of 75 to 325 mg/d were as effective as higher doses of aspirin or other antiplatelet regimens in this meta-analysis. The reader is directed to a review of individual randomized trials of antiplatelet therapy for secondary prevention of vascular events in patients post-myocardial infarction.[202]

Since publication of the 1994 Antiplatelet Trialists' Collaboration overview, the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial has addressed secondary prevention in patients with vascular disease.[203] This trial enrolled 19,185 patients with atherosclerotic vascular disease manifested as either recent ischemic stroke, recent myocardial infarction, or symptomatic peripheral arterial disease to a regimen of clopidogrel (75 mg once daily) or aspirin (325 mg once daily). The study had initially planned to enroll 15,000 patients with 5000 patients in each of the major subgroups of vascular disease. However, the sample size had to be increased partly because of a lower than expected incidence of the composite endpoints in the active control or aspirin group. The primary endpoint of reduction in vascular events defined as ischemic stroke, myocardial infarction, or cardiovascular death occurred in 5.32 percent of patients assigned to clopidogrel and 5.83 percent of patients assigned to aspirin after a mean follow-up of 1.91 years (p=0.043, relative risk reduction of 8.7 percent). Although the overall endpoint was slightly in favor of clopidogrel, the subgroup of patients enrolled with previous myocardial infarction did not have a reduction in the composite endpoint, which occurred in 5.03 percent of patients on clopidogrel and 4.84 percent of patients on aspirin. There were no major differences in adverse effects between the two agents. The incidence of neutropenia was only 0.1 percent, unlike in previous large trials with ticlopidine, a congener of clopidogrel. However, the rather modest benefit of clopidogrel for prevention of vascular events when compared with aspirin presently makes its major indication for patients who are intolerant to or have true aspirin allergy. The mechanism for inhibition of platelet aggregation is different for the two agents, with clopidogrel working through the ADP pathway and aspirin working through the thromboxane pathway. Thus, combination therapy may have the potential for synergistic clinical benefit. This strategy is being explored in ongoing clinical trials.

ANTICOAGULANTS FOR SECONDARY PREVENTION.

The value of long-term oral anticoagulation with warfarin in survivors of acute myocardial infarction remains unresolved after more than five decades of clinical research. The early trials such as the Working Party on Anticoagulant Therapy in Coronary Thrombosis (MRC) and the Veterans Administration Cooperative long-term therapy study (VA Coop) performed in the 1950s to 1970s suggested relative reduction in mortality of 10 to 30 percent as well as significant reduction in reinfarction, venous thrombosis, and embolic events.[204] [205] This efficacy was at the cost of an increase in both total and serious bleeding complications (an absolute increase in total bleeding events by 8 to 15 percent over 5 years). These trials were the basis for long-term

Figure 62-20 Prevention of death, myocardial infarction (MI), and stroke by prolonged antiplatelet therapy. SD=standard deviation; TIA=transient ischemic attack. (From Antiplatelet Triallists' Collaboration. Collaborative overview of randomised trials of antiplatelet therapy--1: Prevention of death, myocardial infarction, and stroke by prolonged antiplatelet therapy in various categories of patients. BMJ 308:81-106, 1994.)

anticoagulant therapy after myocardial infarction as standard of care (Fig. 62-21 and Table 62-1) . The decline in the use of oral anticoagulants in the late 1970s and 1980s was related to the results of the German-Austrian Aspirin (GAMIS) and the Enquete de Prevention Secondaire de L'Infarctus du Myocarde (EPSIM) trials, suggesting that benefits of a magnitude similar to those derived from oral anticoagulants can be realized by chronic treatment with aspirin.[194] [206]

The GAMIS trial randomized 946 patients who had survived a myocardial infarction for 30 to 42 days to aspirin (1.5 gm/d), phenprocoumon, or placebo. Total mortality after 2 years of follow-up was lower but not statistically significant in the aspirin group (8.5 percent) than in the placebo (10.3 percent) and phenprocoumon (12.1 percent) groups. Similar reductions in cardiovascular death and myocardial infarction were observed in the aspirin group compared with either oral anticoagulation or placebo groups but failed to reach statistical significance. The EPSIM trial enrolled 1303 patients to a treatment of either aspirin or oral anticoagulants for secondary prevention after myocardial infarction. After a mean follow-up of 29 months there was identical mortality between the two groups. The incidences of total and severe bleeding were increased in the anticoagulant arm, with rates of 16 percent versus 5 percent and 3 percent versus 1 percent, respectively. The aspirin group was associated with a higher incidence of gastritis and peptic ulceration. These two trials shifted the pendulum in favor of aspirin for secondary prevention of vascular events in survivors of myocardial infarction at least in North America.

The Warfarin-Aspirin Reinfarction Study (WARIS) trial revived the debate of the benefits of long-term oral anticoagulation after myocardial infarction.[207] The trial randomized 1214 patients to a regimen of warfarin (target INR of 2.8 to 4.8) versus placebo for an average treatment period of 37 months. The total mortality based on intention-to-treat was reduced from 20 to 15 percent, a relative risk reduction of 24 percent with warfarin therapy. When the analysis was

Figure 62-21 Long-term therapy with warfarin (Coumadin) in survivors of MI. The figure shows the odds ratio with 95 percent confidence interval for mortality comparing warfarin versus placebo in the major randomized trials spanning over four decades. Pooling of data from all trials shows a significant but modest overall treatment benefit. (From Loscalzo J, Schafer AI [eds]: Thrombosis and Hemorrhage. 2nd ed. Baltimore, Williams & Wilkins, 1998, p 1320.)

TABLE 62-1 -- LONG-TERM COUMADIN THERAPY IN SURVIVORS OF MYOCARDIAL INFARCTION (MI): RESULTS OF MAJOR RANDOMIZED TRIALS

STUDY	YEAR	NO. RANDOMIZED	TARGET INR	WEEKS AFTER MI*	YR OF FOLLOW-UP	INR IN TARGET RANGE (%)
MRC[204]	1955-60	383	2.0-2.5	4-6	4	60

*Enrollment time=weeks after MI.

based on patients actually receiving treatment, striking reductions in mortality (35 percent), reinfarction (43 percent), and cerebrovascular accident (61 percent) were observed. The magnitude of survival benefit afforded by warfarin in this trial was larger than that possible with the use of aspirin alone after myocardial infarction. The investigators attributed the lower mortality to the greater degree of anticoagulation achieved (higher target INRs) and to maintaining a higher proportion of patients in the therapeutic range compared with earlier trials of oral anticoagulation.

The Anticoagulation in the Secondary Prevention of Events in Coronary Thrombosis (ASPECT) trial was initiated before the publication of the WARIS trial.[208] The results of this trial were thus crucial to confirm the magnitude of benefits of oral anticoagulants suggested by the WARIS trial. The ASPECT trial randomized 3404 hospital survivors of myocardial infarction to anticoagulant (target INR 2.8 to 4.8) or placebo treatment within 6 weeks of discharge. During a mean follow-up of 37 months, total mortality was reduced by 10 percent, a difference that was not statistically significant. However, significant reductions of recurrent myocardial infarction by 53 percent, cerebrovascular events by 40 percent, and all vascular events by 35 percent were observed. This efficacy on secondary endpoints was at the cost of 3.87-fold increase in bleeding events with anticoagulation.

Because aspirin and oral anticoagulants mediate their antithrombotic effect through different pathways, the potential for additive or synergistic clinical benefit when the two agents are combined was explored in the Coumadin Aspirin Reinfarction Study (CARS) and in the Combination Hemotherapy and Mortality Prevention (CHAMP) trial.[209] [210] The CARS trial was designed to evaluate whether a combination of low-dose warfarin and low-dose aspirin would reduce vascular events compared with aspirin monotherapy without excessive bleeding risk in patients with previous myocardial infarction. The trial randomized 8803 patients to daily therapy with (1) aspirin (160 mg), (2) warfarin (3 mg) with aspirin (80 mg), or (3) warfarin (1 mg) with aspirin (80 mg). The design reflects the observational data that high doses of aspirin in combination with standard anticoagulation (target INR of 2.5 to 4.5) predisposes patients to an unacceptably high rate of bleeding complications, predominantly gastrointestinal. There were no significant reductions in the incidence of vascular events defined as reinfarction, nonfatal ischemic stroke, or cardiovascular death at 1 year between the groups (8.6 percent, 8.4 percent, and 8.8 percent, respectively). This lack of difference in benefit was associated with a significant increase in spontaneous bleeding complications in the 3 mg warfarin plus 80 mg aspirin group (1.4 vs. 0.7 percent, p=0.014). The CARS trial provides compelling evidence that a combination of low fixed-dose warfarin with 80 mg of aspirin does not provide clinical benefit beyond that achievable with 160-mg aspirin monotherapy. The results of the CHAMP trial also have not demonstrated any benefit of the combination of warfarin and aspirin in comparison with aspirin alone. In summary, the meta-analysis of both antiplatelet and oral anticoagulant trials as well as the more recent combination hemotherapy study demonstrate reductions in all-cause mortality and recurrent myocardial infarctions and cerebrovascular accidents with these agents.

RECOMMENDATIONS.

All survivors of myocardial infarction should be treated with aspirin, 160 to 325 mg daily The magnitude of benefit in most survivors of myocardial infarction with oral anticoagulant alone or in combination with aspirin over and above aspirin monotherapy does not appear large enough to justify the increased rate of nonfatal major hemorrhage and the greater cost and complexity associated with their use. However, patients who develop atrial fibrillation, congestive heart failure, mobile mural thrombus, or systemic/pulmonary embolism after myocardial infarction may benefit from oral anticoagulant therapy.

Acute Coronary Syndromes and ST Segment Elevation Myocardial Infarction

Antiplatelet, anticoagulant, and fibrinolytic therapy have become a mainstay of the modern management of acute myocardial infarction. These important therapies are discussed in the chapter on acute myocardial infarction (see Chap. 35) .

Prevention of Cardiac Chamber and Prosthetic Valvular Thromboembolism

PREVENTION OF LEFT VENTRICULAR THROMBOEMBOLISM AFTER MYOCARDIAL INFARCTION (See alsoChap. 35) .

The underlying substrate for ventricular mural thrombus formation is multifactorial and probably related to a combination of regional myocardial akinesis/dyskinesis, abnormal endocardial surface, aberrant blood flow dynamics associated with low cardiac output, and concomitant atrial fibrillation. The early short-term anticoagulation studies such as the MRC, Bronx Municipal Hospital study, and VA Cooperative study in aggregate demonstrated an absolute reduction in mortality (4.2 percent) and thromboembolism (7.9 percent) with early heparinization soon after the diagnosis of acute myocardial infarction followed by oral anticoagulation.[202] [212] [213] [214] However, changing practices of the care of patients with acute myocardial infarction, such as the advent of coronary care units, thrombolytic therapy, aspirin use, and early mobilization of patients, have challenged the applicability of these early trials to contemporary practice.

The earlier observations that anterior myocardial infarctions are associated with a higher incidence of mural thrombi have been validated by the predischarge echocardiographic observations of the 8326-patient Gruppo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardico-3 (GISSI-3) trial.[215] Although the overall incidence of thrombi in patients at low to medium risk for left ventricular (LV) thrombus formation (patients with severe pump failure and Killip class IV were excluded) was 5.1 percent, the incidence in patients with anterior myocardial infarction was 11.5 percent compared with 2.3 percent for patients with myocardial infarction at other sites (p<0.0001). In addition, patients with LV ejection fraction (LVEF) less than 40 percent had a higher incidence of ventricular thrombi (10.5 percent) compared with those with an EF greater than 40 percent (4 percent).

In a serial echocardiographic study of 99 consecutive patients with anterior wall infarction, Mooe and coworkers observed a 44 percent incidence of LV thrombi during hospitalization and a 30 percent incidence at discharge.[216] Repeat echocardiogram at 1 month, 3 months, and 12 months after hospital discharge showed that the thrombi had resolved in 81 percent, 84 percent, and 90 percent of the patients, respectively. Oral anticoagulants were used in 24 percent of patients and did not enhance the resolution of thrombi at 1 month. Patients with LV thrombi during the hospital stay had more extensive myocardial dysfunction and significantly higher mortality during the follow-up period of over 3 years than those without thrombi (23 vs. 7 percent, p<0.01).

In an observational analysis of 2231 patients post-myocardial infarction enrolled in the Survival and Ventricular Enlargement (SAVE) trial the rate of stroke was 1.5 percent per year of follow-up.[217] The independent risk factors for cerebral thromboembolic event included a lower EF (for every decrease of 5 percentage points in the EF there was an 18 percent increase in the risk of stroke), older age, and the absence of aspirin or anticoagulant therapy (administered on a nonrandomized basis). There was an 81 percent reduction in risk of stroke with anticoagulation in this trial. (This was not a specified endpoint of this trial of angiotensin-converting enzyme inhibitor administration on mortality post-myocardial infarction.) This reduction was of greater magnitude than the reduction in stroke observed in either the ASPECT (39 percent) or the WARIS (55 percent) trials. The use of aspirin was associated with a 56 percent risk reduction for cerebrovascular accidents in the SAVE trial. The limitations of this study include the lack of data on the intensity of anticoagulation and the fact that therapy with aspirin and anticoagulant agents was not randomly assigned.

Randomized trials of high-dose subcutaneous heparin versus placebo during the hospital stay in patients with acute myocardial infarction have shown that this therapy is effective at reducing the formation of LV thrombi by 50 to 66 percent.[218] [219] [220] However, these trials had an adequate sample size only to evaluate the surrogate endpoint of resolution of LV thrombi with active treatment and should not be taken as evidence of benefit in preventing thromboembolic or vascular events.

RECOMMENDATIONS.

Oral anticoagulation with warfarin should be used in patients with large anterior myocardial infarction for 3 to 6 months at a target INR of 2 to 3. Although it is prudent to use oral anticoagulant in patients with protruding or mobile LV thrombi, the routine administration in all patients after acute myocardial infarction must await further clarification. [220]

DILATED CARDIOMYOPATHY (See alsoChap. 48) .

Patients with LV systolic dysfunction due to either ischemic or nonischemic dilated cardiomyopathy are at risk of developing both arterial and venous thromboembolic events.[221] The presence of regional wall motion abnormality, of poor contractility creating areas of relative stasis, of concomitant atrial fibrillation, and of chronic hypercoagulable state are factors that predispose to thromboembolism in these patients.[222] The incidence of thromboembolic events has ranged from 37 to 50 percent in older autopsy studies.[223] However, when clinically apparent events are evaluated, the incidence has been much lower. Fuster and coworkers observed 3.5 clinically apparent embolic events per 100 patient-years in a retrospective analysis of 104 patients with nonischemic dilated cardiomyopathy.[224] In a prospective follow-up of 264 patients with dilated cardiomyopathy, Katz and coworkers observed that the incidence of stroke was 1.7 per 100 patient-years.[225] In a more recent retrospective analysis by Natterson and coworkers of 224 patients awaiting cardiac transplantation, an arterial embolization rate of 3.2 per 100 patient-years was observed.[226]

The observational analysis of the factors predisposing to mortality and cerebral thromboembolism in the large prospective heart failure trials evaluating the use of angiotensin converting enzyme inhibitors (V-HEFT, SOLVD, and SAVE) has been published.[217] [227] [228] [229] Although these trials are not directly comparable to those of patients with dilated cardiomyopathy, the factors predisposing to thromboembolic events for patients with chronically depressed LV systolic function are relevant. These studies, which are elaborated here, have the following limitations: (1) The oral anticoagulant or antiplatelet regimens were not randomly allocated, (2) the intensity or the duration of anticoagulation is unknown, and (3) the number of patients on aspirin alone or warfarin alone is not available from the data base.

The observational analysis of the Veterans Affairs Vasodilator-Heart Failure Trials (V-HEFT I and II) included 642 men with heart failure who were followed for an average of 2.28 years (V-HEFT I) and 804 men were followed for an average of 2.56 years (V-HEFT II).[229] The incidence of all thromboembolic events in V-HEFT I was 2.7 per 100 patient-years, and in V-HEFT II was 2.1 per 100 patient-years; and it was not reduced in patients treated with warfarin. Patients with lower peak oxygen consumption (MV_{O_2}) and lower EF had a higher risk of thromboembolic events, but only the difference in MV_{O_2} was significant. The use of oral anticoagulants was associated with a small but statistically insignificant increase in thromboembolic events in this analysis. There was no significant difference in the rate of thromboembolism between patients with ischemic and non-ischemic cardiomyopathy in this trial.

The retrospective analysis of Studies of Left Ventricular Dysfunction (SOLVD) was limited to the 6378 patients who were in sinus rhythm because of the confounding influence of atrial fibrillation on thromboembolic events.[228] The annual incidence of thromboembolic events was higher in women (2.4 percent) than in men (1.8 percent). Multivariate analysis revealed a 53 percent increased risk of thromboembolism for every 10 percent reduction in EF in women (p=0.02), but no increased risk was observed in men. The use of anticoagulants alone or the combination of anticoagulants plus antiplatelet agents was not associated with significant risk reduction on the incidence of thromboembolism in either men or women. However, aspirin monotherapy resulted in 23 percent risk reduction in men (p=0.06) and 53 percent risk reduction in women (p=0.03).

A separate analysis focusing on warfarin anticoagulation and mortality in the 6797 patients enrolled in the SOLVD prevention and treatment trials has also been reported.[227] This cohort was divided into 861 patients on warfarin and 5652 patients on no oral anticoagulants. The patients on warfarin were sicker, as evidenced by lower mean EF, higher prevalence of atrial fibrillation, and cerebrovascular disease. When all-cause mortality was evaluated without adjusting for differences in baseline characteristics, there was no benefit of warfarin. However, after adjusting for baseline differences, warfarin use was a highly significant predictor of favorable outcome with a hazard ratio of 0.76 (95 percent confidence interval 0.65 to 0.89, p=0.0006). A similar analysis after adjusting for differences in baseline characteristics has not been reported for the V-HEFT. These differences in baseline variables may explain the higher thromboembolic event rate (although not statistically significant) in patients on anticoagulants in the V-HEFT study. The reduction in the relative risk of stroke with anticoagulation (81 percent) and antiplatelet agents (56 percent) in the SAVE trial has been elaborated in the section on prevention of LV thrombi post-myocardial infarction.[217]

RECOMMENDATIONS.

A placebo-controlled randomized trial of long-term anticoagulation in patients with dilated cardiomyopathy has not yet been performed. Thus, the routine use of oral anticoagulants cannot be universally recommended, especially in view of the observed benefits of aspirin monotherapy from CARS and several nonrandomized

trials.[209] [220] Oral anticoagulation should thus be individualized to patients with high-risk characteristics such as large, protruding, or mobile ventricular thrombi and in patients with concomitant atrial fibrillation.

Prosthetic Heart Valves (See also Chap. 46)

Risks associated with implantation of prosthetic heart valves include thromboembolism, particularly stroke, and valve thrombosis. Although patients with bioprosthetic valves are at risk for thromboembolic events primarily during the first 90 days after surgery, those with mechanical valves remain at significant risk indefinitely.[230] [231] In one analysis, the incidence of major embolism in the absence of antithrombotic therapy was calculated to be 4 per 100 patient-years.[232] Factors that are associated with an increased risk of thromboembolism include the presence of older "first generation" mechanical valves (e.g., Starr-Edwards "ball and cage" valve), valves in the mitral position, the presence of more than one prosthetic valve, prior embolism, atrial fibrillation, enlarged left atrium, low LVEF, and advanced age.[232] [233] [234] [235] [236]

ANTIPLATELET THERAPY ALONE.

There have been no randomized placebo-controlled trials assessing antiplatelet therapy alone as an antithrombotic regimen in patients with mechanical heart valves. Nonrandomized studies of aspirin, dipyridamole, or both in patients with mechanical heart valves have shown only modest or no significant protective effect.[232] [237] In one open prospective randomized trial of patients with mitral or aortic Starr-Edwards valves, combination antiplatelet therapy (aspirin plus dipyridamole or aspirin plus pentoxifylline) was associated with a higher incidence of thromboembolism when compared with treatment with warfarin.[238] Based on the previous reports, antiplatelet therapy alone is not considered to provide adequate antithrombotic protection in patients with mechanical prostheses.[239]

There have likewise been no randomized nor placebo-controlled trials of antiplatelet therapy alone in patients with bioprosthetic valves. One series of 185 patients with bioprosthetic valves in the mitral or mitral and aortic positions who were in sinus rhythm reported no thromboembolic events with a mean follow-up of 32 months in patients treated with aspirin (500 mg every other day to 1 gm/d).[240]

WARFARIN THERAPY.

Studies of patients with bileaflet mechanical valves (such as the commonly used St. Jude valve) have shown that oral anticoagulation to achieve lower INRs is not associated with a clinically significant increase in thromboembolic complications compared with those with higher INRs. In one prospective study, subset analysis of patients in sinus rhythm with nonenlarged left atria showed little difference in thromboembolic events when INR values of 1.8 to 2.7 were compared with those of 2.5 to 3.2.[241] In a large series of patients from the Netherlands, patients with bileaflet valves had no more complications at INRs of 2.0 to 2.9 than INRs of 3.0 to 3.9 or 4.0 to 4.9, although those with tilting disc or caged ball or disc valves had less overall adverse outcomes at higher INRs. In the AREVA study, patients at low risk for embolic events randomized to anticoagulation at an INR of 2.0 to 3.0 had similar thromboembolic events and less hemorrhagic events than those randomized to anticoagulation at an INR of 3.0 to 4.5.[242]

Patients treated with bioprosthetic valves, especially in the mitral position, are at significant risk of thromboembolism during the first 90 days after surgery; and this risk is decreased with anticoagulation therapy.[230] In one study of patients who received bioprosthetic valves, those randomized to anticoagulation with an INR of 2.0 to 2.25 had thromboembolic rates comparable to those treated with a target INR of 2.5 to 4.0.[243]

These and other studies have led to lower recommended INR ranges for the prevention of thromboembolic events in patients with mechanical valves (particularly those with St. Jude valves) and with bioprosthetic valves.[231] [239] [244] [245]

WARFARIN PLUS ANTIPLATELET THERAPY.

Several trials have evaluated the utility of combined warfarin and antiplatelet therapy compared with warfarin therapy alone. Turpie and colleagues randomized a group of patients consisting of those with either mechanical heart valves or high-risk characteristics and bioprosthetic valves to treatment with warfarin (target INR 3.0 to 4.5) and either aspirin (100 mg daily) or placebo. Major systemic embolism of vascular death occurred at a rate of 1.9 percent/year in those treated with aspirin and 8.5 percent/year in those treated with placebo. All-cause death occurred in 2.8 percent and 7.4 percent of patients, respectively. Although bleeding was more common in the combined therapy group, most of the increased incidence of bleeding was due to minor bleeding.[246] A meta-analysis of five randomized trials comparing warfarin therapy alone with warfarin therapy combined with antiplatelet therapy (aspirin or dipyridamole) found that combination therapy reduced embolism by 67 percent and overall mortality by 40 percent. Although the risk of bleeding was increased with combination therapy, the benefits of combination therapy appeared to outweigh this increased bleeding risk.[247]

In a trial comparing the combination of lower-intensity anticoagulation with warfarin (INR 2.5 to 3.5) and aspirin (100 mg/d) with higher-intensity anticoagulation alone (INR 3.5 to 4.5), the incidence of thromboembolic events was similar; bleeding tended to be more common in patients treated with higher-intensity anticoagulation therapy.[248] Altman and coworkers found no difference in systemic embolization or vascular death in patients treated with combination therapy between those who received relatively low-dose aspirin (100 mg/d) and those treated with high-dose aspirin (650 mg/d).[249] Thus, combination warfarin and antiplatelet therapy in many patients appears to reduce the risk of thromboembolic events without unacceptably increasing bleeding complications. Antiplatelet therapy with as low as 100 mg/d of aspirin in this setting appears adequate.

RECOMMENDATIONS.

Recommendations regarding antithrombotic therapy in patients with prosthetic heart valves have been published from a consensus conference of the American College of Chest Physicians (ACCP)[239] and others[231] [244] [245] based on the above and other data. The following summarizes in simplified form the latest (as of this writing) ACCP guidelines.

All patients with mechanical prosthetic heart valves should be treated with oral anticoagulants. The intensity of anticoagulation recommended in specific situations can be thought of as a three-tier system, based on the presence or absence of certain factors associated with increased risk of thromboembolism and on the just discussed studies. For patients with a bileaflet valve (e.g., "St. Jude") in the aortic position, without other factors that have been correlated with increased risk of thromboembolism (enlarged left atrium, atrial fibrillation, low LVEF), treatment should be with warfarin with a target INR of 2.5 (range 2.0 to 3.0). For patients with a bileaflet or tilting disc valve in the aortic position with atrial fibrillation or with bileaflet or tilting disc valve in the mitral position, treatment should be with either (1) warfarin alone with a target INR of 3.0 (range 2.5 to 3.5) or with (2) warfarin with a target INR of 2.5 (range 2.0 to 3.0) plus aspirin (80 to 100 mg/d). For patients with caged ball (e.g., "Starr Edwards") or caged disc valves or those with any mechanical valves and other factors associated with increased risk of thromboembolism, combined therapy with warfarin with a target INR of 3.0 (range 2.5-3.5) and aspirin (80-100 mg/d) is recommended.

Patients with bioprosthetic heart valves should be treated with warfarin with a target INR of 2.5 (range 2.0-3.0) for 3 months. After this period, those not at risk of systemic embolism from other factors (e.g., atrial fibrillation) can be treated with aspirin (162 mg/d).

Percutaneous Coronary Interventions

Antiplatelet and anticoagulant therapy has made modern percutaneous arterial interventions practical.[250] The strategies for using these therapies in patients undergoing coronary interventions are discussed in detail in Chapter 38 . A summary of the key findings follows.

ANTIPLATELET AGENTS IN PERCUTANEOUS CORONARY INTERVENTIONS.

In the era of balloon angioplasty alone, before the advent of stents, the utility of aspirin for prevention of periprocedural myocardial infarction and/or recurrent ischemia requiring urgent revascularization was established. The quest to reduce further ischemic complications of percutaneous coronary intervention in the 1990s was aided by the introduction of potent new antiplatelet agents such as the Gp IIb/IIIa receptor inhibitors.[251] [252] [253] [254] [255] [256] The Gp IIb/IIIa receptor antagonists have been evaluated in five major prospective, randomized, double-blind, placebocontrolled trials in patients undergoing balloon angioplasty.[251] [252] [253] [257]

Figure 62-22 The reduction in acute ischemic complications after percutaneous transluminary coronary angioplasty defined as death, myocardial infarction, or urgent target vessel revascularization (triple composite) in trials of GP IIb/IIIa inhibitors versus placebo at 30 days. The odds ratio with 95 percent confidence intervals for each trial is shown. The odds ratio circle for each trial is relatively proportional to its sample size, which is also shown as a number. The embedded table shows the event rate in the treated and control groups. (Adapted from Lincoff AM, Tcheng JE, Califf RM, et al: Sustained suppression of ischemic complications of coronary intervention by platelet GP IIb/IIIa blockade with abciximab: One-year outcome in the EPILOG trial. Evaluation in PTCA to Improve Long-term Outcome with abciximab GP IIb/IIIa blockade. Circulation 99:1951-1958, 1999. Copyright 1999, American Heart Association.)

Although there are some differences between studies, the overall direction has been one of marked reduction in ischemic complications of balloon angioplasty with the use of these agents (Fig. 62-22) .

The success of these early Gp IIb/IIIa inhibitor trials, along with the potential drawbacks of monoclonal Fab fragments such as immunogenicity, a finite incidence of thrombocytopenia (
5 percent), and the extended duration of antiplatelet effect, created an impetus to evaluate other Gp IIb/IIIa receptor antagonists.[258] [259] [260] [261] Two phase III clinical trials using cyclic RGD peptides (eptifibatide) or nonpeptide RGD mimetics (tirofiban) that compete for ligand binding to the Gp IIb/IIIa receptor have been reported. Their results show a similar reduction in triple composite endpoint in the first 24 to 72 hours after percutaneous transluminal coronary angioplasty. However, clinical efficacy with these shorter-acting agents was not sustained at 30 days and 6 months.[252] [253]

ANTICOAGULANTS IN PERCUTANEOUS CORONARY INTERVENTIONS.

Coronary interventions before the Gp IIb/IIIa inhibitor era were often performed by using approximately 150 U/kg of heparin (with a 10,000- to 15,000-unit initial bolus), targeted to an activated clotting time (ACT) between 300 and 350 seconds.[262] [263] The rationale for this level of anticoagulation during angioplasty was the observation of an inverse relationship between ACT and the risk of ischemic complications. Periprocedural ischemic events increase the synthesis of heparin-binding proteins and potentiate the local release of platelet factor 4 (PF4) by platelets.[264] This leads to heparin resistance and/or inactivation with consequent reduction in ACT and aPTT values. These shortcomings of heparin along with the biochemical advantages afforded by the direct thrombin inhibitors hirudin and its congener bivalirudin provided an impetus to test these agents for prevention of ischemic complications and restenosis after angioplasty.[265] After encouraging preliminary studies, two large prospective randomized trials evaluated the two direct thrombin inhibitors in patients undergoing percutaneous coronary intervention (Fig. 62-23) .[266] [267] The failure of the direct thrombin inhibitor to substantially alter the long-term outcome in patients undergoing percutaneous coronary intervention or in acute coronary syndromes may be multifactorial, possibly related to continued thrombin generation during, as well as rebound increase in thrombin activity upon cessation of, infusion.[268]

ANTITHROMBOTIC THERAPY AFTER DEPLOYMENT OF CORONARY STENTS.

Coronary stenting has outpaced balloon angioplasty as the most frequently performed percutaneous revascularization procedure.[250] The early experience with coronary stenting was associated with a 5 to 20 percent incidence of stent thrombosis that frequently resulted in clinical events such as death, myocardial infarction, or urgent target lesion revascularization.[269] [270] [271] The tendency for ischemic complications after stenting occurred despite intense anticoagulation during the procedure with high-dose heparin, dextran, and postprocedure warfarin administration to an INR of 3.0 to 4.5.[271] The need to optimize oral anticoagulation during heparin infusion as well as bleeding complications as a result of intense anticoagulation led to prolonged hospitalizations. The introduction of thienopyridine ADP antagonists (ticlopidine and clopidogrel) and the optimization of stent deployment techniques have eliminated the need to treat patients with warfarin after coronary stenting. Trials have now shown the superiority of the combination antiplatelet regimen of aspirin and ticlopidine over aspirin alone, or aspirin plus oral anticoagulation with warfarin, not only in patients with optimal stent deployment but also in patients who are at high risk of stent thrombosis[272] [273] [274] [275] [276] (Fig. 62-24) .

Although ticlopidine has proven to be effective in preventing stent thrombosis in multiple trials, the enthusiasm

Figure 62-23 The reduction in acute ischemic complications after PTCA defined as death in the hospital, myocardial infarction (MI), abrupt vessel closure, or rapid clinical deterioration of cardiac origin in the HELVETICA and Hirulog in Angioplasty trials. The odds ratio with 95 percent confidence intervals for each trial is shown. The odds ratio of the intravenous (IV) and subcutaneous (SC) arms of HELVETICA, the overall group as well as the postinfarction angina subgroup in the Hirulog in Angioplasty trial, are shown. The odds ratio circle for each trial is relatively proportional to its sample size, which is also shown as a number. The embedded table shows the event rate in the treated and control groups.

Figure 62-24 The reduction in clinical sequelae of stent thrombosis defined as death, myocardial infarction, revascularization of the target lesion, or angiographically evident thrombosis within 30 days in the stent trials. The odds ratio with 95 percent confidence intervals for each trial is shown. The event rate in the control groups is either for aspirin treatment alone (STARS vs. A and Hall and coworkers) or aspirin plus oral anticoagulation with warfarin (STARS vs. OA, ISAR, ISAR H [denoting high-risk group] and MATTIS). The ISAR (H) and the MATTIS trial enrolled patients who were at high risk of stent thrombosis. The odds ratio circle for each trial is relatively proportional to its sample size, which is also shown as a number. The embedded table shows the event rate in the treated and control groups.

Figure 62-25 The incidence and type of each myocardial infarction for each treatment group in the EPISTENT trial. The predominant effect of abciximab was in the reduction of large non-Q wave myocardial infarction which comprised 86 percent of the benefit. (From EPISTENT Investigators: Randomised placebo-controlled and balloon-angioplasty-controlled trial to assess safety of coronary stenting with use of platelet glycoprotein-IIb/IIIa blockade. Evaluation of Platelet IIb/IIIa Inhibitor for Stenting. Lancet 352:87-92, 1998.)

for this agent was tempered by a small but finite incidence of hematological side effects such as neutropenia and thrombotic thrombocytopenic purpura.[277] [278] [279] [280] [281] [282] [283] [284] [285] [286] [287] [288] This provided the impetus to evaluate clopidogrel, a congener of ticlopidine.[289] The preliminary results of the CLASSICS (Clopidogrel plus ASA vs. Ticlopidine plus ASA in patients with stents) study suggest that clopidogrel provides comparable efficacy and fewer side effects than ticlopidine.[211] Recently, TTP has been described in association with clopidogrel as well as with ticlopidine, albeit at lower frequency.[173A]

ROLE OF GP IIB/IIIA INHIBITORS IN CORONARY STENTING.

The EPISTENT trial was designed to evaluate the synergism between optimization of luminal rheology with coronary stenting and potent platelet blockade with Gp IIb/IIIa inhibitors.[254] In this trial, 2399 patients were randomized to a strategy of balloon angioplasty with abciximab, stent deployment with abciximab, and stent deployment with routine anticoagulation with weight-based heparin (100 U/kg). There was a dramatic reduction in the triple composite endpoint of death, myocardial infarction, and urgent target vessel revascularization at 30 days in the two abciximab groups (6.9 and 5.3 percent) compared with stent deployment on the background of routine heparin therapy (10.8, $p<0.007$, and 0.001, respectively). The predominant effect of abciximab was in the reduction of large non-Q wave myocardial infarction that comprised 86 percent of the benefit (Fig. 62-25). The best outcome was in the stent plus abciximab group, indicating that there is synergism between optimization of luminal rheology and potent platelet inhibition. Preliminary data regarding the durability of benefit for the combined abciximab/stent strategy versus stenting alone for reduction of death rates (0.8 percent vs. 2.4 percent) at 1 year are now available. The ESPRIT study is evaluating the potential benefit of treatment with eptifibatide in patients primarily without traditional high-risk clinical or angiographic features who are undergoing coronary stent implantation. Results of this study should be forthcoming.

ANTITHROMBOTIC THERAPY FOR PREVENTION OF CORONARY RESTENOSIS.

The paradigm that coronary restenosis is predominantly a result of mural thrombosis that provides a scaffold for the subsequent migration and proliferation of neointimal smooth muscle cells has recently been challenged by serial intravascular ultrasound studies in patients undergoing percutaneous transluminal coronary angioplasty.[290] These observations have highlighted the importance of both acute vessel recoil and late vascular remodeling as the major factors contributing to luminal narrowing after this procedure.[291] Thus, it is not surprising that a decade of animal and clinical studies with both conventional antiplatelet agents and antithrombins has yielded negative results for the prevention of coronary restenosis.[250]

RECOMMENDATIONS.

All patients undergoing percutaneous coronary intervention should be pretreated with aspirin (160-325 mg/d) in the absence of specific contraindications such as true aspirin allergy. Whereas Gp IIb/IIIa inhibitors should be considered in most patients undergoing percutaneous coronary intervention, their use is strongly recommended for patients at high risk of ischemic complications such as intracoronary thrombus, post-myocardial infarction, and unfavorable lesion morphology. Combination antiplatelet therapy with aspirin and a thienopyridine (ticlopidine or clopidogrel) should be used in all patients undergoing intracoronary stenting for 2 to 4 weeks after stent implantation (and aspirin alone should then be continued indefinitely).

Antithrombotic Therapy after Coronary Artery Bypass Surgery (See also Chap. 37)

The disease process in the vein grafts is initiated at the time of explantation from the leg and progresses through an early thrombotic phase in the first month after surgery, followed by intimal hyperplasia over the next 12 months, which creates a substrate for accelerated atherosclerosis.[292] [293] [294] [295] [296] Saphenous vein graft occlusion in the first month is therefore a result of thrombotic occlusion and is reported to occur in 3 to 12 percent of grafts. The predisposition to thrombosis is initiated at the time of harvesting when high pressure distention is required to overcome venous spasm.[297] [298] [299] [300] This results in prominent endothelial cell loss and medial damage, with consequent deposition of fibrin, platelets, and neutrophils on the denuded luminal surface. In addition, the disruption of endothelial integrity results in reduction of tissue plasminogen activator production, impairment of thrombomodulin mediated inhibition of the coagulation cascade, and exposure of tissue factor.[301] The thrombotic tendency in the first several weeks after aortocoronary bypass led to the use of antiplatelet agents in an effort to prevent graft occlusion (Fig. 62-26) .[292] [293] [296] [302] [303] [304] [305]

Landmark clinical trials conducted in the 1980s by Chesebro and coworkers as well as Goldman and coworkers have shown that (1) aspirin (100 to 975 mg daily) when initiated either before, on the day of, or 1 day after bypass surgery is effective at reducing thrombotic graft occlusion; (2) the combination of dipyridamole and aspirin is no more effective than aspirin alone; (3) initiation of aspirin before bypass surgery is associated with an increase in perioperative bleeding events without an increase in graft patency when compared with aspirin therapy started within the first 24 hours after surgery; (4) aspirin therapy after the first 48 hours is not effective in preventing graft occlusion; and (5) there are no benefits on vein bypass graft patency of aspirin therapy for longer than 1 year.[306]

For patients who are intolerant of or allergic to aspirin, ticlopidine started within the first 2 days after grafting is a viable alternative based on the study by Limet and coworkers.[302] There are no studies of combination therapy with aspirin and ticlopidine or clopidogrel, which is a potentially useful regimen because these agents mediate their

Figure 62-26 The effect of antithrombotic therapy with aspirin alone (100-975 mg), aspirin plus dipyridamole, or ticlopidine compared with placebo on saphenous vein graft patency in different trials is depicted as odds ratio with 95 percent confidence intervals for each trial. The odds ratio circle for each trial is relatively proportional to number of vein grafts evaluated, which is also shown as a number. The embedded table shows the duration of follow-up and the rate of graft patency in the treated versus the control groups.

antiplatelet effect by different pathways. On the basis of the efficacy of combined therapy with aspirin plus ticlopidine or aspirin plus clopidogrel in reducing subacute stent thrombosis, it is reasonable to evaluate the potential synergy of these regimens for prevention of vein graft thrombosis.[289] [307]

The use of oral anticoagulants initiated before or immediately after surgery provides no additional improvement in graft patency when compared with aspirin therapy.[308] [309] [310] In addition, bleeding complications occurred more frequently in the oral anticoagulant group.[308] [309] The Post CABG study evaluated whether aggressive lowering of low-density lipoprotein cholesterol levels or low-dose anticoagulation would delay the progression of atherosclerosis in vein grafts.[311] The study enrolled 1351 patients 1 to 11 years after bypass surgery with at least one patent vein graft in a 2×2 factorial design to aggressive or moderate treatment to lower low-density lipoprotein cholesterol and to treatment with warfarin or placebo. The warfarin group achieved a mean INR of only 1.4. The primary outcome in this trial was angiographic progression of disease that was lowered by aggressive lipid-lowering therapy. However, warfarin was not superior to placebo in influencing rates of disease progression (34 vs. 32 percent; p=0.48) or graft occlusion. These angiographic outcomes were accompanied by no differences in the rates of myocardial infarction (5.0 vs. 5.0 percent) or the need for revascularization (7.8 vs. 7.9 percent) between the warfarin-treated and placebo-treated patients.

The improved understanding of the pathogenesis of early

thrombotic occlusion of vein grafts has led to experimental studies using innovative strategies.[294] [312] [313] The saphenous vein grafts are ideal targets for gene therapy because the explanted veins are available for ex vivo transfer of exogenous genetic material before grafting. The replication-defective adenoviral vectors have been successfully used to transfer genes in experimental porcine vein graft models.[314] In addition, cultured human saphenous veins have been successfully transfected with an adenoviral vector encoding bovine endothelial NOS, yielding a marked increase in venous endothelial NO production.[313] This strategy, if clinically feasible, has the potential to provide a potent local antithrombotic milieu in the early vulnerable period of thrombosis after graft implantation. The administration of platelet selective NO donors and the modulation of tissue factor with anti-tissue factor antibody are some of the other approaches undergoing investigation in experimental animal models.[312] [315]

RECOMMENDATIONS.

Early antiplatelet therapy with aspirin should be used in all patients after coronary artery bypass surgery to prevent vein graft occlusion. Preoperative aspirin may increase intraoperative bleeding and is not more beneficial than aspirin started within the first 24 to 48 hours after surgery. Therefore, for elective surgery and if the clinical situation permits, aspirin should be withheld until after the operation. Aspirin at doses of 100 to 325 mg/d should be started immediately after surgery. A delay in the initiation of aspirin beyond 48 hours is associated with reduced efficacy. The addition of dipyridamole to aspirin has not been shown to enhance vein graft patency.

The appropriate duration of antiplatelet therapy after surgery is controversial. Studies suggest that aspirin therapy for at least 1 year reduces vein graft occlusion. Although studies do not show an improvement in vein graft patency with antiplatelet therapy beyond the first year, the beneficial effects of aspirin for secondary prevention of coronary artery disease argue that it be continued indefinitely in these patients. For patients allergic to aspirin, ticlopidine, 250 mg twice daily, beginning 48 hours after surgery has been reported to be effective and may be considered as an alternative.

Chapter 63 - Diabetes Mellitus and the Cardiovascular System

RICHARD W. NESTO
PETER LIBBY

SCOPE OF THE PROBLEM

In the coming decades, the burden of cardiovascular diseases (CVDs) related to diabetes will increase substantially. Diabetes, formerly thought of as a problem of glucose metabolism, actually produces most of its harm by effects on the cardiovascular system.[1] [2] [2A] Microvascular disease underlies the pathogenesis of diabetic retinopathy, a common cause of blindness. Microvascular disease also causes diabetic renal disease, a major contributor to need for dialysis therapy.

Most diabetics die of CVD, and atherosclerosis accounts for some 80 percent of all diabetic mortality. About three-quarters of the cardiovascular deaths from diabetes result from coronary artery disease (CAD). The remaining quarter results from cerebral or peripheral vascular disease. Atherosclerotic disease causes some three-quarters of all hospitalizations for diabetic complications. Tight control of glycemia consistently reduces the risk of microvascular complications of diabetes in large clinical trials. However, the benefits of glycemic control on the macrovascular complications of diabetes are less firmly established. With the success of currently available hypoglycemic agents in mitigating microvascular disease, a shift toward a preponderance of macrovascular complications may well occur.

The burden of diabetic disease in the population will increase markedly in the coming years. In the United States, the prevalence of diabetes has increased from approximately 2 million cases in the early 1960s to some 15 million in the year 2000. Current estimates project 22 million cases by the year 2025. This increase goes hand in hand with an epidemic of obesity, which affected approximately 18 percent of the U.S. population in 1998.[3] During the 7 years from 1991 to 1998, the body weight of American men increased over 3 percent and that of women almost 5 percent. The significant clustering of atherogenic risk factors, including glucose levels and body weight, links the current epidemic of obesity and diabetes mellitus.[4]

The coming wave of CVD related to diabetes will take a particularly heavy toll in certain minority populations. Hispanics, blacks, Native Americans, and Asian Indians will bear a disproportionate burden of diabetic CVD.[5] The predilection of these ethnic groups to the development of obesity and glucose intolerance on a Western diet may have a genetic basis. The ability to store fat may have conferred a survival advantage in populations subject to famine. This selective pressure could enrich the population in genes that facilitate fat storage, the so-called thrifty gene hypothesis.[6] [7] As discussed below, diabetics with CVD fare worse than their nondiabetic counterparts. Hence, physicians caring for patients with CVD have a compelling need to have a working knowledge of the effects of diabetes mellitus on the heart and blood vessels.

NEW DIAGNOSTIC CRITERIA.

In 1997, the American Diabetes Association promulgated new criteria for the diagnosis of diabetes mellitus. These criteria use a single blood glucose determination after an 8-hour fast (fasting plasma glucose [FPG]) as the major diagnostic criterion (Table 63-1) . An FPG of less than 110 mg/dl is considered normal. A new diagnostic category known as impaired fasting glucose

TABLE 63-1 -- CRITERIA FOR THE DIAGNOSIS OF DIABETES MELLITUS

NORMAL	IMPAIRED FASTING GLUCOSE AND IMPAIRED GLUCOSE TOLERANCE	DIABETES MELLITUS
FPG <110 mg/dl	FPG ;110 mg/dl and <126 mg/dl (IFG)	FPG ;126 mg/dl
2-hr PG* <140 mg/dl	2-hr PG* ;140 mg/dl and <200 mg/dl (IGT)	2-hr PG* ;200 mg/dl
2-hr PG*		Symptoms of DM and random plasma glucose concentration ;200 mg/dl

IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

From The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus: Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. Diabetes Care 22(Suppl 1):5-19, 1999. Reproduced with permission of The American Diabetes Association, Inc.

*Rather than using the classic glucose tolerance curve with multiple time points sampled, the new criteria use, in parallel with fasting plasma glucose (FPG) measurements, a 2-hour post-glucose load (PG) set of criteria. The plasma sample is obtained 2 hours following an oral administration of 75 gm of anhydrous glucose in aqueous solution.

encompasses FPGs greater than 110 but less than 126 mg/dl. An FPG greater than 126 mg/dl establishes the diagnosis of diabetes mellitus.

Type II diabetics, previously known as noninsulin-dependent diabetics, represent about 90 percent of the diabetic population. However, those with type I diabetes (previously known as insulin-dependent or juvenile diabetes) also have an independently higher risk of cardiovascular events, and their disease generally develops at a much younger age than in the type II diabetic population.

PATHOPHYSIOLOGY OF THE CARDIOVASCULAR COMPLICATIONS OF DIABETES

A number of metabolic, cellular, and molecular mechanisms underlie diabetic CVD (Table 63-2) . A brief discussion of the most important pathophysiological concepts follows:

DYSLIPIDEMIA AND ASSOCIATED METABOLIC ABNORMALITIES (see alsoChap. 31).

The longest studied, best understood, and most substantiated mechanism for enhanced atherogenesis in type II diabetes is the dyslipidemia and associated cluster of risk factors known as the "metabolic syndrome" (Table 63-3) . Increased hepatic production of very low-density lipoproteins (VLDLs) by the liver lies at the center of the pathogenesis of diabetic dyslipidemia (Fig. 63-1) . The liver increases its production of VLDL in response to increased delivery of fatty acid from several sources. Uptake of free fatty acids by striated muscle depends on insulin. Under conditions of insulin resistance, striated muscle takes up less free fatty acids, which increases the presentation of free fatty acids to the liver. In addition, central obesity increases the delivery of free fatty acids to the liver. Abdominal obesity, particularly in men, consists primarily of increased visceral adipose tissue that is drained by the portal vein and delivers an excessive load of free fatty acid to the liver, where it furnishes the substrate for increased VLDL synthesis. The accumulation of triglyceride-rich lipoproteins in plasma depends not only on increased production of VLDL by the liver but also on decreased catabolism of triglyceride-rich lipoproteins, including dietary chylomicrons. Lipoprotein lipase activity decreases in uncontrolled type II diabetes. This enzyme

TABLE 63-2 -- MECHANISMS OF VASCULAR ABNORMALITIES IN DIABETES MELLITUS

Hyperglycemia
Increased diacylglycerol, protein kinase C activation
Increased sorbitol
Hyperinsulinemia
Oxidative stress
Reactive oxygen species
Carbonyl overload
Advanced glycation end products (AGEs)
Activation of nuclear factor kappa B (NF-kappaB)
Overproduction of inflammatory cytokines
Dyslipidemia
Small dense LDL
Low HDL
Hypertriglyceridemia
Procoagulant, antifibrinolytic state
Elevated fibrinogen
Increased plasminogen activator inhibitor (PAI)
Heightened platelet function
Genetic abnormalities
Peroxisomal proliferation-activating receptor-gamma (PPAR-gamma) mutations

HDL = high-density lipoprotein; LDL = low-density lipoprotein.

Hyperglycemia
Dyslipidemia
Hypercoagulability
Obesity
Hypertension

plays a key role in clearing postprandial lipemia, which largely consists of triglyceride-rich particles.

The increase in triglyceride-rich lipoprotein partially accounts for the low levels of high-density lipoprotein (HDL) characteristic of diabetic dyslipidemia. The high concentration of triglyceride-rich lipoproteins provides an increase in substrate for cholesterol ester transfer protein, which promotes the flux of cholesterol from HDL particles and decreases the level of HDL cholesterol. Part of HDL's protective effect against atherosclerosis may result from its ability to reduce the oxidation of low-density lipoprotein (LDL). In addition to a quantitative decrease in HDL cholesterol levels in uncontrolled diabetes, recent evidence suggests qualitative differences in HDL particles from poorly controlled type II diabetic patients. In particular, HDL isolated from such patients protects LDL from oxidation less effectively than does HDL from nondiabetic subjects.[8]

Curiously, diabetics tend to not have markedly elevated plasma LDL concentrations. However, LDL particles in uncontrolled type II diabetic patients characteristically have qualitative alterations as well. In particular, LDL from such diabetic subjects tends to be smaller and denser than typical LDL particles. These small, dense LDL particles show greater susceptibility to oxidative modification in vitro. Moreover, LDL from poorly controlled type II diabetics has increased susceptibility to oxidation because of decreased antioxidant defense mechanisms in the plasma of diabetics.[9]

Alterations in the traditional variables of the lipoprotein profile go hand in hand with other risk factors in diabetic patients. In addition to the triad of increased triglycerides, decreased HDL, and small dense LDL, insulin-resistant patients tend to have hypertension and obesity, as well as hyperglycemia (see Table 63-3). Abnormalities in coagulation and fibrinolysis in type II diabetes are considered below. The mechanistic link between visceral adiposity and diabetic dyslipidemia has already been discussed. Many life style or hygienic issues contribute to insulin resistance. For example, the visceral adiposity at the root of diabetic dyslipidemia commonly results from excessive caloric intake in the face of limited physical activity.

Genetic Predisposition.

Increasing evidence, however, supports the concept that genetic predisposition may contribute to the development of type II diabetes. Recent work has defined a specific mutation that leads to severe insulin resistance, diabetes mellitus, and hypertension. In two kindreds, dominant negative mutations in a transcription factor known as peroxisomal proliferation-activating receptor-gamma (PPAR-gamma) caused this insulin resistance constellation in members of two affected kindreds at a relatively young age.[10] Interestingly, the thiazolidinedione family of insulin-sensitizing agents acts by binding and activating the nuclear receptor/transcription factor PPAR-gamma. While this single-gene mutation probably accounts for the insulin resistance syndrome in a small number of individuals, it illustrates how a genetic abnormality can cause this condition. With completion of the human genome project and study of single-nucleotide polymorphisms increasingly practicable, other genetic predisposing factors for type II diabetes will probably emerge. These factors may well involve

Figure 63-1 Pathogenesis of diabetic dyslipidemia. Increased production of very low-density lipoprotein by the liver results from increased delivery of fatty acids because of decreased utilization by muscle and increased delivery of fatty acids from visceral abdominal fat to the liver via the portal circulation. Decreased catabolism of postprandial triglyceride-rich lipoprotein particles because of reduced lipoprotein lipase activity accentuates diabetic dyslipidemia (not shown here; see Fig. 31-4).

haplotypes or polygenic conditions, as well as single-gene mutations, as illustrated by the PPAR-gamma mutation.

OXIDATIVE STRESS IN DIABETES MELLITUS.

Numerous basic science and clinical studies indicate an increased level of oxidative stress in diabetes.[11] Hyperglycemia leads to increased production of reactive oxygen species by several cell types. The reactive oxygen species can, in turn, augment the formation of reactive carbonyl species. Nonoxidative reactions can also increase the concentrations of reactive carbonyl compounds under hyperglycemic conditions. The reactive carbonyl species can derivatize proteins and lipids. The products of reactions of proteins with reactive oxygen and carbonyl species include the advanced glycation end products (AGEs) discussed below. There is little doubt that products of glycation accumulate in diabetic patients. However, they accumulate in nondiabetic elderly individuals as well.[11] Recent evidence suggests that inundation of the detoxification mechanisms for reactive carbonyl groups may account for the increase in oxidant and carbonyl stress in diabetics.

From a practical standpoint, the issue of whether oxidant stress causes diabetic complications or merely serves as a marker of deranged metabolism is crucial. In several recent clinical trials that included diabetic subjects, the lack of a protective effect of antioxidant compounds suggests the importance of emphasizing measures known to improve cardiovascular outcomes in diabetic subjects, such as lipid management and angiotensin-converting enzyme (ACE) inhibitor administration, while awaiting further information regarding the potential benefits of antioxidant strategies.

ADVANCED GLYCATION END PRODUCTS AND THEIR RECEPTORS.

The hyperglycemia characteristic of diabetes leads to nonenzymatic glycation of macromolecules. Use of hemoglobin A_{1c} allows the clinician to gauge the extent of hyperglycemia in a patient by measurement of this glycated form of hemoglobin. In hyperglycemic states, many other proteins and even lipids can become glycated. The chemistry of nonenzymatic glycation involves the formation of a labile covalent link between the aldehyde function on the glucose molecule and amino side chains on sugars and lipids, which results in the formation of an aldimine or Schiff base. The aldimine slowly undergoes a chemical reaction to form a ketoamine by the Amadori rearrangement. The glycated hemoglobin commonly used to monitor diabetic patients is one such Amadori product.

However, more complex chemical reactions can ensue and allow condensation into larger heterocyclic derivatives of sugars linked to macromolecules. These structures, known as AGEs, are fluorescent and actually cause the macromolecule to take on a brown hue. Numerous chemical studies have characterized the structure of AGEs. A great deal of information is emerging regarding the potential significance of AGEs in the pathobiology of the complications of diabetes, notably, the accelerated vascular disease characteristic of this condition.[11] [12] [13] [14] Recent studies have shown accumulation of AGE-modified proteins, aside from hemoglobin, in diabetic subjects. The presence of glycated forms of LDL can engender an immune response and otherwise contribute to macrovascular disease.[15] Phospholipids and apolipoproteins can form AGEs.[16] AGE-modified LDL apoprotein and LDL lipid increase in diabetic subjects in comparison to nondiabetics.[16]

Cells contain several receptors for AGEs that mediate their biological effects. Exposure to AGE-modified proteins can elicit the production of inflammatory cytokines from vascular cells, cause impaired endothelial-dependent vasodilator function, and augment the endothelial expression of various leukocyte adhesion molecules implicated in atherogenesis in vivo.[17] [18] One extensively characterized receptor for AGEs is known as the receptor for advanced glycation end products, or RAGE.[19] Recent experiments support a functional role for RAGEs in the development of experimental atherosclerosis. Mice lacking the apolipoprotein E gene are susceptible to atherosclerosis. Administration of an antibody fragment that neutralizes RAGEs attenuated the atherosclerosis in these mutant mice. This beneficial effect on atherosclerotic lesion development did not depend on a change in blood sugar or lipoprotein profile.[20] These data support a role for AGEs in atherogenesis. However, they do not explain why the link between glycemic control and macrovascular disease in diabetes has proved so elusive.

EFFECTS OF THE DIABETIC STATE ON THROMBOSIS AND FIBRINOLYSIS.

Type II diabetes and its associated metabolic abnormalities favor an imbalance in the coagulation/fibrinolytic systems that support clot formation and stability.[21] Diabetic patients have increased levels of fibrinogen[22] and plasminogen activator inhibitor type 1 (PAI-1) in the plasma and in lesions.[23] [24] They also appear to have abnormal platelet function.[25] These various abnormalities may contribute to heightened susceptibility to the thrombotic complications of atherosclerosis.

ACTIVATION OF PROTEIN KINASE C IN DIABETES.

In diabetes, hyperglycemia can lead to an increased concentration of the metabolite diacylglycerol in the cell. Diacylglycerol, in turn, is a classic activator of a family of enzymes that perform key regulatory functions by phosphorylating proteins important in metabolic control. This family of enzymes, known as protein kinase C (PKC), has some dozen members. A great deal of recent work has implicated activation of the PKC family in the cardiovascular complications of diabetes.[26] [27]

Activation of PKC can inhibit expression of the endothelial form of nitric oxide synthase and thus promote impaired endothelial vasodilator function, as discussed below.[28] PKC can also augment cytokine-induced tissue factor gene expression and procoagulant activity in human endothelial cells.[29] Glucose-induced activation of PKC can augment the production of extracellular matrix macromolecules that accumulate during atherosclerotic lesion formation.[27] PKC activation can also increase the production of proinflammatory cytokines and the proliferation of vascular wall cells.[27] In vivo evidence supports a role of PKC activation in the pathogenesis of various aspects of vascular dysfunction in vivo. Administration of a selective inhibitor of PKC-beta to diabetic rats improves retinal blood flow.[30]

As discussed below, considerable evidence supports the existence of a diabetic form of cardiomyopathy distinct from ischemia. PKC activation may contribute not only to vascular dysfunction but also to cardiomyopathy in diabetes. Indeed, PKC-beta activity increases in the hearts of diabetic rats. Cardiac hypertrophy and fibrosis develop in transgenic mice overexpressing a PKC-beta isoform in the heart.[31] Early thickening of the interventricular septum, left ventricular hypertrophy, and a decrease in left ventricular dP/dt in concert with increased activity of PKC develop in diabetic rats.[32] These various studies provide evidence in vitro and in diabetic animals of a role of the PKC system in diabetic cardiovascular complications. Studies currently in progress will evaluate the relevance of this intriguing laboratory work to the clinical situation.

ABNORMAL VASODILATOR FUNCTION IN DIABETES.

The ability to measure vasodilator function in intact humans has furnished a new window into mechanisms of vascular dysfunction. Numerous studies have documented impaired endothelial-dependent vasodilator function in human arteries. Type I diabetics without hypertension or dyslipidemia had impaired endothelial-dependent vasodilator function when compared with age-matched nondiabetic subjects. The diabetic and nondiabetic groups had similar responses to endothelial-independent vasodilators.[33] Type II diabetic patients appear to have defects in both endothelial-dependent vasodilation and smooth muscle function.[34] [35] Experimental studies have indicated that overproduction of oxygen-derived free radicals in response to elevated glucose contributes to endothelial cell dysfunction.[36] Indeed, high doses of the antioxidant vitamin C can improve endothelial-dependent vasodilation in both type II[37] and type I[38] diabetic subjects. Further mechanistic studies have shown a significant correlation between insulin sensitivity and endothelial nitric oxide production.[39] Insulin's well-known vasodilator response depends in part on endothelial nitric oxide production. Type II diabetic subjects do not show improvement in endothelial-dependent vasodilation in comparison to lean nondiabetic controls when infused with insulin in glucose clamp experiments.[40] Acute hyperglycemia impairs endothelial-dependent vasodilation in both microvessels and macrovessels in normal subjects.[41] In type II diabetics, treatment of the dyslipidemia with a fibric acid derivative improves both fasting and postprandial endothelial function.[42] This finding shows that dyslipidemia, as well as hyperglycemia, can contribute to impaired endothelial vasodilator responses in diabetic humans. It further demonstrates the ability of therapy to improve endothelial-dependent vasodilation in humans.

As noted above, firm evidence now supports a link between genetics and the insulin-resistant syndrome. In this regard, first-degree relatives of type II diabetic patients who are normotensive and without overt diabetes show impaired endothelial-dependent vasodilation and insulin resistance, as determined by clamp studies.[43] This impaired endothelial vasodilatory function in the young first-degree relatives of type II diabetics did not depend on traditional risk factors.

Recent work has identified a novel potential mechanism for mediating impaired endothelial-dependent vasodilator function.[43A] An endogenous competitive inhibitor of nitric oxide synthase known as asymmetrical dimethylarginine (ADMA) is augmented in hypercholesterolemics.[44] Accumulation of ADMA may result from inhibition of its catabolism because of a reduction in activity of the enzyme dimethylarginine dimethylaminohydrolase.[45] Recent evidence suggests that dysregulation of this enzyme may raise levels of ADMA in diabetics.[45] [45A] These new findings provide yet another potential molecular pathway of impaired vascular function in diabetes.

EPIDEMIOLOGY OF CARDIOVASCULAR DISEASE IN DIABETES MELLITUS AND IMPAIRED GLUCOSE TOLERANCE

The prevalence of both diabetes and impaired fasting glucose is increasing within the U.S. population (see Fig. 63-1).[46] Approximately 6 percent of the U.S. population has diabetes, and only half of those cases have been diagnosed. Moreover, impaired glucose tolerance occurs twice as frequently as overt diabetes. This disease places a major demand on resources of the health care system. Data from a managed care organization on the 1-year cost of treating more than 85,000 patients with

diabetes as compared with age- and sex-matched nondiabetic counterparts confirm the impact of CVD in diabetes.[47] The largest proportion (17 percent) of the excess cost associated with diabetes was attributable to CAD. In contrast, end-stage renal disease accounted for 11 percent of the excess costs of treatment. The general population in the United States has enjoyed impressive declines in the mortality associated with heart disease in the last decades. However, the drop in cardiovascular mortality in diabetic men and women has lagged well behind that of the general population.[48] Two other important factors--aging of the U.S. population overall and the increasing prevalence of diabetes--suggest that the relationship between diabetes and coronary heart disease (CHD) morbidity and mortality will become even more important in the future.

CHD MORBIDITY AND MORTALITY IN TYPE II DIABETES MELLITUS

The clinical association between diabetes, elevated glucose, and CVD has been intensively studied for many years.[49] The excess morbidity and mortality remain even after adjustment for traditional CHD risk factors. In the Framingham Study, 20-year follow-up of individuals aged 45 to 74 years at the initial screening showed a twofold to threefold elevation in the risk of clinically evident atherosclerotic disease in those with diabetes as compared with the nondiabetic cohort.[50] These data also showed loss of the protection against CHD in women with diabetes, who had a rate of CHD mortality as high as that in diabetic men. In the Multiple Risk Factor Intervention Trial (MRFIT), more than 5000 men (out of approximately 350,000 screened) who reported taking medications for diabetes were monitored for an average of 12 years.[51] For every age stratum, ethnic background, and risk factor level, men with diabetes had an absolute risk of CHD death more than three times higher than that in the nondiabetic cohort, even after adjustment for established risk factors. Similar findings were seen in a large cohort of 11,554 white men and 666 black men between the ages of 35 and 64 screened from 1967 to 1973 and monitored prospectively for 22 years.[52] A recent Finnish study showed that diabetics without a prior myocardial infarction had the same risk of a first myocardial infarction as did nondiabetic survivors of myocardial infarction (Fig. 63-2) .[53] Data from the Rancho Bernardo Study and the Nurses' Health Study show that women with diabetes experience a disproportionately greater impact from diabetes than do men with diabetes.[54] [55]

CHD MORTALITY IN TYPE I DIABETES MELLITUS

Type II diabetes accounts for more than 90 percent of all cases of diabetes, and most studies of CHD risk have evaluated middle-aged or

Figure 63-2 Marked increase in the risk of coronary artery disease in type II diabetics. These data show a striking increase in the risk of a first or recurrent myocardial infarction in diabetics as compared with nondiabetic subjects in a population-based study in Finland over a 7-year follow-up period. These data also show that a diabetic without a history of previous myocardial infarction has an approximately equal risk for a first myocardial infarction as a nondiabetic subject who has already sustained myocardial infarction. These data support recent recommendations from the American Diabetes Association to treat diabetic subjects as though they already have established coronary artery disease. *(From Haffner SM, Lehto S, Ronnemaa T, et al: Mortality from coronary heart disease in subjects with type 2 diabetes and in nondiabetic subjects with and without prior myocardial infarction. N Engl J Med 339:229-234, 1998.)*

elderly populations consisting of mostly type II diabetics. However, a smaller collection of data also identifies an increased risk of CHD in patients with type I diabetes. In the Framingham Study, 292 patients with type I diabetes monitored for 20 to 40 years had a cumulative CAD mortality that was approximately 4 times that seen in nondiabetics (35 vs. 8 percent by age 55).[56] Regardless of the age of onset, the first deaths related to CAD occurred by the fourth decade of life, and the cumulative mortality rate increased at a similar rate in the subsequent 20 years. The increase in CAD mortality after age 30 appeared particularly striking in patients with renal complications, who had an estimated risk of CAD that was 15 times higher than that in patients without persistent proteinuria. Observational studies in other populations have made similar findings.[57] [58] [59] These data identify persistent proteinuria as a strong predictor of the development of CAD in this population. Proteinuria serves as a marker of generalized vascular damage that on a wider scale emerges as a predisposition to cardiovascular disease.

Aggregation of Traditional CHD Risk Factors in Diabetes

The high prevalence of "established" risk factors for CHD in diabetics complicates the epidemiological assessment of CHD in this patient population.[60] [61] [62] CHD risk factors such as hypertension, dyslipidemia, and obesity cluster in patients with diabetes.[4] In type II diabetics at time of diagnosis, over 50 percent have hypertension and over 30 percent have hypercholesterolemia. In MRFIT, the "classic" risk factors known to predict CVD mortality in nondiabetics--serum cholesterol (;200 mg/dl), systolic blood pressure (;120 mm Hg), and cigarette smoking--independently predict CVD mortality in diabetic subjects.[51] Most men in either the diabetic or nondiabetic group had one or more of these risk factors, with the majority having two or more. Within each stratum of risk (no risk factors, one only, two only, all three), CVD mortality was substantially higher for men with diabetes (Fig. 63-3) . Notably, there was a synergistic effect of diabetes and other risk factors such that the presence of any single risk factor or the combination of any two or all three was associated with a steeper increase in CVD mortality in men with diabetes than in those without it.

Figure 63-3 Age-adjusted cardiovascular disease death rates according to the presence of a number of risk factors for men with and without diabetes at baseline who were screened for the MRFIT. The presence of diabetes confers a steep increase in the cardiovascular death rate at any level of concomitant risk factors. *(From Stamler J, Vaccaro O, Neaton JD, et al: Diabetes, other risk factors, and 12-yr cardiovascular mortality for men screened in the Multiple Risk Factor Intervention Trial. Diabetes Care 16:434-444, 1993. Reproduced with permission of the American Diabetes Association, Inc.)*

The United Kingdom Prospective Diabetes Study (UKPDS) has provided perhaps the most compelling data to support the importance of risk factor aggregation in enhancing the CHD risk profile of patients with newly diagnosed diabetes.[63] This study evaluated a large number of middle-aged subjects with newly detected type II diabetes (n=3055), in 335 of whom CAD developed during a median follow-up of 8 years. CAD was significantly associated with increased concentrations of LDL cholesterol, decreased concentrations of HDL cholesterol, increased levels of hemoglobin A_{1c} and systolic blood pressure, and a history of smoking as measured at baseline.

Plasma Glucose as an Independent Risk Factor for Atherosclerosis

Although diabetes clusters with the admixture of traditional risk factors for CHD mentioned above, the rate of CHD morbidity and mortality in diabetics exceeds the rate expected from the interaction of these multiple risk factors by approximately 50 percent. Hyperglycemia itself has emerged as a leading candidate responsible for this excess CHD risk in diabetes.

Compelling data in this regard have emerged from prospective observations of patients with type II diabetes in which patients were stratified by fasting glucose levels.[64] [65] In one such study, the average fasting blood glucose level independently related to all-cause (p=0.0002), cardiovascular (p=0.0006), and ischemic heart disease (p=0.03) mortality (Fig. 63-4) . No obvious threshold level for this association was noted; rather, the lower the fasting blood glucose level, the better the outcome. Comparable results in the San Antonio Heart Study substantiate a dose-response relationship between hyperglycemia and CVD mortality.[65] In this study, diabetic subjects in the top quartile of FPG had a risk of CVD mortality 4.7 times greater than did diabetic subjects in quartiles 1 and 2 combined (p=0.01). This increase in risk remained after adjustment for other potential risk factors. The graded, continuous pattern linking hyperglycemia and CVD risk in type II diabetes also applies to subjects with type I diabetes. Ten-year follow-up in the Wisconsin Epidemiological Study of type I diabetics showed that for each 1 percent increase in glycated hemoglobin, the hazard ratio for CHD mortality nearly doubled.[66] Indeed, even in individuals without frank diabetes, evidence points to a continuum of CHD risk that is dependent on glucose levels across the spectrum from normal glucose tolerance through impaired glucose tolerance to diabetes.[67] Data from a cohort study performed in Rancho Bernardo showed that in both men and women, the incidence of myocardial infarction and stroke correlated positively with glucose tolerance status. Other studies in diverse populations have also generally

Figure 63-4 All-cause mortality, cardiovascular mortality, and ischemic heart disease mortality in patients with type II diabetes by quintiles of average fasting blood glucose. Cardiovascular mortality and all-cause mortality increase throughout the range of fasting plasma glucose levels in a graded fashion. *(From Andersson DK, Svardsudd K: Long-term glycemic control relates to mortality in type II diabetes. Diabetes Care 18:1534-1543, 1995. Reproduced with permission of the American Diabetes Association, Inc.)*

shown a graded relationship between glucose tolerance and the rate of CHD events.[52] [68] [69]

Investigations into the relationship between glucose and CHD risk in the studies noted above focused on CHD or ischemic mortality as the endpoint. Although powerful indicators of the graded, continuous effect of glucose, these studies do not provide any evidence of glucose's effect on the vessel wall itself. Several studies have evaluated intima-media thickness (IMT) of the carotid artery by ultrasound.[70] [71] [72] [73] Carotid IMT correlates well with cardiovascular risk factors and the occurrence of CHD.[74] In the Atherosclerosis Risk in Communities (ARIC) Study, carotid wall thickness correlated with fasting glucose tolerance in all gender and race subgroups in a large and diverse sample of 15,800 subjects aged 45 to 64 without symptomatic CVD (Fig. 63-5) .[70]

It is still unclear whether CVD risk is distributed across a continuum of glucose values in diabetic subjects or whether a critical value exists above which CVD rates increase. Also, whether evidence of an association is altered by the method of evaluating plasma glucose (postchallenge vs. fasting) requires further investigation. In a study from Japan in a population cohort of men, postchallenge glucose was a better predictor of CVD death than wave fasting glucose levels.[75] In general, the results of studies examining this relationship are difficult to compare because of differences in study design (e.g., longitudinal vs. cross-sectional), endpoints (e.g., CVD event rates vs. changes in carotid IMT), and patient populations.

Insulin Resistance as an Independent Risk Factor

As stated previously, diabetes clusters with other CVD risk factors, among them hypertension, obesity, and dyslipidemia. Almost all subjects with a combination of these metabolic disorders also have insulin resistance.[76] Hyperinsulinemia may provide the crucial link between hyperglycemia and CVD (see Table 63-3).[77] This collective occurrence of multiple metabolic abnormalities in an individual patient has been variously termed syndrome X, the insulin resistance syndrome, and cardiovascular dysmetabolic syndrome. Data from a number of studies indicate that hyperinsulinemia independently predicts CVD risk. For example, in a large (n=1625) triethnic population consisting of equal numbers of subjects with diabetes, hyperglycemia, and normal glucose tolerance, insulin resistance correlated positively with atherosclerosis as assessed by carotid IMT.[78] Since insulin resistance typically precedes the development of hyperglycemia, these findings may explain, in part, the elevated risk of CHD that is found in individuals with newly diagnosed type II diabetes.

Figure 63-5 Sex- and race-specific associations between average carotid artery intima-media thickness (IMT) by fasting glucose status and the presence of diabetes mellitus in participants free of cardiovascular disease at baseline in the Atherosclerosis Risk in Communities (ARIC) Study from 1987 to 1989. The average carotid IMT increases across the entire range of fasting glucose levels. *(From Folsom AR, Eckfeldt JH, Weitzman S, et al: Relation of carotid artery wall thickness to diabetes mellitus, fasting glucose and insulin, body size, and physical activity. Atherosclerosis Risk in Communities [ARIC] Study Investigators. Stroke 25:66-73, 1994. By permission of the American Heart Association.)*

Other data suggest that endogenous insulin itself, rather than insulin resistance, may have direct adverse effects on the cardiovascular system. One case-control study monitored over 2000 nondiabetic men without apparent ischemic heart disease at baseline for 5 years.[79] Individuals who had experienced a CHD event had fasting insulin concentrations at baseline that were 18 percent higher than in controls (p<0.001), an association that remained valid after adjusting for the potentially confounding effects of systolic blood pressure, plasma triglycerides, apolipoprotein B, and LDL and HDL cholesterol.

RISK FACTOR INTERVENTION TO REDUCE CHD IN PATIENTS WITH DIABETES MELLITUS (see also Chap. 32)

Intensive Glycemic Control

Numerous studies have shown a positive correlation between CHD endpoints and increasing glucose levels in patients with diabetes. In the UKPDS, hemoglobin A_{1c} levels above 6.2 percent were associated with an increased risk of macrovascular disease.[63] For each 1 percent elevation in hemoglobin A_{1c} , CHD risk increased by 11 percent. However, it also appeared that the relative risk of CHD did not increase in association with hemoglobin A_{1c} levels below 7 percent, thus suggesting a threshold. Therefore, several clinical trials have sought to determine whether intensive treatment of blood glucose levels can reduce the risk of CHD associated with diabetes.

In the Diabetes Control and Complications Trial (DCCT), 1441 patients with type I diabetes (mean age of 27 years) and no significant retinopathy at baseline were randomized to intensive glycemic control (external insulin pump or three or more insulin injections per day) or conventional therapy (one to two insulin injections per day).[80] Patients were monitored prospectively for a mean of 6.5 years, with regular assessment of microvascular and macrovascular outcomes. After 5 years, the cumulative incidence of retinopathy was approximately 50 percent less in the intensive-treatment group than in the

conventional-treatment group (p < 0.001). Intensive therapy also reduced the risk of macrovascular disease (cardiovascular and peripheral vascular disease) by 41 percent, although the difference between groups lacked statistical significance. A second, smaller Veterans Affairs (VA) Study that tested the feasibility of intensive blood glucose control in type II diabetics also showed no significant differences in cardiovascular endpoints between treatment arms.[81] These two trials had a number of important limitations. Both lacked adequate power to detect a difference in macrovascular events between treatment groups given the small number of events in each group. In the DCCT, the low event rate probably resulted from the relative youth of the study population, and in the VA Study, it probably resulted from the small patient population and a short follow-up period.

Larger, adequately powered studies such as UKPDS showed a nonsignificant trend in favor of intensive blood glucose control in terms of reduction of myocardial infarction.[82] This trial randomized 3867 patients with newly diagnosed type II diabetes to intensive therapy (diet plus oral therapy or insulin) or conventional therapy. Patients entered into the study had a low background prevalence of CHD and a low rate of CHD risk factors. Patients were monitored for approximately 10 years. As in the DCCT, microvascular endpoints were improved in the intensive-therapy arm. A trend toward a reduced rate of myocardial infarction was also noted in the group receiving intensive blood glucose control (p=0.052). [82]

Treatment of Hypertension in Diabetics (see also Chaps. 28 and 29)

Hypertension and diabetes frequently occur together as part of the dysmetabolic syndrome. The addition of hypertension to the clinical picture of diabetes amplifies the already high risk of CVD in these patients. In addition, hypertension significantly contributes to the development of microalbuminuria and retinopathy in diabetes. The role of antihypertensive therapy in reducing cardiovascular morbidity and mortality in patients with diabetes has engendered controversy, as in patients without diabetes. In nondiabetics, older trials of diuretic and beta blocker antihypertensive therapy did not show a reduction in cardiovascular mortality. The deleterious effects of these agents on metabolic indices (triglycerides, HDL, and blood sugar) may have accounted for these findings. Contemporary antihypertensive agents, including calcium channel blockers (CCBs) and ACE inhibitors, do not adversely affect metabolic factors that might counteract the benefits of blood pressure lowering.

Two recent trials compared the effects of CCBs and ACE inhibitors in patients with type II diabetes.[83] [84] They showed a greater reduction in CHD endpoints with an ACE inhibitor than with a dihydropyridine CCB. The results of these two studies suggested that CCBs did not benefit and might even harm diabetic patients at high risk for cardiovascular events. Although the results of these trials imply that ACE inhibitors would be the preferred agents for treating diabetic patients, interpretation of these relatively small studies in which cardiovascular endpoints were not the primary outcome measure requires caution.[85] More rigorously designed studies, such as the UKPDS and the Systolic Hypertension in Europe Trial (Syst-Eur), have not supported the findings of the two smaller trials noted above and have shown beneficial effects for both ACE inhibitors and CCBs in patients with diabetes (Table 63-4) .[85A] For example, in the UKPDS,[86] 1148 hypertensive patients with type II diabetes responded equally well to captopril or atenolol in terms of achieving blood pressure control and had similar reductions in the risk of macrovascular disease. Myocardial infarction declined 21 percent in the group randomized to tight blood pressure control (p=NS). This group also had a 44 percent reduction in the risk of fatal and nonfatal stroke when compared with the group assigned to less tight blood pressure control. Although the blood pressure achieved in the UKPDS subgroup assigned to tight blood pressure control was good (144/82), data from the Syst-Eur Trial[87] [89] and the Hypertension Optimal Treatment (HOT) Trial[88] indicate that achieving even lower blood pressure goals is associated with low rates of cardiovascular complications during CCB-based therapy. A recent analysis of initially nondiabetic subjects in the Atherosclerosis Risk in Communities (ARIC) Study showed no increased risk of developing diabetes when treated with ACE inhibitors, CCB, or thiazides.[89A] However, there was a 28% increased risk of developing diabetes in those who received beta blockers in this study.

Treatment of Dyslipidemia in Diabetics(see also Chaps. 31 and 33)

The central role of diabetic dyslipidemia in accelerating atherosclerosis in type II diabetics has major therapeutic implications. While strict glycemic control in and of itself does not appear to consistently reduce macrovascular disease, tight glycemic control can ameliorate features of the lipoprotein profile associated with increased risk. Thus, as in all individuals with or at risk for atherosclerosis, individuals with impaired glucose intolerance or frank diabetes or those with a strong family history of type II diabetes should have intense counseling regarding life style modification. In particular, achieving and maintaining an ideal body weight and performing regular

aerobic exercise can improve insulin sensitivity. Even though LDL levels often lie within the average range in type II diabetic subjects, treatment with 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors reduces coronary risk.[90] [91] Furthermore, treatment with fibric acid derivatives targets in particular the low HDL and high triglycerides characteristic of diabetic dyslipidemia. The results of the recent Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) suggest that a population of individuals, many of whom have a lipoprotein profile of insulin resistance, show a reduction in coronary events and stroke when treated with a fibric acid derivative.[92] The recent Diabetes Atherosclerosis Intervention Study (DAIS) showed delayed angiographic progression of coronary atherosclerosis in diabetic patients treated with fenofibrate.[92A] The thiazolidinedione agents improve insulin sensitivity by activating PPAR-gamma. Future work should define the role of the thiazolidinediones in preventing the cardiovascular complications of type II diabetes inasmuch as the rationale for a beneficial effect appears strong.

TREATMENT OF ACUTE CORONARY SYNDROMES IN DIABETES MELLITUS

PROGNOSIS.

Diabetic patients have higher mortality than nondiabetics do during the acute phase of myocardial infarction, as well as in short- and long-term follow-up. The diabetic population will comprise a greater proportion of patients with myocardial infarction in the future. Numerous mechanisms in diabetic patients conspire to increase the risk of myocardial infarction. This section will review the state of knowledge regarding optimizing treatments for this important population with acute coronary syndromes

FIBRINOLYTIC THERAPY IN DIABETICS (see also Chap. 35).

Fibrinolytic therapy has reduced early and late mortality from acute myocardial infarction in patients with and without diabetes. Despite some concern that the elevated levels of PAI-1, fibrinogen, coagulation factors, and reactive platelets commonly encountered in diabetes might reduce the likelihood of successful reperfusion,[93] both the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) and the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO-1) thrombolysis trials demonstrated similar infarct-related artery patency rates in diabetic and nondiabetic subgroups.[94] [95] [96] Indeed, diabetic patients experience the same or greater benefit from thrombolysis as nondiabetics do. In the Second International Study of Infarct Survival (ISIS-II), diabetic patients receiving streptokinase had a 31 percent improvement in survival in comparison to placebo, greater than the 23 percent improvement seen in the nondiabetic group. Pooled data from five recent major thrombolysis trials show that 30-day mortality has been substantially reduced to 11 percent in diabetics and 6 percent in nondiabetics--an odds ratio similar to that observed in the earlier literature. Formerly, concern about hemorrhage from diabetic retinopathy made diabetes a contraindication to thrombolysis. However, only 1 of 6011 (0.02 percent) diabetic patients receiving thrombolytic therapy experienced intraocular hemorrhage.[97]

TABLE 63-4 -- LARGE STUDIES EVALUATING ANTIHYPERTENSIVE THERAPY IN PATIENTS WITH DIABETES MELLITUS

SOURCE, YEAR	NO. OF PATIENTS (% WITH DIABETES)	STUDY ENTRY CRITERIA	TYPE OF DRUGS	FOLLOW-UP, YEARS	BLOOD PRESSURE EFFECTS	MAIN RESULTS
Placebo-Controlled Studies						
SHEP,[5] 1996	583 (12.3)	Systolic hypertension defined as 160-219 mm Hg; diastolic, <90 mm Hg	Placebo vs. diuretic-based (chlorthalidone)	4.5	Difference between diuretic and placebo group was 9.8 mm Hg systolic and 2.2 mm Hg diastolic	Benefit of drug similar to cohort without diabetes; 34% decrease in cardiovascular events in cohort with diabetes
Syst-EUR,[6] 1999	492 (10.5)	Systolic hypertension defined as 160-219 mm Hg; double-blind; diastolic, <95 mm Hg	Placebo vs. nitrendipine	2§	Difference between nitrendipine and placebo group was 8.6 mm Hg systolic and 3.9 mm Hg diastolic	Drug benefit greater than in cohort without diabetes; decrease in total mortality (55%), cardiovascular mortality (76%), and cardiovascular events (69%) in cohort with diabetes
HOPE,[7] 2000	3578 (38.5)*	Diabetes and 1 other cardiovascular risk factor or No diabetes and history of cardiovascular disease	Ramipril and vitamin E vs. placebo	4.5¶	Difference between ramipril and placebo group was <2 mm Hg systolic and 1 mm Hg diastolic	Angiotensin-converting enzyme inhibitor superior, decrease in primary outcome (24%) and total mortality (25%) in cohort with diabetes
Treat to Blood Pressure Target Studies						
HOT,[8] 1998	1501 (8)	Diastolic hypertension defined as 100-115 mm Hg; randomized into 3 target blood pressure groups of approximately 500	Felodipine-based and angiotensin-converting enzyme inhibitor, beta-blocker, or diuretic	3.8§	Difference among the 3 groups at end point was approximately 4 mm Hg	Benefit only detected in cohort with diabetes; decrease in cardiovascular mortality (67%) and events (51%) in cohort with diabetes with the lowest levels of blood pressure
UKPDS,[4] [9] 1998	1148 (100)	Open randomization	Less tight blood pressure control vs. tight control; further randomization to captopril or atenolol	8.4§	Less tight blood pressure control, 154/87 mm Hg; tight control, 144/82 mm Hg; similar reduction in blood pressure with both drugs	Captopril treatment not superior; decrease in diabetes-related events (24%) and death (32%); decrease in acute myocardial infarction (21%) in tight blood pressure cohort
Angiotensin-Converting Enzyme Inhibition vs Other Agents Studies						
CAPPP,[10] 1999	572 (5.2)	Diastolic hypertension defined as >100 mm Hg	Captopril vs. diuretic or beta-blocker	>6§	Baseline blood pressure greater in captopril group; similar reduction with both drugs	Captopril treatment superior in cohort with diabetes; decrease in primary end point (40%), acute myocardial infarction (65%), and all cardiovascular events (33%) in cohort with diabetes treated with captopril
ABCD,[11] 1998	470 (100)	Diabetes and diastolic hypertension defined as 90 mm Hg	Nisoldipine vs. enalapril	5¶	Similar reduction in blood pressure with both drugs	Fatal and nonfatal acute myocardial infarction for 25 patients taking nisodipine and 5 cases taking enalapril
FACET,[12] 1998	380 (100)	Systolic hypertension defined as >140 mm Hg or diastolic hypertension defined as >90 mm Hg	Amlodipine vs. fosinopril	<3§	Similar reduction in blood pressure with both drugs	Decrease in cardiovascular events for patients taking fosinopril (14/189 vs. 27/191)

SHEP = Systolic Hypertension in the Elderly Program; Syst-EUR = Systolic Hypertension in Europe; HOPE = Heart Outcomes Prevention Evaluation; HOT = Hypertension Optimal Treatment; UKPDS = United Kingdom Prospective Diabetes Study; CAPPP = Captopril Prevention Project; ABCD = Appropriate Blood Pressure Control in type II diabetes trial; FACET = Fosinopril versus Amlodipine Cardiovascular Events randomized Trial.

From Cooper ME. Johnston CI: Optimizing treatment of hypertension in patients with diabetes. JAMA 283:3178-3179,2000.

§Values are expressed as medians.
* Of the 3578, 1808 received placebo and 1770 received ramipril.
¶Values are expressed as means.

Of the 1148, 390 had less tight blood pressure control. The 758 who had tight blood pressure control were randomized, and 400 received captopril and 358 received atenolol.

Of the 572, 309 received captopril vs. 263 who received a diuretic or beta-blocker.

MECHANISMS OF AGGRAVATION OF OUTCOMES.

Mortality after acute myocardial infarction correlates with the severity of left ventricular dysfunction. The nature and time course of left ventricular remodeling are major determinants of this risk. Numerous factors related to diabetes may adversely affect remodeling. Previous silent infarction, diabetic cardiomyopathy, hypertension,[98] and autonomic dysfunction[99] are conditions that either alone or in combination can affect non-infarct zone function and predispose to ventricular remodeling.[85] [100] [101] Endothelial cell dysfunction may result in impaired coronary perfusion and lead to ischemia.[102] Diabetes also retards coronary collateral development.[103]

Metabolic changes in diabetes may also contribute to the worsened prognosis of this group of patients with acute coronary syndromes. Insulin resistance impairs the ability of the heart to metabolize free fatty acids. Ordinarily, ischemia increases levels of the glucose transporter protein GLUT-4 (the predominant insulin-sensitive glucose transporter) in human myocardium, which augments glycolysis and adenosine triphosphate (ATP) production. In diabetes, elevated free fatty acid levels depress GLUT-4 activity and, hence, glucose entry and glycolysis in myocardial cells. This shift in substrate supply results in less efficient ATP production and the generation of oxygen free radicals, both of which impair left ventricular contractile performance.[104]

Autonomic nervous system (ANS) dysfunction in diabetes can also contribute to excess mortality (see below for an extended discussion of a cardiovascular autonomic neuropathy in diabetes). Approximately 50 percent of people with diabetes for 10 or more years have impaired heart rate variability because of parasympathetic denervation, which results in a relative increase in sympathetic tone. Sympathovagal imbalance may alter hemostasis in favor of thrombosis, lower the threshold for coronary plaque disruption, alter the circadian pattern of ischemia, and increase the risk for reinfarction and ventricular arrhythmia.[105] [106] [107] Elevated levels of PAI-1, fibrinogen, and coagulation factors (factors VII, IX, X, and XII), combined with hyperaggregable platelets, also contribute to an increased risk for early and late reinfarction in diabetic patients.[93] [108] [109]

Such factors may also account for the twofold higher risk of death conferred by diabetes that was observed in the control treatment arms of trials that evaluated the efficacy of platelet glycoprotein IIb/IIIa inhibitors in unstable angina/non-Q-wave infarction, such as the PURSUIT (Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy) Trial or the PRISM PLUS (Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms) Study. At 7 and 30 days, diabetics with unstable coronary syndromes experienced a mortality rate similar to that of nondiabetics with Q wave infarction.[110] [111]

Medical Therapy

ASPIRIN

Studies have consistently shown that patients with either type I or type II diabetes have enhanced platelet aggregation in response to a variety of agonists.[112] Platelets from diabetic patients exhibit increased production of thromboxane, a potent vasoconstrictor and platelet agonist.[113] In the Early Treatment of Diabetic Retinopathy Study (ETDRS), patients with type I or type II diabetes randomized to aspirin 650 mg/d had a significantly lowered risk of myocardial infarction without incurring an increase in the risk of vitreous or retinal bleeding, even in patients with retinopathy.[114] In the Bezafibrate Infarction Prevention Study (BIPS), an observational analysis of aspirin use by individuals with a history of CAD, the absolute benefit per 100 patients treated with aspirin in diabetic patients exceeded that in nondiabetic patients (cardiac mortality reduction, 5 vs. 2.1 percent; total mortality, 7.8 vs. 4.1 percent).[115] The American Diabetes Association currently recommends enteric-coated aspirin in a dose of 81 to 325 mg/d (1) as secondary prevention in men and women with diabetes and evidence of macrovascular disease and (2) as primary prevention in persons with type I or II diabetes and additional coronary risk factors.[116]

BETA-ADRENERGIC BLOCKING AGENTS

Despite overwhelming evidence that beta-adrenergic blocking agents (beta blockers) reduce mortality and reinfarction in patients with myocardial infarction, their use in diabetic patients has only recently become accepted. Beta blockers produced an early and late post-myocardial

infarction survival benefit in comparison to placebo in patients with diabetes that exceeded the degree of benefit seen in their nondiabetic counterparts in several studies.[117] Although these data derive from retrospective subgroup analyses of trials in the prethrombolytic era, they concur with more recent results. The National Cooperative Cardiovascular Project reviewed over 45,000 patients, 26 percent of whom had diabetes. After adjusting for confounding variables, beta blocker use was associated with a lower 1-year mortality rate in diabetic patients without an increase in diabetes-related complications.[118] Furthermore, a recent post hoc analysis of the BIPS Study demonstrated that the use of beta blockers was associated with improved long-term survival in a large group of type II diabetic subjects, 30 percent of whom had never experienced a prior myocardial infarction.[119]

The greater relative benefit of beta blockers in the presence of diabetes may derive from several factors. Beta blockers can help restore sympathovagal balance in diabetic patients with autonomic neuropathy. These drugs may also decrease free fatty acid utilization within the myocardium and hence reduce oxygen need. Beta blockers can, however, mask the warning signs of hypoglycemia, inhibit the glycemic response to hypoglycemia by suppressing glycogenolysis, interfere with insulin release, and further impair glucose tolerance in patients with diabetes. In addition, some clinicians have concerns that beta blockers may elevate serum triglycerides, reduce HDL, and increase LDL and thereby potentially counteract some of the widely accepted cardioprotective benefits of these drugs. However, recent data indicate that the currently used beta blockers may not adversely affect the lipid profile.[120] Much of the concern surrounding the use of these drugs in diabetes stems from earlier experience with noncardioselective agents in higher dosage. The risk of hypoglycemia in diabetic hypertensive patients taking cardioselective beta blockers was no different from that of patients taking placebo.[121] Cardioselective agents have less tendency to worsen glycemic control than nonselective agents do, although diabetes may develop in over 20 percent of nondiabetic hypertensive patients given beta blockers.[89A]

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors reduce infarct size, limit ventricular remodeling, improve survival after myocardial infarction, and may be of particular benefit in patients with diabetes.[85] A post hoc analysis of one thrombolytic trial (Grupo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardico-3 [GISSI-3]) revealed that early administration of lisinopril in the setting of acute myocardial infarction reduced 6-week and 6-month mortality comparatively more in diabetic versus nondiabetic patients (30 vs. 5 percent reduction at 6 weeks and 20 vs. 0 percent at 6 months, respectively). Lisinopril administration resulted in 37 lives saved per 1000 treated diabetic patients. Another retrospective analysis, the Trandolapril in Patients with Reduced Left Ventricular Function after AMI (TRACE) Study, compared the effect of oral trandolapril versus placebo in anterior myocardial infarction in patients with and without diabetes.[122] Patients with diabetes experienced a greater relative improvement in survival over 5 years of follow-up than did the nondiabetic cohort. Furthermore, ACE inhibitor treatment reduced by nearly 50 percent the risk of sudden death, reinfarction, and progression of congestive heart failure (CHF) in patients with diabetes, whereas subjects without diabetes experienced only trends in protection against these secondary outcomes.

Many factors may explain the particular benefits of ACE inhibitors in diabetic patients with acute myocardial infarction. These agents can prevent or limit remodeling of the ventricle, particularly when administered early in the course of acute myocardial infarction,[123] reduce recurrent ischemic events,[124] and restore sympathovagal imbalance.[125] ACE inhibitors may also improve endothelial function in diabetes,[126] counteract reduced fibrinolysis by suppression of PAI-1 expression,[127] and decrease insulin resistance.[128] In one recent study (Heart Outcomes Prevention Evaluation [HOPE]), ramipril significantly reduced the rates of myocardial infarction, stroke, and cardiovascular death in diabetic subjects with or without a prior history of CAD or CHF over a 5-year period when compared with placebo.[129] The ACE inhibitor's efficacy in the absence of a clinical history of CHF and hypertension in the majority of patients in the HOPE Study points to the importance of these nonhemodynamic benefits of ACE inhibitors.

These potent antiplatelet agents have improved outcomes in patients with unstable angina and non-Q-wave infarction. Overall, glycoprotein IIb/IIIa antagonists have equal or better efficacy in diabetic than nondiabetic patients. Adverse effects (mostly bleeding) also appear equivalent in diabetics.

The PRISM PLUS Study compared heparin with heparin plus tirofiban

in 362 patients with diabetes and 1208 without diabetes.[111] At 7 days, the cumulative endpoint of death, myocardial infarction, refractory ischemia, or rehospitalization for unstable angina in diabetic patients was reduced from 21.8 percent with heparin alone to 14.8 percent with heparin plus tirofiban. In nondiabetic subjects, the cumulative endpoint was reduced from 16.7 to 12.4 percent when tirofiban was added to heparin. Despite the increased aggregability of platelets in patients with diabetes, no significant difference was observed in the ability of standard dosing of abciximab to achieve 80 percent or greater platelet inhibition during a 12-hour infusion in patients with and without diabetes.[130]

In the EPILOG (Evaluation of PTCA to Improve Long-Term Outcomes by c7E3 Glycoprotein IIb/IIIa Receptor Blockade) Trial, abciximab treatment resulted in fewer acute adverse events after percutaneous transluminal coronary angioplasty (PTCA) in both the diabetic and nondiabetic groups, although longer-term follow-up revealed a higher rate of target vessel revascularization if diabetes were present.[131] In the EPISTENT (Evaluation of Platelet IIb/IIIa Inhibition in Stenting) Trial, however, a highly significant 51 percent decrease (8.1 vs. 16.6 percent; p=0.02) in target vessel revascularization at 6 months was experienced by stented diabetic patients randomized to abciximab versus stented diabetic patients receiving placebo.[132]

INSULIN

Recent studies have evaluated the role of strict glycemic control in diabetic patients during the acute phase of myocardial infarction. The blood glucose level may increase in proportion to infarct size and hemodynamic stress in nondiabetic patients with myocardial infarction as catecholamines, cortisol, and growth hormone are released. These hormones may create "transient" insulin resistance, with serum glucose returning to normal at discharge. In some cases, a very high admission glucose level out of proportion to infarct size indicates previously undiagnosed diabetes. Nevertheless, substantial evidence points to the admission glucose level as an independent predictor of early and late mortality after myocardial infarction in patients with and without diabetes mellitus.[133] [134] [135] [136]

The Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) Study randomized 620 diabetic patients with acute myocardial infarction to either intensive insulin therapy (insulin-glucose infusion for 24 hours, followed by subcutaneous insulin injection for 3 months) or a standard glycemic control strategy.[137] Those receiving the intensive insulin regimen had a lower blood glucose level during the first hour (9.6 vs. 11.7 mmol/liter; $p < 0.01$) and at discharge (8.2 vs. 9.0 mmol/liter; $p < 0.01$) than the control group did. The infusion group had a significant reduction in 1-year mortality when compared with the control group (19 vs. 26 percent; $p < 0.027$). The two groups were similar in baseline characteristics and in other treatments received. After 3.4 years, mortality remained lower in the insulin infusion group than the group receiving conventional care (33 percent in the infusion group and 44 percent in the control group; p=0.011). Predictors of mortality were age, history of CHF, diabetes duration, admission glucose, and admission hemoglobin A_{1c} level.[138] The greatest survival benefit was seen in the subgroup whose diabetes had been managed with diet or oral hypoglycemic drugs before infarction.

Several mechanisms may explain the findings of the DIGAMI Trial. Insulin-glucose infusion may (1) increase the availability of glucose as a substrate for ATP generation in cardiac muscle; (2) reduce lipolysis and decrease the generation of free fatty acids, which can impair myocardial contractility and trigger ventricular arrhythmia; and (3) shift cardiac metabolism from free fatty acid oxidation to glycolysis. In addition, tight glycemic control can reverse hyperglycemia-induced platelet reactivity and reduce the typically elevated PAI-1 activity in patients with diabetes. Part of the benefit derived from the use of insulin in the tight control arm may have resulted from the removal of any potential cardiac risk associated with the use of sulfonylureas (see below).

SULFONYLUREAS

In the 1970s, the University Group Diabetes Program (UGDP), a prospective trial evaluating the efficacy of tolbutamide versus insulin in patients with type II diabetes, reported an increase in cardiovascular mortality and CAD in the group assigned to tolbutamide.[139] A smaller study reported similar results.[140] Despite controversy at the time, the sulfonylurea class of hypoglycemic agents have become widely used as the benefits of improved glycemic control in preventing diabetes-related microvascular complications have become established.

The UKPDS investigated the impact of tight glycemic control with a variety of treatment strategies on the incidence and severity of microvascular and macrovascular complications in newly diagnosed diabetes. A higher incidence of sudden death or myocardial infarction was not seen in patients assigned to sulfonylureas over a 10-year follow-up.[82] A retrospective study recently identified sulfonylurea use as a risk factor for in-hospital mortality among diabetic patients undergoing PTCA for acute myocardial infarction.[141]

Concern over the use of sulfonylureas, particularly in the setting of myocardial injury, stems from their blockade of ATP-sensitive potassium channels (K^+ -ATP). [142] [143] In the pancreas, such inhibition results in the secretion of insulin, thus accounting for the hypoglycemic effect of these drugs. In the myocardium, however, blockade of K^+ -ATP channels may limit ischemic preconditioning, a cardioprotective mechanism, and attenuate coronary vasodilation.[144] [145] [146] In patients undergoing PTCA 90 minutes after receiving either glibenclamide or placebo, intracoronary electrocardiograms (ECGs) were recorded at the end of the first and second balloon inflations. The group pretreated with glibenclamide experienced no difference in the degree of ST segment shift from the first to the second inflation. The placebo group, however, demonstrated less ST segment shift and had less pain with the second balloon inflation, which is an indication of induction of ischemic preconditioning not present in the sulfonylurea-treated patients.[147] Another study using treadmill-induced ischemia showed no abolition of ischemic preconditioning with glibenclamide versus placebo.[148] The number of sulfonylurea drugs has grown since the initial concerns raised by the UGDP Study. Glibenclamide but not glimepiride significantly inhibited the forearm vasodilator response to the activation of K^+ -ATP channels by diazoxide, which suggests that different sulfonylureas have different specificities for vascular and/or myocardial K^+ -ATP channels.[149] Sulfonylureas may be either proarrhythmic or antiarrhythmic, depending on the presence or absence of ischemia, as a result of the role of the K^+ -ATP channel in regulating the duration of the cardiac action potential.[150] [151] The choice of specific sulfonylureas for patients with diabetes on the basis of the presence or absence of coronary disease remains unclear at this time.

Coronary Revascularization (see also Chaps. 37 and 38)

PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY.

Large-scale trials have generally not shown a benefit of aggressive revascularization after thrombolytic therapy for acute myocardial infarction. Similar considerations apply to diabetic patients.[152] Although diabetic and nondiabetic patients have similar rates of initial angioplasty success,[153] diabetics have higher restenosis rates after PTCA[154] [155] and worse longer-term outcomes.[156] [157]

Diabetics also have a higher risk of in-hospital mortality, restenosis, and long-term mortality after coronary artery stenting and atherectomy.[155] [158] Although stenting has reduced restenosis rates in both diabetics and nondiabetics overall, smaller lumina in the stented vessels and a significantly higher restenosis rate (55 vs. 20 percent; p=0.001) were seen in diabetics within 4 months of the procedure despite similar baseline and procedural characteristics.[158] The mechanisms underlying the increased restenosis rate in diabetes after coronary intervention is unclear. Serial intravascular ultrasonography has suggested that exaggerated intimal hyperplasia develops in diabetics after intervention.[159] Histological study found increased collagen-rich fibrous tissue in atherectomy specimens from diabetics.[160]

CORONARY ARTERY BYPASS GRAFT SURGERY.

Most studies comparing outcomes in diabetic and nondiabetic patients undergoing coronary artery bypass graft surgery (CABG) show an increased risk of postoperative death, 30-day and long-term mortality, and need for subsequent reoperation. Diabetic patients have a worse risk profile, tend to be older, and have more extensive CAD and poorer left ventricular function than nondiabetic patients do.[161] However, their higher long-term mortality is in part independent of these factors and continues to diverge from that in nondiabetic patients during long-term follow-up. This difference probably reflects accelerated disease progression in both the nonbypassed and the bypassed native coronary vessels.

The Bypass Angioplasty Revascularization Investigation (BARI) Trial, which included 641 patients with and 2962 patients without diabetes, evaluated the role of CABG

in diabetic patients.[162] Five-year mortality was higher in diabetic patients. After 5 years of follow-up, Q wave myocardial infarction occurred more frequently in diabetic patients (8 vs. 4 percent). CABG significantly reduced the mortality after a myocardial infarction when compared with angioplasty, whereas no such protective effect of surgery was noted in nondiabetic patients experiencing myocardial infarction.

TABLE 63-5 -- INDICATIONS FOR CARDIAC TESTING IN DIABETIC PATIENTS

Testing for CAD is warranted in patients with the following:
Typical or atypical cardiac symptoms
Resting electrocardiogram suggestive of ischemia or infarction
Peripheral or carotid occlusive arterial disease
Sedentary life style, age ;35 yr, and plans to begin a vigorous exercise program
Two or more of the following risk factors in addition to diabetes
Total cholesterol ;240 mg/dl, LDL cholesterol ;160 mg/dl, or HDL cholesterol <35 mg/dl
Blood pressure >140/90 mm Hg
Smoking
Family history of premature CAD
Positive microalbuminuria/macroalbuminuria test
CAD = coronary artery disease; HDL = high-density lipoprotein; LDL = low-density lipoprotein.
Taken from Consensus Development Conference on the Diagnosis of Coronary Heart Disease in People With Diabetes. Diabetes Care 21:1551-1568, 1998.

CABG VERSUS PTCA.

In general, randomized trials comparing PTCA with CABG have reported similar outcomes. Diabetes, however, may alter the outcomes of these different revascularization treatments.[163] The BARI Trial, which randomized patients with multivessel disease to CABG or PTCA, found that bypass surgery in treated diabetic patients was associated with a higher survival rate at 5 years than was PTCA (80.6 vs. 65.5 percent; p=0.003).[164] The benefit of CABG accrued primarily in patients receiving internal mammary artery conduits. Cardiac mortality was 2.9 percent when an internal mammary artery graft was used as compared with 18.2 percent when only saphenous vein grafts were used, a mortality similar to that observed with PTCA.[165]

Screening for Coronary Artery Disease

Because diabetics have blunted anginal symptoms and a poor outcome following coronary events, the issue of screening for CAD in patients with diabetes mellitus has particular importance.[166] A recent American College of Cardiology/American Diabetes Association Consensus Development Conference established guidelines for screening diabetic individuals for CAD (Table 63-5) .[167] Screening in asymptomatic diabetic individuals will establish a diagnosis of significant CAD in 5 to 15 percent of those without diabetic complications, in 20 to 60 percent of patients with peripheral or carotid arterial disease, and in the majority of those with chronic renal failure.[168] A number of factors specific to diabetic patients may interfere with the sensitivity and specificity of noninvasive diagnostic tests for myocardial ischemia.[168] However, most agree on the need to perform screening in diabetic patients before major noncardiac or vascular surgery or before initiation of an exercise program.[169] These subgroups face definable periods of excess cardiac risk, and discovery of significant CAD can have a major impact on management.

DIABETIC CARDIOMYOPATHY

Over the years, substantial evidence has accumulated that a specific, "true" diabetic cardiomyopathy distinct from ischemic injury does indeed exist.[170] [171] [172] The exact prevalence, nature, and cause of cardiac dysfunction directly attributable to diabetes have given rise to considerable debate inasmuch as other factors common in diabetes, such as hypertension, coronary atherosclerosis, and microvascular dysfunction, can independently impair myocardial performance.

EPIDEMIOLOGICAL EVIDENCE.

Data from the Framingham Heart Study corroborated early observations suggesting the existence of a diabetic cardiomyopathy. In the Framingham cohort, after adjustment for age, blood pressure, cholesterol level, obesity, and history of CAD, the presence of diabetes quadrupled the risk for CHF in men 35 to 64 years old and doubled it in men 65 years or older. In women 35 to 64 years of age, diabetes entailed an eightfold increase in CHF and a fourfold increase in risk in older women.[173]

More recent epidemiological studies using case-control analyses have confirmed the association between diabetes and idiopathic cardiomyopathy in men[174] and in women[175] and have emphasized a possible interaction between diabetes and a history of hypertension. In men screened for the MRFIT Study who had cardiomyopathy, diabetes was a risk factor for mortality.[176] By combining the original Framingham Study Cohort and the Framingham Offspring Study, gender-specific linear regression analysis probed the contribution of diabetes and glucose intolerance to age-adjusted echocardiographic parameters in more than 4500 men and women. Diabetic individuals, particularly women, had higher heart rates and greater left ventricular wall thickness and cardiac mass than unaffected subjects did.[177]

PATHOLOGY.

Early postmortem studies in diabetic subjects revealed myocyte hypertrophy, myofibril depletion with replacement fibrosis, interstitial deposition of periodic acid-Schiff-positive material, and perivascular fibrosis. Coronary arterioles demonstrate increased thickening of basement membranes and microaneurysms in autopsy specimens, as well as in tissue obtained at the time of coronary bypass surgery.[178] [179] More recently, endomyocardial biopsies from patients with diabetes have demonstrated a range of ultrastructural changes, including capillary basement membrane thickening and interstitial fibrosis, that are accentuated by coexisting hypertension.[180] Coexisting hypertension and diabetes accentuate myocardial fibrosis and collagen content.[98]

Noninvasive methods have confirmed fibrosis as a key feature of the heart in diabetic patients without evident cardiac disease. Ultrasound tissue characterization with backscatter analysis has been used to evaluate the myocardium of type I diabetic individuals with normal systolic function but with a variety of diabetes-related complications. When compared with an age-matched population, the diabetic group exhibited cardiac acoustic abnormalities suggesting increased collagen content of the myocardium.[181] Another study compared 26 type I diabetic subjects without hypertension or CAD with an age- and sex-matched control group by using a similar technique to assess myocardial acoustic properties. This study documented increased myocardial echodensity suggestive of increased collagen deposition despite normal septal and posterior wall thickness.[182]

MECHANISMS OF DIABETIC CARDIOMYOPATHY (Table 63-6) .

AGEs accumulate in tissue exposed to hyperglycemia and may contribute to the vascular complications of diabetes mellitus, as discussed above.[12] [13] Accumulation of AGE-modified extracellular matrix results in inelasticity of the vessel wall and could interfere with myocardial function as well. Serum levels of AGEs correlate with microvascular and renal complications in type I diabetes. In 52 patients with type I diabetes, prolongation of the isovolumic relaxation time as assessed by Doppler echocardiography correlated with serum levels of AGEs after adjustment for age, diabetes duration, renal function, blood pressure, and autonomic function parameters.[183] Experimental studies in diabetic dogs have also shown decreased left ventricular compliance associated with intramyocardial deposition of collagen in the absence of hypertrophy.[184] These data help explain the clinical observation that diabetic patients can have CHF as a result of diastolic dysfunction in the absence of hypertension and/or increased wall thickness.

Abnormalities in myocardial calcium handling may also contribute to abnormal cardiac mechanics in the diabetic heart.[185] Insulin-dependent diabetes impairs

sarcoplasmic reticular Ca^{2+} pump activities, which reduces the rate of calcium removal from the cytoplasm in

TABLE 63-6 -- POSSIBLE CONTRIBUTORS TO DIABETIC CARDIOMYOPATHY

Collagen accumulation decreasing myocardial compliance, accumulation of advanced glycosylation end product-modified extracellular matrix proteins leading to diastolic dysfunction[183] [184]
Abnormalities in myocardial calcium handling may also contribute to abnormal cardiac mechanics in the diabetic heart[185] [186] [187] [188]
Activation of protein kinase C triggered by increased intracellular diacylglycerol[27]
Cardiac autonomic neuropathy[189]
Genetic abnormalities[190] [191] [192]

diastole. Such alterations may contribute to the increased diastolic stiffness that characterizes diabetic cardiomyopathy.[186] [187] Diabetes-related changes in troponin T, the contractile regulatory protein of the thin myofilament, may also contribute to both diastolic and systolic dysfunction.[188] In addition, activation of PKC may contribute to cardiac hypertrophy and failure, as discussed above.[27] In addition, a possible major cause of or contributor to chronic left ventricular dysfunction (cardiomyopathy) may be the direct effects of hyperglycemia and insulin resistance on myocardial cellular metabolism. The unavailability of glucose as an energy substrate and the shift in intracellular metabolism from glycolysis to free fatty acid oxidation can result in inadequate ATP generation and increased production of oxygen free radicals, both of which lead to depressed contractile function.[188A]

A recent study showed that a subset of type I diabetics without overt cardiac disease had abnormal left ventricular function with exercise despite normal contractile indices at rest. This decrement in left ventricular reserve correlated with evidence of reduced sympathetic innervation (see below), thus implicating dysautonomia in the pathogenesis of diabetic cardiac dysfunction.[189]

Genetic abnormalities may predispose to the development of cardiomyopathy in diabetics. Mitochondrial DNA mutations and deletions associated with diabetes mellitus may increase the risk for cardiac disease.[190] [191] A recent cross-sectional analysis evaluated the relationship between the ACE I/D genotypes and left ventricular mass in 289 type II diabetic subjects.[192] Presence of the ACE D/D genotype was independently associated with an increase in left ventricular mass.

CLINICAL FEATURES.

In diabetic patients, the range of pathological and cellular abnormalities in the diabetic myocardium discussed above can reduce left ventricular compliance and cause shortness of breath out of proportion to the degree of systolic dysfunction. The natural history of diabetic cardiomyopathy is poorly understood. Many diabetic patients have diastolic dysfunction recognized on clinical grounds, but subsequent systolic dysfunction does not appear to develop. In others, left ventricular systolic dysfunction does intervene to produce a typical "congestive" cardiomyopathy.

Even young, asymptomatic type I diabetics frequently have echocardiographic evidence of diastolic dysfunction.[193] [194] It is more difficult to isolate diabetes-specific abnormalities in left ventricular function in type II diabetics because many of these individuals also have hypertension and/or CAD, which alone or together can cause diastolic and/or systolic dysfunction. However, considerable evidence suggests more decline in both systolic and diastolic function in diabetics than nondiabetics.[195] [196]

As noted above in the Framingham Study (without separation into type I and type II), women with diabetes had increased wall thickness, end-diastolic dimensions, and cardiac mass when compared with their nondiabetic counterparts.[177] Women with glucose intolerance showed similar, but less significant trends in these echocardiographic parameters, thus supporting the concept that changes in cardiac structure and function may occur in the setting of insulin resistance before the onset of hyperglycemia and a diagnosis of diabetes. In addition, the increased relative risk for cardiac death in diabetic women as opposed to diabetic men may result in part from these sex-specific effects on cardiac mass, an important independent predictor of outcome in the Framingham Study. Increased cardiac mass in the normotensive nondiabetic obese population is strongly associated with the degree of insulin resistance measured by the insulin and glucose response to an intravenous glucose tolerance test.[197] This relationship was independent of body weight, age, and blood pressure. A hemodynamic study comparing diastolic function in lean and obese nonhypertensive and hypertensive adults without CAD showed that left ventricular chamber stiffness was highest in the obese hypertensive individuals.[198] These subjects had the highest fasting glucose levels (within the normal range), which implicates insulin resistance as an important cofactor for the development of decreased left ventricular compliance even in the absence of diabetes. Elevated plasma insulin levels may induce myocardial hypertrophy by a direct growth-stimulating effect on myocardial cells.[199] Hyperinsulinemia increases salt reabsorption by the kidney. The expanded extracellular fluid compartment and blood volume could also lead to an increase in cardiac mass over time. When combined with hypertension, itself a cause of increased cardiac mass, these factors may result in proportionately more left ventricular hypertrophy than when hypertension is not associated with insulin resistance.

CARDIOVASCULAR AUTONOMIC NERVOUS SYSTEM DYSFUNCTION IN DIABETES MELLITUS

Cardiovascular autonomic neuropathy (CAN) probably contributes to the poor prognosis of CVD in both type I and type II diabetes mellitus. The majority of patients with CAN come to clinical attention with complaints of postural hypotension, resting tachycardia, exercise intolerance, or painless myocardial ischemia or infarction. The risk for CAN depends on the duration of diabetes and the degree of glycemic control and tends to parallel the development of other end-organ diseases related to diabetes such as retinopathy, nephropathy, and vasculopathy. Symptoms and signs of CAN often occur relatively late in the natural history of this complication. Because reliable and quantitative noninvasive methods to assess ANS function have now become available, the diagnosis of CAN may now precede the development of symptoms. Most clinicians regard CAN as a major complication of type I diabetes because the challenge of managing this complication often dominates the care of these patients. CAN tends to be less fully expressed in a patient with type II diabetes, who is typically older and has a wider variety of comorbid conditions.

DIAGNOSIS.

A variety of tests can assess parasympathetic and sympathetic function in diabetics. A series of bedside maneuvers can aid in the diagnosis of CAN and differentiate the relative contribution of parasympathetic and sympathetic dysfunction in CAN. These tests use the ECG to measure beat-to-beat heart rate variation during deep breathing, at assumption of an upright posture, and during the Valsalva maneuver.[200] Recently, tests have emerged that can detect the presence of CAN before symptoms develop. A number of methods assess heart rate variability during 24-hour recordings and thereby permit detection of subtle disorders in autonomic balance. Cardiac radionuclide imaging with the norepinephrine analog metaiodobenzylguanidine (MIBG) can directly image the sympathetic nerve activity of the myocardium. Diabetic individuals generally have less myocardial MIBG uptake with more pronounced regional differences from base to apex than do patients without diabetes. In addition, positron-emission tomographic (PET) scanning with the sympathetic neurotransmitter analog ^{11} C-labeled hydyoxyephedrine can evaluate myocardial sympathetic innervation. These noninvasive methods, alone or in combination with the standard bedside examination, can establish the presence and severity of CAN and be used to evaluate the effects of interventions.[201]

PREVALENCE.

The prevalence of CAN varies with the method used and the population studied, but CAN appears to be quite common. In a large group of type I and II diabetic subjects, heart rate variability on 24-hour ambulatory ECG showed abnormalities in nearly 50 percent of diabetics, far more than in controls.[202] MIBG scintigraphy in patients with type I diabetes for at least 10 years who had CAD excluded by thallium single-photon emission computed tomography (SPECT) revealed regional adrenergic denervation

in 18 of 24 subjects.[203] In newly diagnosed type I diabetic individuals examined by a battery of tests, 8 percent had definite CAN.[200]

PROGNOSIS.

Numerous studies have documented increased mortality in diabetic patients with CAN.[204] [205] [206] In type I diabetics, 5-year mortality in patients with CAN exceeded the 5-year mortality in those without CAN by fivefold.[205] Another study involving both type I and type II patients examined the relationship between ANS function and

retinopathy, nephropathy, glycemic control, and cardiovascular risk factors. CAN conferred excess mortality beyond that attributable to other risk factors.[207] The relationship of ANS dysfunction to outcome in type II diabetic patients is less well characterized. In a Finnish study, 70 men with newly diagnosed type II diabetes and baseline, 5-year, and 10-year assessment of heart rate variability were compared with a control group. Sympathetic ANS dysfunction at the 5-year examination predicted the 10-year cardiovascular mortality.[99]

EFFECTS OF TREATMENT.

Institution of strict glycemic control in type I diabetic patients can reverse abnormalities in heart rate variability in diabetic patients with early CAN[208] and reduce the degree of left ventricular sympathetic denervation on PET scanning with labeled hydroxyephedrine.[209] Pancreatic-kidney transplantation in type I patients can result in an improvement in cardiovascular reflexes.[210] Other treatment modalities found to improve autonomic function include the antioxidant alpha-lipoic acid,[211] an ACE inhibitor,[212] [213] and aldose reductase inhibition.[214] [215]

Mechanisms Responsible for Increased Morbidity and Mortality

Numerous mechanisms may underlie the increased cardiovascular morbidity and mortality associated with CAN in diabetes mellitus (Table 63-7) .

IMPAIRED ANGINA PERCEPTION.

Clinicians have recognized for some time that myocardial ischemia or infarction may be associated with less severe angina in a diabetic versus a nondiabetic patient. CAN may explain the blunted appreciation of cardiac ischemic pain in diabetic patients. Instead of typical angina, patients may have shortness of breath, diaphoresis, gastrointestinal complaints, profound fatigue, or abrupt changes in glycemic control. When compared with nondiabetic patients with exercise-induced ischemia, diabetic individuals are less apt to be limited by angina at the time of ST segment depression than nondiabetics are.[216] In one study that used ambulatory ST segment monitoring to examine diabetic patients with documented

TABLE 63-7 -- CARDIOVASCULAR AUTONOMIC NEUROPATHY AND INCREASED CARDIOVASCULAR MORBIDITY AND MORTALITY IN DIABETES MELLITUS

EFFECTS OF SYMPATHOVAGAL IMBALANCE
Impairs angina recognition
Silent ischemia and infarction
Alters threshold for ischemia
Increased resting heart rate and blunted chronotropic response to exercise
Impaired coronary vasomotor regulation
Causes abnormal diastolic and systolic function
Factor in cardiac cardiomyopathy
Increases risk for ventricular arrhythmia
In presence or absence of myocardial ischemia
Alters circadian pattern of triggering of acute cardiac events
Loss of nocturnal protection against myocardial infarction
Alters circadian blood pressure regulation
Increased cardiac mass
Risk factor for microalbuminuria and diabetic nephropathy
Adversely affects the natural history of congestive heart failure
Causes hemodynamic instability in the perioperative period

CAD, over 90 percent of ischemic episodes were asymptomatic.[106] Shortness of breath reflecting ischemia-induced heart failure may precede the perception of angina during treadmill testing and correlates with the degree of CAN on cardiovascular reflex testing[217] [218] and MIBG scanning,[219] thus suggesting a direct link between autonomic neuropathy and defective angina recognition. Histological damage to cardiac afferent nerve fibers has been demonstrated in diabetic patients with silent myocardial infarction.[220] The blunted recognition of ischemia because of CAN may delay treatment and worsen the outcome.[96] [221] Blunted perception also makes it difficult to monitor antiischemic treatment or determine whether restenosis has occurred after coronary intervention.

CAN AND MYOCARDIAL INFARCTION TRIGGERING.

Diabetic patients with CAN show a homogeneous distribution of myocardial infarction throughout the full 24-hour period,[106] while diabetics without CAN have a circadian pattern of ischemia like that seen in nondiabetic patients, with a typical prominence in the early morning.[105] [222] [223]

CAN AND THE THRESHOLD FOR MYOCARDIAL ISCHEMIA.

Myocardial ischemia occurs when there is an imbalance between myocardial oxygen supply and demand, both of which can be affected by CAN. Resting tachycardia caused by parasympathetic denervation, an early manifestation of CAN, increases myocardial oxygen demand and can place diabetic patients with CAD closer to their ischemic threshold. Even transient sympathovagal imbalance can trigger ischemia-mediated sudden death. In a small group of patients with CAD who had sudden cardiac death during Holter monitoring, transient decreases in heart rate variability preceded onset of the ST segment shift and precipitated life-threatening arrhythmias in all eight cases.[224]

EFFECT OF CAN ON CORONARY BLOOD FLOW REGULATION.

The status of the ANS can affect coronary blood flow regulation independent of mechanisms mediated by endothelial cell function.[225] Diabetic patients with sympathetic nervous system dysfunction have impaired dilation of coronary resistance vessels in response to cold pressor testing when compared with diabetics without defects in cardiac adrenergic nerve density.[226] In another study, global myocardial blood flow and coronary flow reserve in response to adenosine were subnormal in diabetics with CAN as defined by similar PET criteria.[227] The aspects of CAN described above may well provoke ischemic episodes by upsetting the balance between myocardial supply and demand.

CAN AND SUDDEN CARDIOVASCULAR DEATH IN DIABETICS.

It has been recognized for some time that sudden death can occur in the absence of CAD in patients with diabetes mellitus. The association of abnormal cardiovascular reflex testing and sudden cardiac death in early case studies pointed to a direct link between autonomic balance and arrhythmogenesis. The relationship of sudden death (defined as unexpected death within 1 or 24 hours of symptoms) to glucose intolerance was examined in 8006 Japanese-American men after 23 years' follow-up in the Honolulu Heart Program.[228] After adjustment for recognized cardiac risk factors, the relative risks for sudden death within 24 hours in subjects with high normal glucose (151 to 224 mg/dl), asymptomatic high glucose values (>225 mg/dl), and diabetes versus those with lower glucose values (<151 mg/dl) were 1.59, 2.22, and 2.76, respectively ($p < 0.05$).

The recognition that sympathetic imbalance relates to the pathophysiology of sudden death in the familial long QT syndrome has supported CAN as a risk factor for premature cardiac death in individuals with diabetes. Prolongation of the corrected QT interval in diabetic patients correlates with the degree of autonomic neuropathy.[229] Newer methods to assess arrhythmogenic potential have firmly established CAN as a risk factor for sudden death in diabetes. The presence of QT dispersion on the 12-lead ECG reflects dispersion of ventricular refractoriness and increased risk for arrhythmia. When compared with a nondiabetic control

group and a diabetic group without CAN, QT dispersion was greatest in diabetic patients with CAN.[230] Diabetic patients with the most advanced cardiovascular sympathetic denervation have the highest mortality rate. This apparent paradox may be explained by recent data demonstrating that diabetic patients with severe autonomic neuropathy can have marked heterogeneity in left ventricular sympathetic neuronal uptake on PET scanning with the neurotransmitter analog ^{11}C-hydroxyephedrine.[231]

PERIOPERATIVE HEMODYNAMIC INSTABILITY.

Perioperative hemodynamic instability in the setting of CAN may contribute to the twofold to threefold greater risk of cardiac morbidity and mortality in diabetics undergoing noncardiac surgery. During induction of general anesthesia, heart rate and blood pressure may decline to a greater degree than in patients without diabetes. In rare cases, cardiovascular collapse has occurred after brachial plexus block.[232] Diabetics with autonomic neuropathy require perioperative pharmacological support with pressors to stabilize blood pressure more often than do diabetics without CAN.[233] Despite the preponderance of data linking diabetes and perioperative cardiac risk, no relationship was seen between autonomic function and hemodynamic behavior in a recent study comparing diabetic and nondiabetic patients undergoing CABG surgery.[234]

FUTURE PERSPECTIVES

Cardiovascular complications have emerged over the last decade as the key target to reduce morbidity and mortality in diabetics. The focus in treatment of diabetes is shifting from blood sugar to the blood vessel. Future studies will doubtless more often specify cardiovascular events as major endpoints rather than merely specifying surrogates such as glycemia. Evaluation of the possible cardiovascular protective effects of new classes of agents such as the insulin sensitizers (thiazolidinediones) is under way, for example. The role of fibrates in place of or in addition to statins for the treatment of diabetic dyslipidemia needs careful evaluation. The benefits of initiating treatment of individuals with impaired glucose tolerance to slow the progression to overt diabetes also merits study. Inevitably, this challenging group of patients will become more and more an integral part of the daily practice of cardiology in the years to come.

Chapter 64 - The Heart in Endocrine Disorders

ELLEN W. SEELY
GORDON H. WILLIAMS

In 1835, Robert Graves described "three cases of violent and long-continued palpitation in females" with thyrotoxicosis.[1] Twenty years later, Thomas Addison reported that patients with disease of the "suprarenal capsules" had a "pulse, small and feeble . . . excessively soft and compressible." As the disease progressed, "the body wastes . . . the pulse becomes smaller and weaker, and . . . the patient at length gradually sinks and expires."[2] Thus, since the mid-19th century, it has been known that deranged hormonal secretion can significantly alter cardiovascular function. The purpose of this chapter is to summarize the more important cardiovascular manifestations of endocrine and nutritional diseases.

ACROMEGALY

The anterior pituitary gland secretes at least seven polypeptide hormones. Four (adrenocorticotropic hormone [ACTH] and related peptides, follicle-stimulating hormone, luteinizing hormone, and thyroid-stimulating hormone [TSH]) primarily produce their biological effect indirectly by altering hormonal secretion from a specific target gland (adrenal cortex, gonad, or thyroid). Thus, the pathophysiological manifestations of a derangement in their secretion are the same as those of their target organs and will be discussed later. No cardiovascular manifestations of altered prolactin secretion are known, but acromegaly (growth hormone [GH] excess) is associated with a number of clinical signs and symptoms related to the cardiovascular system.

ACTIONS OF GROWTH HORMONE.

GH is only one of a family of peptides whose overall function is to regulate growth of the organism.[3] [4] Two hormones secreted by the hypothalamus (somatotropin-releasing hormone and somatostatin) regulate the release of GH from the anterior pituitary, with the former stimulating and the latter suppressing its release.[5] [6] A variety of other factors also modify GH release, many of which work through a GH secretagogue receptor.[7] An orally active agonist of this receptor, MK-677, can stimulate GH release in normal and elderly individuals.[8] [9] Whether it can do so in pathophysiological states in which GH is suppressed is uncertain.

After GH is released into the circulation, it binds to a plasma protein that is identical in amino acid composition to the extracellular domain of the GH receptor. The purpose of the binding protein is unclear. It may prolong the plasma half-life of GH and thereby its biological effect. Contrariwise, GH-binding protein can compete with the GH receptor and thereby reduce GH's biological effect. The GH receptor consists of nearly equal extracellular and intracellular domains with two GH-binding sites per receptor.[10] It is a member of the cytokine receptor superfamily and mediates its effects via activation of the JAK (Janus Kinase) family of intracellular tyrosine kinases and the STAT (signal transducer and activator of transcription) family of transcription factors.[11] GH mediates its effects in two ways: directly and by increasing the production of somatomedins (insulin-like growth factors [IGFs] I and II).[3] [4] [11] GH's predominant effect is on modifying IGF-I's synthesis as suggested by the following: GH-deficient individuals are deficient in IGF-I but not IGF-II, and IGF-I reduces GH release from the pituitary.

In humans, the gene for IGF-I is located on chromosome 12 and that for IGF-II on chromosome 11 near the insulin gene. Expression of mRNA from these genes occurs in many tissues, particularly in the fetus. They are homologs of the proinsulin molecule and exert biological effects that are qualitatively similar to those of insulin.[3] [12] Postpartum, mRNA levels are highest in the liver but are also found in a number of other tissues. IGF is synthesized in the liver in response to GH and, for the most part, is bound to one of six specific binding proteins. Because production of these binding proteins can be regulated by growth factors, they may play a functional role by producing a readily available circulating reservoir of growth factors.[13] While many of the actions attributed to GH are actually produced by IGFs, GH does have direct effects, some of them the opposite those of IGFs. For example, GH antagonizes the action of insulin while the IGFs mimic it. GH's other direct effects include increasing amino acid transport and incorporation in the heart and stimulating outgrowth of vascular smooth muscle cells in culture. However, in this chapter, by convention the term *growth hormone effects* is used, although most of these effects are probably mediated by the IGFs, particularly IGF-I.

Much of our knowledge of GH's action comes from animal and/or in vitro studies with all their limitations, and relatively little information is available in humans because of the scarcity of human GH until recently. Thus, the following description needs to be interpreted with caution until more human data are available. GH's effects influence many metabolic processes, but the net effect is anabolic. Thus, when GH is administered to a GH-deficient individual, positive nitrogen balance with retention of calcium, sodium, potassium, magnesium, and chloride is manifested within days.[3] [4]

GH also induces changes in both fat and carbohydrate metabolism.[3] [4] When administered for a short time, it increases the uptake and utilization of glucose by fat cells, thus increasing lipogenesis. However, when administered over a long period, it promotes lipolysis, thus increasing plasma free fatty acid levels and their oxidation and promoting ketogenesis, particularly in diabetic patients or animals. GH reduces glucose uptake by fat and muscle cells, increases gluconeogenesis, and increases peripheral resistance to insulin; as a consequence, plasma glucose levels rise. Because of this reduced tissue uptake of glucose and the increased blood levels of free fatty acids and ketones, tissues, such as the myocardium, that are able to use these latter compounds as energy substrates do so. In contrast, if IGF-I is administered to patients with noninsulin-dependent diabetes mellitus, glycemic control improves and insulin sensitivity increases.[14]

EFFECT OF GROWTH HORMONE AND SOMATOSTATIN ON THE HEART.

Specific receptors for GH and IGF-I in the heart promote cardiac remodeling and inotropism. Activation of these receptors induces the expression of genes for specific contractile proteins and also those responsible for myocyte hypertrophy. GH also increases the force of contraction and shifts the myosin form to the low-adenosine triphosphatase (ATPase) activity V_3 isoform[15] (see Chap. 14) . Short-term administration of GH to normal subjects, which produces changes in GH levels similar to those observed in patients with mild acromegaly, increases the heart rate and myocardial contractility, the latter reflected

in fractional shortening of the left ventricle and mean circumferential shortening of velocity as determined by echocardiography.[16] GH has no effect on mean arterial blood pressure. In adults with GH deficiency, replacement therapy also modifies cardiac function, but the changes differ from those observed in normal subjects given GH. Left ventricular mass, stroke volume, and cardiac output increase significantly, whereas total peripheral resistance and arterial pressure decrease. However, systolic blood pressure does not change either at rest or during exercise.[17]

Somatostatin has an effect on the heart beyond that induced by its effect on GH secretion. Infusion of somatostatin causes bradycardia and a fall in cardiac output.

Furthermore, in some cases of supraventricular arrhythmias, somatostatin administration restores sinus rhythm.[18] Finally, cardiac nerves have been shown to contain somatostatin, which suggests that this hormone may be an important physiological regulator of cardiac conduction.

CLINICAL AND BIOCHEMICAL MANIFESTATIONS.

Acromegaly is almost invariably the result of a GH producing chromophobic or eosinophilic pituitary adenoma, although it may rarely be secondary to ectopic production of GH or somatotropin-releasing hormone.[19]

A derangement in carbohydrate metabolism is the most common metabolic consequence of chronic overproduction of GH. Impaired glucose tolerance is found in half the patients, and hyperinsulinemia is present in nearly all; thus, a state of insulin resistance exists. However, clinical diabetes mellitus is present in only 20 to 30 percent of patients, which suggests that only in those who are predisposed and have limited insulin reserve does overt disease actually develop.[3] [19] The insulin-resistant state may also contribute to other features of the disease, e.g., the hypertension. Nearly three-quarters of subjects are overweight. Thus, it might be anticipated that hyperlipidemia would be common in acromegaly. Yet, it is in fact infrequently observed except in patients with clinical diabetes mellitus.[3] [4] [17] Even in these patients it is probably secondary to the decreased secretion of insulin rather than the increased secretion of GH.

Cardiovascular Manifestations

The cardiac manifestations of acromegaly include cardiac enlargement that is greater than would be anticipated for the generalized organomegaly. In addition, the frequency of a number of other cardiovascular disorders is increased in patients with acromegaly: hypertension, premature coronary artery disease, congestive heart failure, and cardiac arrhythmias, particularly frequent ventricular premature beats and intraventricular conduction defects.[16] [20] Indeed, because of the frequent occurrence of congestive heart failure and cardiac arrhythmias in patients who otherwise have no predisposing factors (e.g., no hypertension or arteriosclerosis), it has been suggested that a specific acromegalic cardiomyopathy exists (see below).

CARDIOMEGALY.

Nearly all patients with acromegaly have cardiomegaly (Fig. 64-1) (Figure Not Available) , particularly after the fifth decade.[16] [20] [21] Echocardiographic assessment suggests that cardiac mass is frequently increased, particularly asymmetrical septal hypertrophy, with a sizable minority having left ventricular dilatation and a reduced ejection fraction.[20] [21] [22] [201A] Although the cardiomegaly may be related to the generalized effect of GH on protein synthesis, some data suggest that other factors may also be important. For example, enlargement of the heart is often greater than that of other organs. Furthermore, no direct relationship can be found between the degree of cardiomegaly and the level of circulating GH.[20] [21] However, the duration of acromegaly correlates with the severity of cardiac hypertrophy. Other factors that may be important in the genesis of cardiomegaly include the hypertension and atherosclerosis that occur with increased frequency in acromegaly. Focal cardiac interstitial fibrosis and myocarditis with a lymphocytic infiltrate have also been reported in the majority of cases.[16] The former is probably due to the effect of GH on collagen synthesis. Additionally, small-vessel disease of the myocardium may occasionally be present. The resultant dysfunction in cardiac contraction secondary to any of these pathological changes could also contribute to the cardiac enlargement. Finally, the cardiomyopathy characteristic of acromegaly may also contribute to the cardiomegaly.

HYPERTENSION.

The most common cardiovascular manifestation of acromegaly, hypertension, occurs in 25 to 50 percent of patients in most studies if individuals with hypopituitarism are excluded. However, the frequency of hypertension may be overestimated if hypertension is defined by 24-hour blood pressure monitoring. Minniti and colleagues found that 60 percent of patients with acromegaly reported to be hypertensive by traditional criteria were normotensive by 24-hour ambulatory blood pressure data.[23] Hypertensive acromegalic patients tend to be older and to have had their acromegaly longer than nonhypertensive acromegalic patients. The underlying pathophysiology is uncertain. However, the hypertension is usually mild, uncomplicated, and readily responsive to drugs.[19] Most investigators either have searched for factors other than GH that could cause hypertension or have attempted to determine how GH itself may produce hypertension. In many respects, patients with acromegaly appear to have an expanded plasma volume; the presence of an increase in the glomerular filtration rate, renal plasma flow, extracellular fluid volume, and sodium space and a reduction in plasma renin activity all support this hypothesis.[3] [4] [24] Indeed, the striking increase in plasma volume in active acromegaly is reduced following treatment.

A number of studies have suggested that GH itself may be responsible for the hypertension. Thus, pituitary irradiation

Figure 64-1 (Figure Not Available) Opened left ventricle of the heart of an acromegalic patient showing marked dilatation and hypertrophy, with fibrosis in the left septal endocardium. (From Rossi L, Thiene G, Caragaro L, et al: Dysrhythmias and sudden death in acromegalic heart disease. A clinicopathologic study. Chest 72:496, 1977.)

or hypophysectomy significantly reduces arterial pressure in hypertensive acromegalic patients, even with full glucocorticoid replacement, unless GH levels are not normalized.[21] Indeed, the apparent volume expansion may relate directly to the elevated GH levels because administration of GH can produce retention of sodium, expansion of extracellular fluid volume, and abnormalities in white blood cell sodium transport. It has been proposed that the pathophysiology of the hypertension in acromegaly may be similar to that in essential hypertension. In both conditions, cardiac output may be initially elevated secondary to expansion of the extracellular fluid volume (see Chap. 28) . This response could elevate arterial pressure and ultimately lead to changes in the peripheral vasculature that produce fixed hypertension.

ATHEROSCLEROSIS.

In view of the alterations in carbohydrate and lipid metabolism caused by GH (see above), as well as the high incidence of hypertension, it is not surprising that premature atherosclerosis occurs in patients with acromegaly. What is uncertain is its frequency.[19]

Acromegalic Cardiomyopathy

Some patients with acromegaly but no evidence of hypertension or atherosclerosis have significant cardiac dysfunction.[20] [25] They primarily have cardiomegaly, congestive heart failure, and/or cardiac arrhythmias[10] [20] [25] [26] [27] ; the congestive heart failure is particularly resistant to conventional therapy. It has been suggested that these manifestations of acromegalic cardiomyopathy are related to the higher collagen content per gram of heart than found in normal myocardium. Histological observations show cellular hypertrophy, patchy fibrosis, and myofibrillar degeneration (Fig. 64-2) . Sudden death has been associated with inflammatory and degenerative damage to the sinoatrial perinodal nerve plexus and degeneration of the atrioventricular (AV) node.

It is not clear whether acromegalic cardiomyopathy is a specific entity. The evidence favoring this view, although indirect, comes from five types of observations: (1) Nearly 50 percent of acromegalic patients have electrocardiographic abnormalities.[26] The most common findings are ST segment depression with or without T wave abnormalities, patterns consistent with left ventricular hypertrophy, intraventricular conduction disturbances--specifically, bundle branch block--and supraventricular or ventricular ectopic rhythms. Indeed, in one controlled study, 48 percent of acromegalic patients had complex ventricular arrhythmias as compared with 12 percent of normal subjects. Although no correlation has been found between the severity of ventricular arrhythmias and GH levels, the frequency of premature ventricular contractions increases with the duration of acromegaly.[26] Although hypertension or signs of atherosclerosis are present in many, 10 to 20 percent of patients with acromegaly and electrocardiographic changes have no evidence of these conditions. (2) Ten to 20 percent of acromegalics have overt congestive heart failure. Perhaps a fourth of such individuals have no known predisposing cause.[27] (3) The majority of patients with acromegaly but without hypertension or atherosclerosis have subclinical evidence of cardiac, particularly diastolic, dysfunction.[20] (4) Approximately half of all patients with acromegaly, including patients without hypertension, have echocardiographic evidence of left and right ventricular hypertrophy.[20] [27] [28] [29] These patients have GH levels that are significantly higher than those of patients without left ventricular hypertrophy. Half of the patients with left ventricular hypertrophy exhibit asymmetrical septal hypertrophy, and these patients have a significantly greater percentage of internal dimensional shortening during systole than do either patients with concentric hypertrophy or those without left ventricular hypertrophy. (5) The most compelling evidence for a specific effect of GH hypersecretion inducing cardiac abnormalities comes from the impact of administration of the somatostatin analogs octreotide and lanreotide, which inhibit secretion of GH. In one study, 7 patients with acromegaly, 3 of whom had refractory congestive heart failure, were given octreotide subcutaneously three times daily. Right-heart catheterization performed before and after 3 months of therapy showed an 18 percent increase in stroke volume and a return of the cardiac index to normal. Within 40 days of treatment, the 3 patients with congestive heart

Figure 64-2 Histopathological features of acromegalic heart disease. *A,* Nonspecific myocardial hypertrophy and interstitial fibrosis (F). *B,* Myocarditis with predominantly lymphomononuclear cell

infiltrate. *C,* Small-vessel disease (proliferative fibrous wall thickening) or intramural coronary artery branches. (From Lie JT: Acromegaly and heart disease. Prim Cardiol 7:53, 1981.)

failure had dramatic clinical improvement that was sustained for up to 3 years.[30] In a second study, within 1 week of initiating octreotide therapy, left ventricular mass was reduced, as assessed by echocardiography.[31] In a third study in 11 normotensive patients with active acromegaly, 6 months of octreotide therapy produced a significant reduction in left ventricular mass index, mean wall thickness, and isovolumic relaxation time, as well as a significant increase in the ratio of early to late peak velocity of right ventricular filling. This improvement in diastolic function was not accompanied by significant differences in systolic function indices.[32] Finally, 1 patient treated for 1 year with octreotide had substantial improvement in the histopathological appearance of myocardial biopsy specimens.[33] However, improvement in left ventricular function does not universally occur following correction of the excess GH production. In some patients who have had longstanding active acromegaly, left ventricular filling abnormalities may be only partly reversible. In these patients, presumably nonreversible interstitial fibrosis prevents correction of the GH-induced cardiomyopathy.[34]

DIAGNOSIS AND TREATMENT

The *diagnosis* of acromegaly is established by documenting the nonsuppressibility of serum GH levels following glucose loading.[5] [4] In most laboratories, GH concentrations in normal subjects are less than 2 ng/ml 120 minutes after the oral administration of 100 gm of glucose. IGF-I levels may be more useful than GH levels to diagnose and monitor the course of the disease after treatment because of IGF-I's greater stability and longer serum half-life. It is also important to evaluate the integrity of the other pituitary hormones and, in hypertensive patients, to rule out an associated pheochromocytoma or aldosteronoma. The presence of sinus tachycardia or atrial fibrillation in a patient with acromegaly warrants a careful search for coexisting hyperthyroidism.

Surgery and irradiation remain the mainstays of treatment. The surgical approach is more often transsphenoidal rather than transfrontal; heavy-particle (proton beam) instead of conventional irradiation is often used.[3] Because of the delayed reduction in GH levels with the latter method, progression of cardiovascular disease in acromegalics continues even though GH levels are falling if they are not normal.[21] Secretion of GH can be suppressed in some acromegalics with somatostatin analogs.[30] [31] [32] [33] Whether these agents have any effect on tumor growth, however, is unclear.

Acromegalic patients with cardiovascular abnormalities usually respond to conventional therapeutic measures for hypertension, heart failure, and arrhythmias. Two caveats should be taken into consideration: (1) Those with hypertension appear particularly responsive to volume-depleting maneuvers, i.e., diuretics and sodium restriction, perhaps even more so than patients with essential hypertension; (2) on the other hand, some patients with congestive heart failure, primarily those *without* underlying hypertensive heart disease (i.e., those who are considered to have acromegalic cardiomyopathy), appear particularly resistant to therapy.

THYROID DISEASE

Thyroid hormone has a profound effect on a number of metabolic processes in virtually all tissues, with the heart being particularly sensitive to its effects. Therefore, it is not surprising that thyroid dysfunction can produce dramatic cardiovascular effects, often mimicking primary cardiac disease. Thyroid's actions on the heart can be grouped into three broad categories: (1) direct cardiac effects, (2) effects mediated by thyroid hormone's action on the sympathetic nervous system, and (3) effects secondary to hemodynamic changes.

ACTION OF THYROID HORMONE.

Two biologically active hormones are secreted by the thyroid: thyroxine (T_4) and triiodothyronine (T_3). Most studies support the hypothesis that T_3 is the final mediator and T_4 is a prohormone, primarily because of the universal presence of T_3 but not T_4 nuclear receptors in tissues responsive to thyroid hormone, specifically the heart.[35] [36] [37] [38]

Nuclear-Mediated Effects of Thyroid Hormone.

The majority of thyroid hormone's effects are mediated via a change in the expression of responsive genes. This process begins with diffusion of T_4 and T_3 across the plasma membrane because of their lipid solubility. In the cytosol, T_4 is converted into T_3 by the action of 5
-monodelodinase, the concentration of which varies from tissue to tissue in direct relation to the tissue's responsiveness to thyroid hormone. Then, the circulating and newly synthesized T_3 passes through the nuclear membrane to bind to specific thyroid hormone receptors (THRs). The THR is part of the nuclear receptor superfamily of proteins, which also includes proteins that act as receptors for steroids, vitamin D, and retinoic acid.

There are two THR genes--THRalpha located on chromosome 17 and THRbeta located on chromosome 3. The predominant THR form in the heart is $alpha_1$, whereas the predominant receptor form in the pituitary and liver is the beta isoform. Several other isoforms have also been reported, the functions of which are unclear.[39] The THR is located almost exclusively within the nucleus. After interacting with T_3 and other protein transcription factors, the entire complex binds to thyroid response elements (TREs) located on the promoter region on specific genes (for additional details, the reader is referred to a review by Tsai and O'Malley[40]).

Thyroid hormone's effect on the synthesis of specific proteins can be either direct or indirect. Indirect effects include a change in production of an intermediate factor necessary for the function or activity of a more distant targeted protein. Thyroid hormone can have a positive or negative effect on regulating gene transcription. Positive effects have been documented for the following genes: myosin heavy-chain alpha,[41] Ca^{2+} -ATPase,[42] Na+, K+-ATPase, [43] $beta_1$ -adrenergic receptor,[44] glucose transporter (Glut-4),[45] cardiac troponin, [46] [47] and atrial natriuretic protein.[48] Thyroid hormone also can negatively regulate genes, e.g., myosin heavy-chain beta and the glucose transporter Glut-1, at least neonatally.[45]

Thyroid Extranuclear Actions.

Whereas the predominant effects of thyroid hormone are via its effect in regulating gene expression as noted above, thyroid hormone has also been clearly documented to have extranuclear effects. For example, T_3 increases both glucose and calcium uptake by the heart. Although some of these effects could be nuclear-mediated events, some studies suggest that thyroid hormone must also have a membrane effect. Evidence supporting a membrane effect includes rapid onset (for calcium uptake, maximum effect is achieved within 30 seconds), independence from new protein synthesis, and thyroid hormone specificity in that analogs of thyroid hormone that have no biological effect do not produce similar changes.[37] [49] [50]

In summary, thyroid hormone's nuclear and extranuclear effects on the heart lead to changes in the proportion of myosin heavy-chain protein from beta to alpha, thereby increasing myosin V_1 and decreasing myosin V_3 isoenzyme levels and thus leading to an increased velocity of contraction and diastolic relaxation. It also increases transcription of the calcium-ATPase gene. Extranuclear effects include thyroid hormone's direct effect on calcium current and cytosolic calcium changes induced by inotropic factors, including isoproterenol and the external calcium concentration.[51] [52]

As a secondary event, thyroid hormone also increases ATP consumption. However, because less of the chemical energy is used in the contractile process and more is dissipated as heat, myocardial metabolism is less efficient.[35] [51] [52]

RELATIONSHIP BETWEEN THE THYROID AND THE SYMPATHETIC NERVOUS SYSTEM

It has been proposed that some of the effects of thyroid hormone on the heart are indirect and secondary to changes in activity of the sympathetic nervous system (Table 64-1) . Many of the cardiovascular effects of hyperthyroidism, i.e., tachycardia, systolic hypertension, increased cardiac output, and myocardial contractility, can be abolished or reduced by blocking the activity of the sympathetic nervous system.[53] Thyroid hormone may alter the relationship between the sympathetic nervous and cardiovascular systems either by increasing the activity of the sympathoadrenal system or by enhancing the response of cardiac tissue to normal sympathetic stimulation. Also, it has been suggested that sympathetic stimuli merely exert a direct additive effect on cardiovascular function above that produced by thyroid hormone. On the other hand, evidence has also been presented that hyperthyroidism reduces the sensitivity of cardiac tissue to sympathetic stimuli.[49]

Thus, the results of experiments on the relationship between the sympathoadrenal system and hyperthyroidism have evoked considerable controversy. Thyroid hormone's effect in three areas has been explored: adrenergic output, adrenergic receptors, and adrenergic transduction mechanisms. Plasma and urine levels of norepinephrine, epinephrine, dopamine, and beta-hydroxylase are either low or normal in hyperthyroidism and either normal or elevated in hypothyroidism. Therefore,

the sympathomimetic features of hyperthyroidism cannot be due simply to an overall increase in adrenergic activity but are rather due to a change in the affinity of catecholamines for their receptors or a change in receptor number or to modification of a postreceptor mechanism. In the rat heart, which has been the organ most extensively studied, administration of thyroid hormone causes an increase in both the number of receptors and their affinity for their ligand, while hypothyroidism induces the opposite effect.[49] Thyroid hormone also increases mRNA levels for the $beta_1$ -adrenergic receptor.[44] [49]

TABLE 64-1 -- CLINICAL FEATURES OF HYPERTHYROIDISM

DIRECT THYROID HORMONE EFFECT*	BETA-ADRENERGIC-LIKE EFFECT*
Resting heart rate >90/min (90%)	Resting heart rate >90/min (90%)
	Palpitations (85%)
Palpitations (85%)	Exertional dyspnea (80%)
Atrial fibrillation (10%)	Increased pulse pressure (systolic hypertension)
Pedal edema (30%)	Active apical impulse
Increased oxygen consumption (basal metabolism)	Loud first heart sound and pulmonic component of the second heart sound
Weight loss	Midsystolic murmur, usually basal
Skeletal muscle myopathy	Third heart sound (occasional)
Increased bone turnover (occasional osteoporosis or hypercalcemia)	Means-Lerman scratch (rare)
Fair skin	
Fine brittle hair	Tremor
Brittle nails	Brisk reflexes
Oligomenorrhea or amenorrhea	Increased perspiration
Increased bowel frequency	Heat intolerance
	Insomnia
	Anxiety
	Stare, lid lag§

*Both types of effects contribute to the tachycardia and palpitations.

Numbers in parentheses are approximate prevalence of the findings compiled from several large series. Goiter is almost always present, although in elderly patients thyroid enlargement may be minimal or absent.

A systolic scratch or click in the 2nd left intercostal space that is probably generated by the pleura and pericardium rubbing together.
§These effects reflect upper lid retraction. Infiltrative ophthalmyopathy with exophthalmos is found only when Graves disease is the cause of the hyperthyroidism and is not related to the hyperthyroid state per se.*From Kaplan MM: The thyroid and the heart: How do they interact? J Cardiovasc Med 7:893, 1982.*

These changes in receptor number and affinity then lead to changes in sensitivity of the myocardium to beta adrenoceptor agonists. For example, stimulation of adenylate cyclase activity by isoproterenol is increased in hyperthyroidism and reduced in hypothyroidism. Changes are also seen in the force of contraction, with increased sensitivity of ventricular muscle to isoproterenol-induced contraction in hyperthyroidism and reduced sensitivity in hypothyroidism.[49] These effects were also observed in vivo in dogs, in which propranolol-induced reductions in heart rate and myocardial contractility were greater in hyperthyroid than euthyroid animals.[54]

Circulating blood elements have also provided additional evidence in support of the concept that thyroid hormone "upregulates" beta adrenoceptors. When patients are used as their own control, both the number of beta adrenoceptors and the sensitivity of adenylate cyclase to isoproterenol stimulation in mononuclear cells are increased by thyroid hormone.[55] [56] Additionally, in circulating reticulocytes of hypothyroid animals, the number of receptors is decreased.[49]

Evidence supporting an effect of thyroid hormone in modifying the transduction mechanisms mediating adrenergic effects is less clear. In cultured developing rat myocardial cells, the addition of T_3 increased the level of G_{salpha} protein while reducing G_{salpha} and the beta subunits of G proteins. These results suggest that thyroid hormone elevates G protein subunits that activate adenylate cyclase and suppresses those that inhibit it. However, Levine and colleagues could not document an effect of thyroid hormone on G_{salpha} subunits in adult rat ventricles, although an apparent inhibitory effect of thyroid hormone on G_{salpha} 2 and 3 protein, G_{beta} 1 and 2 protein, polypeptide, and mRNA levels was confirmed.[57] Similar effects have been reported for adipose tissue,[58] which probably explains the reduced lipolytic response to catecholamines in hypothyroidism. Thus, thyroid hormone has a complex interaction with the adrenergic nervous system. Hyperthyroidism increases the number and potentially the affinity of beta-adrenergic receptors and also modifies the intracellular G protein milleu to enhance the transduction potential of agonists binding to the adrenergic receptor.

Effect of Thyroid Hormone on the Heart

Abundant evidence indicates that thyroid hormone may alter cardiac function directly, as noted above. additionally, the increased heart rate and myocardial contractility observed in experimental hyperthyroidism are not completely reversed by either sympathetic or parasympathetic blockade.[54] Finally, T_4 enhances the rate of contraction of cardiac muscle, even in the presence of adrenergic blockade. Right ventricular papillary muscles isolated from cats rendered hyperthyroid exhibited augmented myocardial contractility, as reflected in an upward shift of the myocardial force-velocity curve, along with greatly increased velocity of myocardial fiber shortening, reduced time to peak tension during isometric contraction, and development of augmented peak tension. Single ventricular myocytes isolated from hyperthyroid rats exhibited marked augmentation in twitch velocity and abbreviated contraction and relaxation times. Prior catecholamine depletion by pretreatment with reserpine did not alter this inotropic effect of hyperthyroidism, thus providing further evidence for a direct cardiac effect. This hypothesis has been assessed in intact conscious animals. The results suggest that the major actions of T_4 on the left ventricle are (1) a direct positive inotropic effect and (2) an increase in the size of the ventricular cavity without a change in end-diastolic pressure or length of the sarcomere in diastole, although hypothyroidism does not necessarily impair pump function.[49]

The available data suggest that the direct effect of thyroid hormone on the heart is primarily mediated via a change in protein synthesis, as described above. Specifically, synthesis of myosin heavy chains is changed from the beta to the alpha form, thereby increasing the level of the more mobile myosin isoenzyme (V_1). With the reduction in mRNA levels for beta-myosin heavy chain, the slower V_3 myosin isoform is substantially reduced. Goto and associates demonstrated in the hyperthyroid rabbit heart that an increase in the myosin isoform V_1 /V_3 ratio is associated with decreased contractile efficiency and increased energy cost of excitation-contraction coupling.[59] This change produces a less efficient system, thereby leading to more heat production per contractile response. In contrast to thyroid hormone's marked effect on myosin isoenzyme composition in rats and rabbits, in humans there appears to be much less of an effect. The myosin heavy-chain beta form is the isoenzyme overwhelmingly present in human hearts and is little affected by thyroid status. Even the alpha form increases very little when thyroid hormone is given to severely hypothyroid subjects.[60]

Thyroid hormone's effect on cardiac contractility also appears to be mediated in part by changes in intracellular calcium handling. Thyroid hormone increases expression of sodium-calcium-ATPase, which augments transsarcolemmal calcium influx in cultured ventricular cells.[61]

In ferret ventricular muscle, hypothyroidism reduces peak tension and prolongs the duration of contraction in association with changes in cytosolic calcium that are decreased and prolonged in relation to ventricular muscle obtained from euthyroid animals (Fig. 64-3) . Hyperthyroidism produces the opposite changes. Thus, alteration in intracellular calcium handling, specifically that related to recycling of calcium by the sarcoplasmic reticulum, may account for the thyroid-induced changes in myocardial contractile function.[62] Finally, the effect of T_4 on myosin isoenzyme appears to be localized primarily to the ventricles, with atrial isoenzymes relatively unaltered by changes in thyroid hormone. Thus, while thyroid hormone itself has a major direct effect on modifying protein synthesis, changes in cardiac workload may also contribute. Studies using heterotrophic cardiac isografts suggest that the changes in myosin enzyme levels may in part be secondary to changes in workload.[63] Again, how much the changes described in rodents apply to humans is uncertain.

Thyroid hormone modifies the electrical activity of the heart by several mechanisms. It increases recruitment of slower inactivating sodium channels.[64] It also modifies the expression and/or composition and thereby the activity of

Figure 64-3 The thyroid state influences the time course of the isometric contraction and the Ca^{2+} transient. The isometric tension (T) and the aequorin light signal, reflecting intracytoplasmic $[Ca]^{2+}$ (L), were recorded from myocardium obtained from a hypothyroid (*A*), euthyroid (*B*), and hyperthyroid (*C*) ferret at 30°C, 0.33 Hz stimulation. I is expressed in millinewtons per square meter muscle cross-sectional area. The Ca^{2+} transients (aqueorin signals) are scaled to equal amplitudes and superimposed in *D.* In *E,* the tensions have been scaled to equal amplitudes and superimposed. The time from the beginning of the stimulus sweep (S) to the stimulus represents 100 milliseconds. (From MacKinnon R, Gwathmey JK, Allen PD, et al: Modulation by the thyroid state of intracellular calcium and contractility in ferret ventricular muscle. Circ Res 63:1080, 1988. By permission of the American Heart Association.)

one or more potassium channels and several calcium channels.[52] [65] [66] [67] These effects probably result from altered gene transcription because of thyroid hormone. In general, these channel effects lead to a reduction in early repolarization in the absence of thyroid hormone and an accelerated decline in the action potential when thyroid hormone is present in excess. The tachycardia observed in hyperthyroidism appears to be due to a combination of an increased rate of diastolic depolarization and a decreased duration of the action potential in the sinoatrial node cells. The propensity for the development of atrial fibrillation may be due to the shortened refractory period of atrial cells.

Hyperthyroidism

Hyperthyroidism is the clinical state resulting from excess production of T_4 , T_3 or both. The most common cause is a diffuse toxic goiter (Graves disease). Although the etiology of this condition is still unknown, the hyperproduction of T_4 and T_3 is thought to result from circulating IgG autoantibodies that bind to the thyrotropin receptor on the thyroid gland. The second most common form of hyperthyroidism is nodular toxic goiter, a condition in which localized areas of the gland function excessively and autonomously.[68]

Hyperthyroidism is a relatively common disease that occurs four to eight times more often in women than men, with a peak incidence in the third and fourth decades. Commonly associated signs and symptoms (see Table 64-1) include fatigue, hyperactivity, insomnia, heat intolerance, palpitations, dyspnea, increased appetite with weight loss, nocturia, diarrhea, oligomenorrhea, muscle weakness, tremor, emotional lability, increased heart rate, systolic hypertension, hyperthermia, warm moist skin, lid lag, stare, and brisk reflexes. Serum T_4 levels are increased and serum TSH is suppressed.

CARDIOVASCULAR MANIFESTATIONS.

The heart is among the most responsive organs to thyroid hormone. Cardiovascular signs and symptoms are therefore important clinical features of hyperthyroidism.[68] [69] Palpitations, dyspnea, tachycardia, and systolic hypertension are common findings. Diastolic hypertension can also occur. Typically noted are a hyperactive precordium with a loud first heart sound, an accentuated pulmonic component of the second heart sound, and a third heart sound; occasionally, a systolic ejection click is heard. Midsystolic murmurs along the left sternal border are common, and a systolic scratch, the so-called Means-Lerman scratch, is occasionally heard in the 2nd left intercostal space during expiration. It may represent a pulmonic flow murmur related to cardiac output.

As would be anticipated, the cardiac and stroke volume index, mean systolic ejection rate, velocity and extent of wall shortening (Fig. 64-4) , and coronary blood flow are all increased, the systolic ejection period and preejection period are abbreviated, the pulse pressure is widened, and systemic vascular resistance is reduced in hyperthyroidism. The changes in left ventricular performance induced by thyroid hormone appear to be secondary to augmented contractility rather than alterations in loading conditions or a change in heart rate. If the hyperthyroidism is relatively mild, many of the indices of left ventricular function are normal, with exercise needed to bring out abnormalities.[69] It has been suggested that many of the changes in cardiac function are secondary to the increased metabolic demands of peripheral tissue. However, the increase in cardiac output is greater than would be predicted on the basis of the increased total-body oxygen consumption, thus supporting the view that thyroid hormone exerts a direct cardiac stimulant action independent of its effect on general tissue metabolism, as noted above. Furthermore, normalization of the myocardial contractile response to exercise may not occur until several months after normalization of thyroid function. However, it is likely that the overall pathological consequences associated with thyrotoxicosis result from an interaction between the effect of thyroid hormone on the heart and its effect on the peripheral circulation (Fig. 64-5) .

Roentgenographic and electrographic changes are common, but nonspecific in hyperthyroidism.[69] Thus, on chest x-ray the left ventricle, aorta, and pulmonary artery are

Figure 64-4 Rate-corrected velocity of shortening in SD units from the normal mean regression line obtained from 11 patients at varying levels of the free thyroxine index. A strong positive correlation can be seen between the level of thyroid hormone and the change in contractile state. The shaded area represents the normal range for the serum free thyroxine index. (From Feldman T, Borow KM, Sarne DH, et al: Myocardial mechanics in hyperthyroidism: Importance of left ventricular loading conditions, heart rate and contractile state. J Am Coll Cardiol 7:967, 1986. Reprinted with permission from the American College of Cardiology.)

prominent, and in some cases, generalized cardiac enlargement can be noted. In patients with sinus rhythm, the magnitude of the tachycardia in general parallels the severity of the disease. Sinus tachycardia is present in 40 percent of patients with hyperthyroidism and occurs most frequently in the younger age groups and often at night.[70] Ten to 15 percent of patients with hyperthyroidism have persistent atrial fibrillation, which is often heralded by one or more transient episodes of this arrhythmia.[69] Shortening of the AV conduction time and functional refractory period results in an increased frequency at which the AV conduction system transmits rapid atrial impulses. Intraatrial conduction disturbances, manifested by prolongation or notching of the P wave and prolongation of the PR interval in the absence of treatment with digitalis, occur in 15 and 5

Figure 64-5 Cardiovascular effects of hyperthyroidism. Cardiac output is increased as a result of thyroid hormone augmentation of the hemodynamic parameters indicated in the figure. LVEDV = Left ventricular end-diastolic volume; LVESV = left ventricular end-systolic volume. (Modified from Woeber KA: Thyrotoxicosis and the heart. N Engl J Med 327:94, 1992.)

percent of patients with hyperthyroidism, respectively. Occasionally, second- or third-degree heart block may result. The cause of the AV conduction disturbance is not clear because animal experiments have shown that the functional refractory period of the AV conduction system and the conduction time were shortened in dogs with hyperthyroidism and prolonged in dogs with hypothyroidism.[71] Intraventricular conduction disturbances, most commonly right bundle branch block, occur in about 15 percent of patients with hyperthyroidism without associated heart disease of other etiology. Paroxysmal supraventricular tachycardia and flutter are rare in hyperthyroidism. Finally, occult thyrotoxicosis may underlie either chronic or paroxysmal isolated atrial fibrillation.[72]

Both angina pectoris and heart failure occur in patients with hyperthyroidism. For many years it was assumed that these conditions were seen only in the presence of underlying cardiovascular disease. More recently, however, five lines of evidence have suggested otherwise: (1) Congestive heart failure has been produced in experimental animals by simply administering T_4 . (2) Congestive heart failure may develop in children with thyrotoxicosis and no underlying cardiac disease.[73] (3) Angina has been reported in a hyperthyroid patient with normal coronary arteries, presumably secondary to thyroid-induced coronary artery spasm. (4) The abnormal left ventricular function observed during exercise in hyperthyroid subjects is not reversed by beta blockade but is reversed by treating the hyperthyroidism.[49] [68] [69] (5) Finally, Ebisawa and coauthors reported that the cardiomyopathy in patients with thyrotoxicosis may be irreversible. Four patients with this condition had increased left ventricular end-diastolic volumes and reduced ejection fractions, even 13 to 15 years following treatment of their hyperthyroidism. Myocardial biopsies, performed in two patients, showed no specific light microscopic abnormalities.[74]

Thus, when it is severe and persistent, thyrotoxicosis can overtax even a normal heart, although in most instances the development of clinical manifestations of heart failure and myocardial ischemia in patients with hyperthyroidism signifies the presence of underlying cardiac or coronary vascular disease. The frequency of hyperthyroidism is also increased in patients with familial hypertrophic cardiomyopathy. In one kindred, 3 of 17 members with hypertrophic cardiomyopathy also had hyperthyroidism.[75] Finally, hyperthyroidism is associated with mitral value prolapse in more than a third of cases.[49] [68] [69]

TREATMENT OF CARDIOVASCULAR DISEASE IN HYPERTHYROIDISM.

Hyperthyroid patients with cardiovascular disease are particularly resistant to therapy. It has been well documented that both heart failure and arrhythmias are resistant

to conventional doses of cardiac glycosides. Although the specific mechanisms underlying these altered responses remain obscure, they may be related to both systemic and local effects.[76] First, serum levels of cardiac glycosides are diminished in hyperthyroidism, not primarily because its metabolism is increased but because its volume of distribution is greater. Second, experimental hyperthyroidism reduces the enhancement in myocardial contractile force and the prolongation in the AV nodal refractory period produced by these agents.[76] Because of this decreased sensitivity to cardiac glycosides, toxicity may develop at a dose that has relatively little therapeutic effect.

DIAGNOSIS AND TREATMENT OF HYPERTHYROIDISM

The mainstay of treatment is beta-adrenergic blocking agents pending initiation of more definite treatment of the hyperthyroidism. Hyperthyroidism in most patients is clinically manifested as described above. The diagnosis is confirmed with a low TSH level, which reflects an elevated level of thyroid hormone in the blood. In elderly patients with apathetic hyperthyroidism, cardiovascular manifestations predominate, specifically, atrial fibrillation and/or congestive heart failure, and therefore evaluation of thyroid function in such patients is particularly important.

Definitive treatment of hyperthyroidism is surgical removal of the gland or irradiation with radioactive iodide. In severely ill patients, particularly those with thyroid storm, significant cardiovascular symptoms, or both, neither of these therapies is appropriate. Thus, medical therapy is directed at reducing both the production and the biological effect of thyroid hormone with thionamides and beta blockers.[76] [77] [78] Tachycardia, palpitations, tremor, restlessness, muscle weakness, and heat intolerance are reversed by these agents, which offer the additional benefit of inhibiting the conversion of T_4 to the biologically active T_3 in peripheral tissues.

TREATMENT OF CARDIOVASCULAR MANIFESTATIONS OF HYPERTHYROIDISM.

Prompt treatment of hyperthyroidism can significantly reduce, if not eliminate the associated cardiovascular symptoms. About half of patients with concurrent onset of hyperthyroidism and angina pectoris experience complete remission of this symptom after treatment of hyperthyroidism.[78] Furthermore, in 30 to 40 percent of thyrotoxic patients with atrial fibrillation sustained for 1 week or longer, spontaneous reversion to sinus rhythm occurs when they become euthyroid.[49] [68] [69]

Beta blockers can be administered orally or intravenously, but because these drugs interfere with the effects of sympathetic stimulation on the heart, they must be used with caution in patients with congestive heart failure. However, if the heart failure is in part related to the tachycardia, beta blockade may be beneficial.[77] Beta-blocking drugs also slow the ventricular rate in atrial fibrillation. The most useful agents for correcting the fundamental defect are thionamides such as propylthiouracil,[76] which inhibits thyroid hormone synthesis. Iodine inhibits the release of thyroid hormones from the thyrotoxic gland, and its beneficial effects occur more rapidly than those of thionamides. It is therefore useful for rapid amelioration of the hyperthyroid state in patients with thyroid heart disease. Ipodate may be particularly useful for this purpose. Iodine may also be used along with antithyroid agents to control thyrotoxicosis following ^{131}I treatment until the radioactive iodide has had time to take effect. Most hyperthyroid patients, however, escape from the effects of iodide after 10 to 14 days.

Hypothyroidism

Hypothyroidism results from reduced secretion of both T_4 and T_3 , which occurs in most cases as a consequence of destruction of the thyroid gland itself, usually by an inflammatory process. The most common cause in the United States is Hashimoto's thyroiditis. Less commonly, it is secondary to decreased secretion of TSH because of either pituitary or hypothalamic disease. In secondary hypothyroidism, the signs and symptoms associated with deficiency of other pituitary hormones are also usually present. The incidence of hypothyroidism peaks between the ages of 30 and 60 years, and it is twice as common in women as men. The following signs and symptoms are common: cold intolerance, dryness of the skin, weakness, impairment in memory, personality changes, shortness of breath, constipation, hoarseness, menorrhagia and other forms of menstrual dysfunction, and occasionally, heart failure.

CARDIOVASCULAR MANIFESTATIONS (Fig. 64-6) .

The heart in overt myxedema is often pale, flabby, and grossly dilated. Histological examination discloses myofibrillar swelling, loss of striations, and interstitial fibrosis. With early detection and treatment of hypothyroidism, the classic findings of cardiac enlargement, cardiac dilatation, significant bradycardia, weak arterial pulses, hypotension, distant heart sounds, low electrocardiographic voltage, nonpitting facial and peripheral edema, and evidence of congestive heart failure, such as ascites, orthopnea, and paroxysmal dyspnea, are now seen only infrequently. However, exertional dyspnea and easy fatigability continue to be common complaints.

Myxedema is associated with increased capillary permeability and subsequent leakage of protein into the interstitial space; these abnormalities result in pericardial effusion, a common clinical finding in overt myxedema that occurs in about one-third of all patients. Rarely, it is complicated

Figure 64-6 Cardiovascular effects of hypothyroidism. Cardiac output is decreased because of diminished total blood volume, impaired left ventricular contractility, and bradycardia. Hypertension results from increased systemic vascular resistance. Pericardial effusion results from increased capillary permeability and interstitial protein leak.

by cardiac tamponade. [49] [68] Echocardiography is the most useful method of establishing the diagnosis. The effusions disappear with thyroid replacement therapy. Myxedema-associated cardiogenic shock has also rarely been reported, and it, too, responds to thyroid replacement therapy.[79]

Electrocardiographic changes include sinus bradycardia and prolongation of the QT interval. The P wave amplitude is usually very low. It is possible that hypothyroidism may contribute to reentrant ventricular arrhythmias,[80] which may be due to prolonged action potential duration.[80A] The incidence of AV and intraventricular conduction disturbances is about three times greater in patients with myxedema than in the general population. Incomplete or complete right bundle branch block has been observed, and a primary myocardial abnormality suggestive of cardiomyopathy has been reported.[81] Other electrocardiographic changes are those associated with pericardial effusion.

The frequency of hypertension is increased in patients with hypothyroidism, although not in patients with severe myxedema.[49] [68] In one study of 477 patients, 15 percent of the hypothyroid subjects had a blood pressure greater than 160/95 as compared with 5.5 percent in age-matched euthyroid subjects. Replacement of thyroid hormone resulted in a substantial reduction in blood pressure in the hypertensive patients.[82] In a study of 688 consecutive hypertensive patients, hypothyroidism was found in 25 (3.6 percent). In nearly one-third of this subgroup, treatment of the hypothyroidism lowered the blood pressure to within the normal range.[83] Thus, individuals with mild to moderate hypothyroidism have an increased possibility of the development of hypertension, particularly diastolic hypertension, whereas individuals with severe hypothyroidism are more likely to have normal or slightly low blood pressure.[82] [83]

MYOCARDIAL EFFECTS.

Hypothyroid patients have reduced cardiac output, stroke volume, and blood and plasma volume.[49] [68] [84] Right- and left-heart filling pressures are usually within normal limits unless they are elevated by pericardial effusion. Blood flow is redistributed, with mild reductions in cerebral and renal flow and significant reductions in cutaneous flow. The ventricular isovolumetric relaxation time is prolonged but is normalized during T_4 replacement.[85] The impact of hypothyroidism on cardiac function can occur quickly in patients rendered hypothyroid for assessment of thyroid status in the treatment of thyroid cancer. Two weeks after discontinuing thyroid medication, the left ventricular end-diastolic diameter and

peak velocity of early diastolic filling, as well as the heart rate, were reduced. No changes were observed in systolic or diastolic blood pressure.[86]

Cardiac muscle isolated from cats with experimentally produced hypothyroidism exhibited reduced contractility characterized by depression of the myocardial force-velocity curve, a reduction in the rate of tension development, and prolongation of the contractile response.

Congestive heart failure is not common in myxedema, nor does it occur in the absence of other cardiac disease. Presumably, the depressed myocardial contractility is sufficient to sustain the reduced workload placed on the heart in hypothyroidism. However, it may be difficult to distinguish between symptoms of myxedema and heart

failure. Dyspnea, edema, effusions, cardiomegaly, and T wave changes occur in both conditions. In left-sided heart failure, pulmonary arterial pressure is usually elevated during exercise, cardiac output fails to rise normally, and the Valsalva response is normal, whereas the opposite occurs in myxedema. Also, the hemodynamic changes in myxedema respond to thyroid hormone administration.

Cardiac catecholamine levels are not reduced in hypothyroidism. Neither the sensitivity of the mechanical performance of the heart to sympathetic nerve stimulation nor the response of cardiac adenylate cyclase to norepinephrine is altered in hypothyroidism. However, the total number of myocardial beta receptors is reduced.[62] [56] Both isoproterenol-stimulated contractility and the accumulation of cyclic adenosine monophosphate are reduced in hearts obtained from hypothyroid rats. In experimental hypothyroidism, calcium in isolated myocardial sarcoplasmic reticulum particles is reduced, which may explain the altered contractile state.[59]

Finally, while the clinical and morphological cardiac features of hypothyroidism resemble those associated with dilated cardiomyopathy few clinical data are available to support a connection between these conditions. Fruhwald and colleagues examined the prevalence of thyroid abnormalities in 61 patients with idiopathic dilated cardiomyopathy. By ultrasonography, 8 percent had morphological abnormalities of the thyroid. Yet none had clinical or biochemical evidence of hyperthyroidism or hypothyroidism. In the 10 patients who were taking amiodarone, the frequency of morphological thyroid abnormalities was similar to the frequency of abnormalities with the rest of the patients.[87]

ATHEROSCLEROSIS.

It has been suggested that patients with hypothyroidism have an increased risk of atherosclerosis because of significant changes in lipid metabolism. Hypercholesterolemia and hypertriglyceridemia, which are associated with the development of premature coronary artery disease, are commonly found in patients with hypothyroidism.[88] Treatment of the hypothyroidism corrects the abnormal lipid pattern. For example, Arem and Patsch noted a 22 percent reduction in the mean low-density lipoprotein (LDL) cholesterol concentration after 4 months of thyroid replacement therapy.[89] High-density lipoprotein (HDL) cholesterol levels did not change appreciably. Support for a connection between hypothyroidism and atherosclerosis has come from several sources, including the documentation that the latter occurs with twice the frequency in patients with myxedema than in age- and sex-matched controls and that the development of atherosclerosis in cholesterol-fed animals is enhanced by the presence of hypothyroidism and reduced when thyroid hormone is administered. Yet myocardial infarction and angina pectoris are relatively uncommon in hypothyroidism. This low frequency of cardiac complications from atherosclerosis may simply reflect the decreased metabolic demand on the myocardium in hypothyroidism. However, the known effects of hypothyroidism on serum enzyme concentrations do complicate the assessment of chest pain in patients with myxedema.

DIAGNOSIS AND TREATMENT OF HYPOTHYROIDISM

Diagnosis is made by documentation of an elevated serum TSH level. Caution must be exercised in treating hypothyroid patients who are elderly and who may have underlying heart disease to avoid precipitating myocardial infarction or severe congestive heart failure; a slow replacement program is indicated in these individuals.

Treatment of congestive heart failure is particularly difficult in patients with myxedema, both because of the effect of thyroid hormone on the heart and because the heart's response to cardiac glycosides is altered. Patients with severe angina pectoris and untreated myxedema pose a difficult clinical dilemma because angina may be exacerbated by thyroid hormone replacement and the usual medical management of angina with beta blockers may induce severe bradycardia. Coronary arteriography often shows severe coronary artery disease in these patients, and an excellent surgical team can perform successful coronary revascularization with minimal thyroid replacement. Full thyroid replacement can then be safely achieved during the postoperative period, without the recurrence of angina.[90]

Amiodarone and the Thyroid

The widespread use of amiodarone for cardiac arrhythmias is now one of the most common causes of thyroid abnormalities in patients with cardiovascular disease[91] [92] (see also Chap. 23) . Amiodarone has structural similarity to T_4 and T_3 and is also rich in iodine. Amiodarone decreases the peripheral conversion of T_4 to T_3 , which leads to elevated levels of circulating T_4 and lower levels of circulating T_3 . Since this inhibition occurs in the pituitary gland as well, a transient increase in TSH is seen early in treatment but usually resolves over the next 3 months.[93] [94] These laboratory test changes are common and not usually associated with any clinical manifestations of thyroid dysfunction.

HYPOTHYROIDISM.

Hypothyroidism, the most common clinical manifestation of amiodarone-induced thyroid dysfunction in the United States and United Kingdom, occurs in as many as 13 percent of patients.[91] [92] The mechanism of this dysfunction is not clearly defined but may be related to the effect of the large iodine load on inhibition of thyroid hormone release and synthesis superimposed on underlying autoimmune thyroid disease.[95] It has also been suggested that amiodarone itself may cause autoimmune thyroid dysfunction by altering T-cell function.

Symptoms are the same as those seen in other forms of hypothyroidism, and the diagnosis is confirmed with the demonstration of an elevated TSH level. Some patients will regain normal thyroid function several months after stopping amiodarone therapy, although others will have permanent hypothyroidism. If thyroid function does not return to normal with discontinuation of therapy or if amiodarone administration is continued, thyroid hormone replacement at a dose that normalizes the TSH level will treat the condition.

HYPERTHYROIDISM.

Amiodarone-induced hyperthyroidism most commonly occurs in areas of the world with iodine deficiency but can be seen in iodine-replete individuals as well.[91] [92] Patients may demonstrate typical symptoms of hyperthyroidism such as weight loss, heat intolerance, and tremor, but at times the initial symptom may be the onset or recurrence of cardiac arrhythmias. Diagnosis is made by the patient's history, clinical examination, and thyroid function testing, which shows low TSH and elevated T_4 . Since low TSH and elevated T_4 levels can also be commonly seen in the early phase of amiodarone therapy without symptoms, measurement of total T_3 may be helpful in distinguishing these conditions. In the early phase of treatment with amiodarone, T_3 levels are decreased, whereas in hyperthyroidism, the T_3 level is increased.[96]

Two mechanisms have been proposed for amiodarone-induced hyperthyroidism. Type I occurs in abnormal thyroid glands and is caused by iodine-induced increased thyroid hormone synthesis in subjects with nodular goiters or latent Graves disease. Type II occurs in what is a normal gland. It is presumably secondary to a thyroid-destructive process caused by iodine or amiodarone per se.[97] In the latter case, amiodarone may induce thyrotropin receptor

antibodies, which then cause the hyperthyroid state.[98] Some investigators have suggested that type I (hypervascular state) and type II (hypovascular state) thyrotoxicosis can be distinguished by color flow Doppler sonography. Another sometimes useful distinguishing feature is an increased serum interleukin-6 level in type II but not type I. It has been reported to be important to distinguish these two types since their treatments differ. Patients with type II but not type I sometimes respond very well to glucocorticoids.[99]

Cessation of amiodarone therapy will lead to eventual resolution of the hyperthyroidism, although normalization can sometimes take several months. However, amiodarone therapy often cannot be stopped, in which case other treatment modalities must be instituted. The two primary modalities are thionamides and surgery. Propylthiouracil or methimazole may be successful, but not in all cases. When medical management fails, thyroidectomy may be the procedure of choice to allow continuation of amiodarone therapy. Radioactive iodine therapy is most commonly not an option because of the high iodine content of amiodarone and the resultant increased thyroidal stores leading to very low radioactive iodine uptake by the thyroid.

THYROID MONITORING.

Because of the frequency of thyroid dysfunction with amiodarone therapy, routine monitoring of thyroid function tests is recommended. Several algorithms for monitoring have been published. One such algorithm is depicted in Figure 64-7 .

DISEASES OF THE ADRENAL CORTEX

Since Addison's description in 1855 of adrenal insufficiency,[2] it has been appreciated that steroids secreted by the adrenal cortex exert a significant effect on the

cardiovascular system. For many years, the primary influence was assumed to be mediated by the adrenal steroids' effect in modifying blood pressure. Recently, it has been proposed that these steroids, particularly aldosterone, have a much broader impact on cardiovascular function. Yet diseases of the adrenal cortex are often associated with changes in blood pressure. Adrenal insufficiency is characterized by hypotension, whereas hypertension often accompanies excessive production of adrenal steroids.

Three classes of steroids are secreted by the adrenal cortex: glucocorticoids, e.g., cortisol; mineralocorticoids, e.g., aldosterone; and androgens, e.g., dehydroeplandrosterone. In this section, the physiology and pathophysiology of glucocorticoid and mineralocorticoid secretion are addressed.

Figure 64-7 Algorithm for evaluating thyroid status in patients taking amiodarone. Amiodarone withdrawal may also be appropriate in some cases. TPO = thyroid peroxidase. (Adapted from Newman CM, Price A, Davies DW, et al: Amiodarone and the thyroid: A practical guide to the management of thyroid dysfunction induced by amiodarone therapy. Heart 79:121, 1998.)

HORMONE ACTIONS

CORTISOL.

The primary glucocorticoid, cortisol, is synthesized from cholesterol in the inner layers of the adrenal cortex. Its average plasma concentration is 15 mug/dl in the morning, which falls to 5 mug/dl by early evening.[100] The fundamental mechanism of action of the glucocorticoids is similar to that of other steroid hormones. They enter a target tissue by diffusion and combine with a specific high-affinity intracellular receptor protein. The receptor-cortisol complex can then bind to promoters of target genes and regulate their transcription. The major action of glucocorticoids is to promote gluconeogenesis, and in that respect, they have both catabolic and antiinsulin properties.

Glucocorticoids also have antiinflammatory effects. They maintain normal vascular responsiveness to circulating vasoconstrictors such as norepinephrine and have a major effect on both the distribution and excretion of body water.

ALDOSTERONE.

The major mineralocorticoid produced by the human adrenal gland is aldosterone. It is also synthesized from cholesterol, but almost exclusively in the outer layer (glomerulosa) of the adrenal cortex. Aldosterone has two important functions: (1) It is a major regulator of extracellular fluid volume by its effect on sodium retention, and (2) It is a major determinant of potassium metabolism. Aldosterone acts predominantly on the distal convoluted tubule and/or collecting duct of the kidney, where it promotes the reabsorption of sodium. Potassium then diffuses into the lumen of the tubules because of the change in electrochemical gradient produced by active reabsorption of the positively charged sodium ion. Hydrogen ion may also be more freely excreted because of this change in the electrochemical gradient. Although aldosterone also acts on salivary and sweat glands and on epithelial cells of the gastrointestinal tract, these actions have little impact on total-body sodium and potassium homeostasis.

Three well-defined mechanisms control aldosterone release.[100] [101]

1. The renin-angiotensin system is the major system for control of extracellular fluid volume by regulating aldosterone secretion. Aldosterone is linked in a negative feedback loop with the renin-angiotensin system. Thus, during periods registered as volume deficiency, release of the enzyme renin from the juxtaglomerular cells of the kidney is increased. Renin then increases the production of angiotensin I from its substrate. Angiotensin I is rapidly converted into the biologically active angiotensin II, which increases aldosterone secretion. Angiotensin II also produces vasoconstriction, thereby raising blood pressure and reducing blood flow to a variety of tissues, especially the kidney.
2. Potassium ion also regulates aldosterone secretion independent of the renin-angiotensin system; an elevated potassium concentration increases aldosterone secretion and vice versa. The adrenal cortex is very sensitive to changes in potassium concentration, with as little as a 0.1-mEq/liter increment producing significant changes in plasma aldosterone levels.
3. ACTH also affects aldosterone secretion profoundly. However, because control of aldosterone release is not appreciably altered in patients who have been on a long-term regimen of steroid therapy, ACTH probably has a smaller role than the other two factors do in maintaining normal aldosterone secretion.

In addition to these major stimuli controlling aldosterone secretion, salt-losing hormones such as atrial natriuretic peptide and dopamine inhibit aldosterone secretion, particularly in response to angiotensin II.[101] Finally, poor dietary intake of both sodium and potassium alters the magnitude of the aldosterone response to acute stimulation, sodium restriction, and potassium loading, both of which enhance the response of the adrenal, perhaps by modifying the local (adrenal) renin-angiotensin system.[100] [101]

ALDOSTERONE: A CARDIOVASCULAR RISK FACTOR.

While diseases of the adrenal cortex primarily affect the cardiovascular system via changes in blood pressure or volume homeostasis, even at physiological levels aldosterone may enhance the risk of cardiovascular damage. This increased risk is mediated, in part, by aldosterone's classic action on epithelial cells (e.g., renal tubular cells) whereby sodium, volume, and potassium homeostasis is modified and in part, by several nonclassic effects on nonepithelial cells (e.g., myocytes and fibroblasts) in which a variety of functions are modified. For example, aldosterone has a direct effect on collagen metabolism in cardiac fibroblasts. In rats treated with a high-salt diet and aldosterone, cardiac fibrosis develops within 6 weeks.[102] [103] [104] [105] A clinical correlate of this effect is a reactive perivascular and interstitial cardiac fibrosis in patients with primary aldosteronism that does not seem to be due to pressure overload alone. In the stroke-prone, spontaneously hypertensive rat, administering an angiotensin-converting enzyme (ACE) inhibitor markedly attenuates the early death rate.[106] Since this manipulation will reduce both angiotensin II and aldosterone levels, either could be involved in mediating this damage. When Rocha and colleagues returned angiotensin II levels to normal with an infusion of angiotensin II, the damage recurred unless the animals were adrenalectomized or the mineralocorticoid receptor blocked biochemically before the infusion began. By this technique, not only the cardiac damage but also the renal and cerebral damage was prevented even in the face of an increased angiotensin II level and persistently elevated blood pressure.[107] [108] [109] [109A] [109B] These data strongly support the hypothesis that it is aldosterone and not angiotensin II that is the principal mediator of this damage. Finally, aldosterone also may increase plasminogen activator inhibitor type 1 (PAI-1) expression and secretion and contribute to the inflammatory response accompanying microvascular disease.[109A] [109B]

Support for these experimentally derived data comes from clinical studies. Increased plasma aldosterone levels in patients with essential hypertension are associated with decreased systemic arterial compliance.[110] Plasma aldosterone levels more closely correlate with left ventricular mass than does plasma renin activity.[111] Finally, results of the Randomized Aldosterone Evaluation Study (RALES) provide strong support for a role of aldosterone independent of effects on electrolytes[112] (see also Chap. 18) . Over 1600 patients with New York Heart Association (NYHA) Class III or IV heart failure were randomized to treatment with a low-dose mineralocorticoid receptor antagonist (spironolactone) or placebo on top of standard therapy (ACE inhibitors, loop diuretics, and in the majority, digoxin). A highly significant (30 percent) reduction was noted in all-cause mortality in the treatment group. The magnitude of this effect, observed despite concomitant therapy with an ACE inhibitor, is comparable in magnitude to the benefit of an ACE inhibitor alone in this population. The applicability of these findings to other cardiovascular diseases and milder forms of hypertension awaits the results of future studies.

Cushing Syndrome (see also Chap. 28)

In 1932, Harvey Cushing reported a syndrome characterized by truncal obesity, hypertension, fatigue, weakness, amenorrhea, hirsutism, purple abdominal striae, glucosuria, edema, and osteoporosis.[113] The majority of cases are secondary to bilateral adrenal hyperplasia, with the predominant feature being excess production of glucocorticoids and androgens.[100] Some cases are due to ACTH-producing tumors of either the pituitary gland (Cushing disease) or nonendocrine tissue (ectopic ACTH production). Fifteen to 20 percent of cases are due to primary adrenal neoplasia, either adenoma or carcinoma. Most patients have a typical body habitus: central obesity and slender extremities with proximal muscle weakness. Hypertension is present in 80 to 90 percent of patients, and diabetes occurs in 20 percent, probably in individuals with a predisposition.[100] Evidence of androgen excess may also be present, including hirsutism, amenorrhea, and clitorimegaly.

Laboratory tests disclose evidence of excess production of both glucocorticoids and androgens in the majority of cases. Thus, urinary metabolites of these steroids, 17-ketosteroids and 17-hydroxysteroids, are characteristically increased. Most patients show some evidence of glycosuria or hyperglycemia.

CARDIOVASCULAR MANIFESTATIONS.

Before the development of effective therapy for Cushing syndrome, accelerated atherosclerosis was a common finding. Early death usually occurred from myocardial infarction, congestive heart failure, or stroke. Even with more effective treatment, the mortality of patients with Cushing syndrome is still significantly higher than that in the general population, primarily because of an increased risk of cardiovascular disease.[114] Although the pathophysiology of the accelerated atherosclerosis is not clear, the hypertensive process probably contributes. Chronic excess production of cortisol leads

---

to hyperlipidemia and hypercholesterolemia, both of which may promote the development of atherosclerosis.[100]

The pathophysiology of the hypertension in Cushing syndrome has been much debated. Early studies suggested that it was secondary to volume expansion as a result of cortisol's mineralocorticoid properties. Support for this mechanism comes from the demonstration of increased levels of atrial natriuretic hormone in patients with Cushing syndrome, which suggests a volume-expanded state.[115] However, recent studies have not supported this hypothesis. Alternative hypotheses include glucocorticoid potentiation of the response of vascular smooth muscle to vasoconstrictive agents and ACTH- or cortisol-induced increases in renin substrate.[100] The latter thesis suggests that the increased blood pressure is secondary to increased generation of angiotensin II. Support for the potentiation hypothesis comes from a documented increased vascular response to both angiotensin II and catecholamines in patients with Cushing syndrome as compared with normal subjects.[116] [117] A final possibility is increased vasoconstrictor sensitivity to cortisol itself, which has been suggested to occur in essential hypertension, probably by modifying renal vascular resistance.[118] [119] Thus, the pathophysiology of the hypertension may be multifactorial and related to volume expansion, increased production of vasoactive agents, e.g., angiotensin II, and increased sensitivity of vascular smooth muscle to vasoactive agents.

Hemodynamic, electrocardiographic, and roentgenographic studies of patients with Cushing syndrome have revealed no specific abnormalities except those that are in general associated with either hypertension or hypokalemia. PR intervals tend to be shorter than normal. Echocardiograms have shown ventricular hypertrophy with asymmetrical septal thickening. The frequency of these abnormalities is greater than that seen in patients with essential hypertension and equivalent levels of blood pressure.[120]

Rarely, Cushing syndrome and cardiac myxoma occur in the same individual. In addition to having these two conditions, 80 percent of patients have a cutaneous abnormality. In most, it is a pigmented lesion; in some, it is a subcutaneous myxoma. Histologically, the adrenal glands show nodular hyperplasia.[121]

DIAGNOSIS AND TREATMENT.

The diagnosis of Cushing syndrome is established by the lack of appropriate suppression of cortisol secretion by dexamethasone. The best screening test is the administration of 1 mg of dexamethasone at bedtime with measurement of plasma cortisol between 7 and 10 the next morning.[100] In normal subjects, cortisol levels are less than 5 mug/dl. Some patients, particularly the obese, may have false-positive responses, but false-negative responses occur only rarely. Definitive diagnosis of Cushing syndrome is made by the administration of 0.5 mg of dexamethasone every 6 hours for 2 days, with measurement of either plasma cortisol levels at the end of the second day (normal, <5 mug/dl) or the 24-hour cortisol excretory rate on the second day of dexamethasone suppression (normal, <10 mug/24 hr).[100]

Therapy for Cushing syndrome is usually directed at the specific cause. Thus, patients with adrenal carcinoma or adenoma or an ACTH-producing pituitary tumor are treated surgically. In some cases, patients with adrenal carcinoma have nonresectable lesions, and therefore surgery is combined with chemotherapy. Treatment of patients with bilateral hyperplasia but no evidence of an ACTH-producing tumor is controversial because the cause is often unknown. In some centers, bilateral adrenalectomy is the treatment of choice, while more commonly, therapy directed at the pituitary (either surgery or irradiation) is used.[100]

Treatment of the *cardiovascular abnormalities* associated with Cushing syndrome is directed at lowering blood pressure and correcting the hypokalemia if present. Caution should be exercised in treating the hypertension with potassium-losing diuretics because of the tendency for hypokalemia to develop in these patients. Thus, potassium-sparing diuretics or potassium supplements are often required. As in all clinical conditions in which hypokalemia may be present, cardiac glycosides should be used with caution in patients with Cushing syndrome.

The hypertension is often resistant to conventional antihypertensive programs. Fallo and coworkers reported that only 15 percent of their hypertensive patients with Cushing syndrome had control of blood pressure with conventional medications: diuretics, calcium antagonists, and ACE inhibitors either as single agents or in combination. In 12 patients who failed conventional therapy, treatment with ketoconazole, an adrenal enzyme inhibitor, normalized blood pressure in all but 1 subject. In that 1 subject cortisol levels were not decreased. Thus, specific therapy directed at lowering cortisol production appears to be more effective than conventional antihypertensive therapy is in controlling hypertension in patients with Cushing syndrome.[122]

Hyperaldosteronism (see also Chap. 28)

CLINICAL AND BIOCHEMICAL MANIFESTATIONS.

Aldosteronism is a syndrome associated with hypersecretion of aldosterone. Primary aldosteronism signifies that the stimulus for the excess aldosterone production resides within the adrenal. In secondary aldosteronism, the stimulus is of extraadrenal origin.

In patients with primary aldosteronism, which is most commonly due to an aldosterone-producing adrenal adenoma, hypertension, hypokalemia, and metabolic alkalosis are common.[100] [123] Polyuria may exist because of the hypokalemia, and glucose intolerance is increased in frequency. Muscle cramps secondary to the hypokalemia may be present, but little else distinguishes this type from other forms of hypertension. Laboratory studies confirm the presence of hypokalemic alkalosis with a low specific gravity of urine and normal levels of adrenal glucocorticoids. The incidence of primary aldosteronism is between 0.5 and 2 percent of the hypertensive population, and it occurs twice as frequently in females as in males, with the initial manifestation usually occurring between the ages of 30 and 50 years.[100]

CARDIOVASCULAR MANIFESTATIONS.

Many of the cardiovascular effects of aldosteronism are nonspecific and are related to aldosterone's effect on atrial pressure and potassium balance. Thus, T wave flattening or U wave prominence on the electrocardiogram and the presence of premature ventricular contractions and other arrhythmias as a result of hypokalemia are observed. Traditionally, it has been assumed that primary aldosteronism is not associated with significant cardiovascular complications. However, recent studies do not support this conclusion.[124] [125] [126] [127] [128] [129] Nishimura and colleagues identified cardiovascular complications in 34 percent of their patients, with 16 percent having strokes and 7 percent having renal insufficiency.[128] Halimi and Mimram reported that albuminuria was greater and more frequent in patients with primary aldosteronism than in those with essential hypertension matched for age, gender, and severity and duration of hypertension.[126] Finally, strokes occur in 11 to 16 percent of patients with glucocorticoid-remediable aldosteronism (see below) before the age of 30.[129] Thus, these data support the hypothesis that in hypertensive patients, the presence of hyperaldosteronism represents an independent cardiovascular risk factor.

DIAGNOSIS AND TREATMENT.

The diagnosis of primary aldosteronism is made by the presence of diastolic hypertension without edema, hypersecretion of aldosterone that fails to be appropriately suppressed during volume expansion, hyposecretion of renin, and hypokalemia with inappropriate urinary potassium loss during salt loading. The state of the renin-angiotensin system is often used to distinguish primary aldosteronism from other conditions that produce hypertension and hypokalemia. For example, hypertension

---

and hypokalemia may be part of the clinical picture of secondary aldosteronism that accompanies malignant or accelerated hypertension or is associated with renal artery stenosis. Secondary aldosteronism can be readily distinguished from primary aldosteronism by plasma renin activity, which is increased in the former and reduced in the latter. However, the combination of hypertension and low plasma renin activity does not necessarily mean primary aldosteronism. Between 15 and 30 percent of patients with essential hypertension have low renin levels, so-called low-renin essential hypertension.[123] The possibility of excess mineralocorticoid secretion

has been extensively evaluated in these patients; however, no definitive evidence for such exists (see Chap. 28) .

Another entity that mimics primary aldosteronism is glucocorticoid-remediable aldosteronism (see also Chaps. 28 and 56) . This condition is an inherited hypertensive disorder with dysregulation of aldosterone secretion secondary to a gene mutation. The mutation is a fusion gene product between two genes coding for the enzymes responsible for the last step in the biosynthesis of aldosterone and cortisol, i.e., 11-beta-hydroxylase/aldosterone synthase. This chimeric enzyme is expressed in fasciculata cells, thereby leading to ACTH control of aldosterone synthase--a condition that normally does not occur. These patients can be distinguished by either genetic assessment or measurement of unique 18-hydroxycortisol steroids in the urine.[130]

The principal therapy for primary aldosteronism is surgical removal of the aldosterone-producing adenoma. In some cases, removal is not possible because of the excessive risk imposed by the general physical status of the patient, in which case spironolactone, which pharmacologically blocks the effects of aldosterone, is used long-term. This form of therapy may be of limited benefit in men because compliance is reduced by the undesirable side effects of gynecomastia and impotence, particularly when doses greater than 200 mg/d are required.[100]

In some patients, primary aldosteronism is due not to a solitary adenoma but to bilateral hyperplasia.[123] Although the clinical characteristics of these two conditions are similar, their responses to surgery are different. In both cases, hypokalemia is corrected, but patients with bilateral hyperplasia often do not exhibit a reduction in arterial pressure. Patients with bilateral hyperplasia are best treated with aldosterone receptor antagonists (e.g., spironolactone) and other antihypertensive agents. Thus, preoperative distinction between bilateral hyperplasia and an adrenal adenoma by adrenal venography or adrenal scanning is important.

Adrenal Insufficiency

Clinically, patients with adrenal insufficiency can be divided into four types[100] : (1) the most common, primary insufficiency (Addison disease); (2) secondary insufficiency caused by a lack of ACTH; (3) selective hypoaldosteronism; and (4) enzyme deficiency (congenital adrenal hyperplasia).

Addison disease may occur at any age and affects both genders equally. It is commonly due to a destructive process involving both adrenal glands; this process is sometimes infectious, but most often it is autoimmune.[100] Nearly all patients with primary adrenal insufficiency have weakness, increased skin pigmentation, significant weight loss, anorexia, nausea, vomiting, and hypotension, particularly postural. As the disease progresses, serum levels of sodium, chloride, and bicarbonate are gradually reduced, and potassium levels are increased.

CARDIOVASCULAR MANIFESTATIONS.

The most common cardiovascular finding in adrenal insufficiency is arterial hypotension. In severe cases, blood pressure may be in the range of 80/50 mm Hg, with postural accentuation. Indeed, syncope occurs in a significant percentage of patients. In severe cases, heart size and peripheral pulses decrease. The most common electrocardiographic abnormalities are low or inverted T waves, sinus bradycardia, a prolonged QT_c interval, and low voltage. Conduction defects also occur, with first-degree block present in 20 percent of patients. Changes secondary to the hyperkalemia are not common, and cardiac failure is unusual.[131]

DIAGNOSIS AND TREATMENT.

Decreased response of the adrenal cortex to ACTH establishes the diagnosis of Addison disease. The best screening test is the administration of synthetic ACTH (cosyntropin) 0.25 mg intramuscularly or intravenously, with measurement of plasma cortisol levels 30 to 60 minutes later. Cortisol levels double or increase by 10 mug/dl in normal subjects. Definitive evaluation is by prolonged (usually 24-hour) infusion of ACTH with assessment of either plasma cortisol excretion of cortisol or both.[100]

It is possible to differentiate primary adrenal insufficiency from secondary adrenal insufficiency, isolated hypoaldosteronism, or congenital adrenal hyperplasia because one of the adrenal hormonal functions is normal in each of the latter three conditions.

An increasingly common form of hypoaldosteronism is that associated with *hyporeninism.* Most commonly, this syndrome is observed in older diabetic patients with a mild degree of renal impairment and hypertension; acidosis is also common. Usually, these patients have unexplained hyperkalemia. The cause is unknown but may be secondary to damage to the juxtaglomerular apparatus and/or reduced conversion of a renin precursor into the active enzyme. This clinical syndrome is particularly important in the presence of cardiovascular disease. Furthermore, commonly used drugs (beta blockers and calcium antagonists) can exacerbate this condition by further compromising aldosterone release.[132]

Treatment of adrenal insufficiency is accomplished by replacement of the deficient steroid. In adults with primary or secondary insufficiency, hydrocortisone 20 to 30 mg daily is administered in divided doses, usually two-thirds in the morning and one-third in midafternoon. In patients with associated aldosterone deficiency, 9-alpha-fluorohydrocortisone 0.05 to 0.10 mg daily is given. During periods of significant stress (surgery, infection, or trauma), the glucocorticoid dose should be increased.

PHEOCHROMOCYTOMA (see also Chap. 28)

Effects of Catecholamines on the Cardiovascular System

The adrenal medulla and sympathetic nervous system are linked morphologically, biochemically, and physiologically and are often referred to as the sympathoadrenal system.[133] [134] In addition to their important effects on the cardiovascular system, cathecholamines also have significant metabolic effects consisting of stimulation of glycogenolysis and gluconeogenesis, that is, increasing the production of glucose from glycogen and amino acid precursors and stimulating lipolysis.

CLINICAL AND BIOCHEMICAL MANIFESTATIONS.

A pheochromocytoma is a catecholamine-producing tumor derived from chromaffin cells. Those arising from extraadrenal chromaffin cells are called nonadrenal pheochromocytomas or paraganglionomas. Rarely, these tumors occur in the heart or pericardium.[135] [136] Probably less than 0.1 percent of patients with hypertension have a pheochromocytoma. Although it is an uncommon disease, pheochromocytomas generate a great deal of interest, largely because of the significant morbidity and mortality associated with these tumors, with detection often resulting in cure. Pheochromocytomas are highly vascular tumors; less than 10 percent are malignant as indicated by local invasion or metastasis, but as with other endocrine tumors, malignancy cannot always be determined by microscopic appearance alone.

Although the vast majority of tumors occur sporadically, approximately 5 percent are inherited as an autosomal trait, by which they are often part of a pluriglandular neoplastic syndrome,[133] [134] which in addition to pheochromocytoma may consist of medullary carcinoma of the thyroid, parathyroidadenoma, and retinal or cerebellar hemangioblastomas. Most pheochromocytomas are solitary adrenal tumors, with 10 percent being bilateral and 10 percent nonadrenal. However, in the familial form of pheochromocytoma, nearly half of patients have bilateral adrenal tumors.

CARDIOVASCULAR MANIFESTATIONS.

Hypertension is the major cardiovascular manifestation of pheochromocytoma. The features that suggest pheochromocytoma in hypertensive patients are (1) paroxysmal attacks of any kind, (2) headaches, (3) excessive sweating, (4) signs of hypermetabolism, (5) orthostatic hypotension, and (6) unusual blood pressure elevation as a result of trauma or surgery.[133] [134] Many of the features are similar to those of hyperthyroidism. Although paroxysmal attacks are the hallmark of pheochromocytoma,

more than half the patients have fixed hypertension and nearly 10 percent are normotensive.

The lability of blood pressure in patients with pheochromocytoma has been suggested to be due not only to episodic discharge of catecholamines but also to a reduction in plasma volume, as well as impaired sympathetic reflexes. A number of observations suggest that chronic volume depletion is present.[137] For example, alpha adrenoceptor blockade or removal of the tumor produces severe hypotension, which is correctable by volume expansion.[133] Cardiac output has been reported to be normal, whereas the heart rate is increased and orthostatic hypotension is accompanied by decreased stroke volume and inadequate adjustments in peripheral resistance indicative of impaired peripheral vascular reflexes.[133] An occasional patient has markedly elevated central aortic pressure and severe systemic hypotension

resulting from severe arterial vasoconstriction. Patients with pheochromocytoma may also have acute pulmonary edema.[138] Some patients with pheochromocytoma have hemodynamic features indistinguishable from those of essential hypertension. These results suggest that long-term exposure to high circulating levels of catecholamines may produce a different clinical picture than that observed after acute administration. These differences may be due to desensitization induced by chronic exposure to catecholamines.[137]

The electrocardiogram is abnormal in as many as 75 percent of patients with pheochromocytoma. Changes consist of T wave inversion, left ventricular hypertrophy, sinus tachycardia, and in some cases, other alterations in rhythm, such as frequent supraventricular ectopic beats or paroxysmal supraventricular tachycardia.[139] [140] An occasional patient has a short PR interval and a narrow QRS complex, which suggests that catecholamines are modifying the AV conduction system. When arterial pressure increases markedly, changes suggestive of myocardial damage are present, including transient ST segment elevations, marked diffuse T wave inversions, and depression of ST segments. These changes are usually transient, and the electrocardiographic pattern reverts to normal after removal of the tumor or pharmacological blockade.[134] However, the acute rise in blood pressure does not seem to be related to the development of complex arrhythmias. These hypertensive events are associated with a significant reduction in vagal tone. However, this finding is similar to what is observed in essential hypertension.[139] Some of the electrocardiographic abnormalities are presumably due to hypertensive heart disease or myocardial ischemia. However, a specific catecholamine-induced myocarditis and/or cardiomyopathy has also been suggested.[138] [141] [142] Interestingly, a patient with catecholamine-induced cardiomyopathy was treated with captopril, with resolution of the cardiomyopathy within 2 weeks.[143] In rats with pheochromocytoma, treatment with captopril also markedly attenuated the cardiomyopathy but did not modify contraction of isolated rings of the thoracic aorta in response to either epinephrine or angiotensin II.[144] The mechanism by which captopril produced these beneficial effects is unclear but could be related to inhibiting angiotensin II-induced cardiac fibrosis.[103]

The echocardiogram often shows left ventricular hypertrophy with normal left ventricular systolic function but occasionally mimics hypertrophic obstructive cardiomyopathy.[140] During a hypertensive crisis the electrocardiogram may show systolic anterior involvement of the anterior mitral leaflet, paradoxical septal motion, and proximal excursion of the posterior wall.

Myocarditis.

Pathologically, the myocarditis consists of focal necrosis with infiltration of inflammatory cells, perivascular inflammation, and contraction band necrosis[133] [145] [146] (Fig. 64-8), finally resulting in fibrosis. In some studies, 50 percent of patients who died of pheochromocytoma had myocarditis, usually accompanied by left ventricular failure and pulmonary edema. Although coronary atherosclerosis is usually present, medial thickening is the most characteristic lesion of the coronary arteries. When norepinephrine is infused into the rabbit, sustained coronary

Figure 64-9 Pheochromocytoma-induced cardiomyopathy. *Left,* Chest x-ray on admission. Cardiomegaly, right pleural effusion, and signs of congestive heart failure are present. *Right,* One month after removal of the tumor, no signs of congestion and a significant decrease in heart size are noted. (From Velasquez G, D'Souza VJ, Hackshaw BT, et al: Phaeochromocytoma and cardiomyopathy. Br J Radiol 57:89, 1984.)

vasoconstriction occurs and within 48 hours leads to histologically documented myocardial damage.[147] Occasionally, patients with pheochromocytoma have manifestations of cardiomyopathy that may be reversed when the tumor is removed (Fig. 64-9) . The myositis is not necessarily limited to the myocardium; it may also occur in skeletal muscle.[148]

DIAGNOSIS AND TREATMENT.

The diagnosis of pheochromocytoma is established by documenting increased urinary or plasma levels of catecholamines or one of their metabolites.[133] Three tests are commonly used: (1) total catecholamines, (2) vanillylmandelic acid, and (3) metanephrine. The last two are metabolites of catecholamine and were first used to screen for pheochromocytoma because they are present in greater quantities. When reliably performed, these tests are probably equivalent in accuracy. The probability of pheochromocytoma being present in a hypertensive patient with a single normal urine level is less than 5 percent. It is most desirable to measure both the catecholamines and one of the two metabolites, preferably metanephrine, when screening for pheochromocytoma. If the blood pressure fluctuates, it is particularly important to collect the urine at a time when the pressure is elevated. Chromogranin A blood levels are another potential screening test for pheochromocytoma. Chromogranin A is a cosecretory product from neuroendocrine tumors and does not have a known biological effect. Reliability, sensitivity, and precision estimates in comparison to urine hormonal measurements have not yet been reported, however.[149] Specific pharmacological tests to screen for pheochromocytoma are of limited benefit, usually hazardous, and therefore warranted only in unusual circumstances. Clonidine has been proposed as a useful definitive test for pheochromocytoma, although it is necessary only in unusual cases. Catecholamine levels are suppressed in normal subjects via stimulation of central alpha adrenoceptors; after clonidine administration in patients with pheochromocytoma, however, catecholamine levels are not suppressed.[150] Unfortunately, profound and prolonged hypotension has been reported in some patients during the course of this test.

Once the diagnosis of pheochromocytoma is established, specific pharmacological blockade should be initiated.[133] Administration of phenoxybenzamine hydrochloride should be begun, with the initial dosage being 10 mg every 12 hours; the dose is then gradually increased every 2 to 3 days until arterial pressure is restored to normal. Alternatively, prazosin may be used. However, it should be noted that alpha adrenoceptor blockade may induce a decline in arterial pressure accompanied by serious postural hypotension, presumably because of the vasodilation occurring in the presence of hypovolemia. This hypotensive response can be prevented by adequate sodium intake; if the response is very striking, infusion of saline may be required. Adequate control of arterial pressure is essential before any arteriographic procedure, before initiating beta adrenoceptor blockade, and before surgery. Calcium antagonists may be useful both in treating the hypertension associated with pheochromocytoma and in reducing catecholamine production.

Beta adrenoceptor blockade is useful in patients with pheochromocytoma who have significant tachycardia, palpitations, and catecholamine-induced arrhythmias. However, beta blockade with a drug affecting $beta_2$ receptors must not be initiated prior to inadequate alpha blockade since severe *hypertension* may occur as a result of unopposed alpha-stimulating activity of the circulating catecholamines.

Definitive treatment is surgical removal of the tumor, usually after localization with computed tomography, arteriography, or scanning with a radioactive iodide derivative of guanethidine as the scanning agent.[151] [152] Scanning may be particularly important in localizing extraadrenal, e.g., thoracic, pheochromocytomas. Precise definition of the anatomical boundaries of this tumor is important preoperatively if surgery is to be successful.[153] In patients with inoperable lesions, long-term use of a combination of alpha and beta adrenoceptor blockers has been helpful. Drugs that inhibit the biosynthesis of catecholamines, such as alpha-methyltyrosine, and generalized chemotherapeutic agents have also been used in patients with malignant pheochromocytoma.[154] Although rare, of particular importance to the cardiologist is the presence of a cardiac pheochromocytoma.[135] [136] [153]

PARATHYROID DISEASE

Disordered parathyroid secretion is associated with two cardiovascular disturbances: cardiac arrhythmias and hypertension. Changes in calcium metabolism, as well as a direct effect of parathyroid hormone (PTH) on the cardiovascular system, appear to be responsible.

CLINICAL AND BIOCHEMICAL MANIFESTATIONS.

PTH is a single-chain polypeptide of 84 amino acids. Its major biological effect is to increase mobilization of calcium into the extracellular fluid from a variety of tissues; this action is linked in a negative feedback loop with the serum unbound calcium concentration. Thus, an increase in serum calcium concentration reduces PTH release and vice versa.[155] PTH also increases urinary excretion of phosphate, augments bone resorption, and reduces the urinary excretion of calcium.

Primary hyperparathyroidism, the excess production of PTH, is usually secondary to a solitary parathyroid adenoma. Occasionally, generalized parathyroid hyperplasia exists, and infrequently, carcinoma of the parathyroid gland is found. The signs and symptoms of primary hyperparathyroidism are related to the direct effects of PTH on kidney or bone or those associated with the hypercalcemia. Nearly half the patients have signs and symptoms of renal dysfunction, such as polyuria, nocturia, renal

stones, and in severe cases, nephrocalcinosis and renal failure.

Cardiac hypertrophy is found with increased frequency in patients with hyperparathyroidism, even in the absence of hypertension. In one study, 5 of 18 patients with hypertrophic cardiomyopathy had raised serum PTH levels but normal serum calcium levels. In contrast, left ventricular hypertrophy did not occur in 6 patients with hypercalcemia alone.[155]

Cardiovascular Manifestations of Parathyroid Diseases

CARDIAC EFFECTS.

Although most of the effects of PTH on the heart are probably secondary to a change in extracellular calcium, PTH also has direct effects on the heart that result in an increased beating rate of isolated heart cells and positive inotropic action.[156] [157] [158] [159] [160] These effects are probably mediated by PTH binding to specific receptors, which leads to increased entry of calcium into cardiac cells, and by PTH increasing the release of endogenous myocardial norepinephrine. The direct effect of PTH may be deleterious

Figure 64-10 Heart showing the distribution of calcific deposits in the tricuspid and mitral valve annuli and at the bases of both pulmonic and aortic valve cusps in a 43-year-old woman with hypercalcemia secondary to primary hyperparathyroidism. (From Roberts WC, Waller BF: Effect of chronic hypercalcemia on the heart: An analysis of 18 necropsy patients. Am J Med 71:371, 1981.)

because it causes necrosis of rat myocytes and may be directly responsible for the increased accumulation of calcium in dystrophic muscles and for the heart damage found in uremia. On the other hand, hypoparathyroidism may cause a dilated cardiomyopathy, presumably secondary to the hypocalcemia.[161] [162] However, because longstanding hypocalcemia does not necessarily produce left ventricular dysfunction,[163] hypomagnesemia and reduced circulating PTH may also be involved. PTH also has a direct effect on vascular smooth muscle and causes vasodilation.

Chronic hypercalcemia from a variety of causes is associated with increased deposition of calcium in the fibrous skeleton of the heart and valvular cusps, as well as in coronary arteries and myocardial fibers[164] (Fig. 64-10) . Chronic hypercalcemia may also be a risk factor for accelerated coronary atherosclerosis.[162]

The plateau of the action potential of cardiac fibers is prolonged by low and shortened by high extracellular calcium concentrations (see Chap. 22) . The changes in duration of the action potential are accompanied by corresponding changes in duration of the refractory period, the ST segment, and the QT interval. Thus, the major electrocardiographic change in hypercalcemia is shortening of the QT interval. Less frequently, disorders of intraventricular conduction have been reported with shortening of the PR interval. Complete heart block occurs only rarely.

Hypocalcemia produces the opposite effect on the electrocardiogram: prolongation of the QT interval and nonspecific ST and T wave changes. Normal contractile function of cardiac muscle requires calcium, and heart failure has been reported in patients with chronic hypocalcemia secondary to hypoparathyroidism.[165]

HYPERTENSION.

Hypercalcemic patients detected by routine serum calcium screening techniques have higher arterial pressure than do matched normocalcemic subjects.[162] Yet in patients with hyperparathyroidism, the level of serum calcium is similar in those who are normotensive and those who have hypertension, which suggests that hypercalcemia per se is not the dominant cause of the hypertension. Thus, the pathophysiology of the hypertension is uncertain and may be multifactorial.[166] [167] [168] Hypercalcemia produces nephrocalcinosis, which may lead to renal failure and hypertension. Thus, reversal of hypertension after successful parathyroid surgery is more likely to occur when renal function is normal. Increased serum calcium also increases myocardial contractility, peripheral resistance, and release of or vascular sensitivity to vasoconstrictor agents such as angiotensin II and norepinephrine. Although hypercalcemia can increase cardiac contractility and arterial pressure acutely, it is unlikely that this action produces a significant alteration in cardiac output or performance on a long-term basis in the absence of PTH. Thus, elevated peripheral resistance is the most likely cause of the hypertension associated with hyperparathyroidism. Although PTH itself is a vasodilator, except subacutely,[166] characteristic changes in other hormones that occur in hyperparathyroidism may contribute to the hypertension. For example, PTH increases 1-alpha-hydroxylation of 25(OH) vitamin D, thereby leading to higher levels of $1,25(OH)_2$ vitamin D. $1,25(OH)_2$ vitamin D enhances vascular reactivity,[169] and the higher levels in hyperparathyroidism could contribute to hypertension. Finally, a circulating hypertensive factor produced in the parathyroid gland has been identified and termed "parathyroid hypertensive factor" (PHF).[170] [171] PHF is distinct from PTH and has the ability to increase the intracellular calcium concentration in vascular smooth muscle cells primarily via opening L-type calcium channels.[172] PHF was first found in the parathyroid glands of spontaneously hypertensive rats,[171] but it has since been found in the circulation of essential hypertensives, especially those who are salt sensitive and have low renin levels.[173] Elevated levels have been reported to predict a beneficial response to calcium channel blockers.[174] However, further support for the existence and physiological role of PHF is required.

DIAGNOSIS AND TREATMENT

An elevated or even a normal concentration of PTH in the presence of hypercalcemia establishes the diagnosis of hyperparathyroidism; many patients with this condition manifest hypercalcemia for the first time after starting thiazide therapy for the associated hypertension. Treatment consists of surgical removal of the parathyroid tumor or hyperplastic glands.

Patients with hypertension should have a determination of serum calcium levels before therapy is begun. If thiazide diuretics are used in treatment, serum calcium levels should be determined every 6 months. If thiazide-induced hypercalcemia occurs, serum calcium should be determined for 2 to 3 months after discontinuation of thiazide treatment. Persistence of the hypercalcemia suggests that the patient has primary hyperparathyroidism.[165]

Patients with hypoparathyroidism and hypocalcemia are usually treated with calcium supplementation and vitamin D or one of its metabolites such as calcitriol (1,25-dihydroxyvitamin D).

GONADAL HORMONES AND THE CARDIOVASCULAR SYSTEM

Estrogen (see also Chap. 58)

The past several years have witnessed an explosion in the investigation of estrogen's effects on the cardiovascular system. It has long been observed that premenopausal women enjoy protection against cardiovascular disease and that this protection is lost at menopause. Based on this observation, it has been hypothesized that it is the loss of estradiol with menopause that is responsible for the loss of cardiovascular protection. It has therefore been postulated that giving postmenopausal women estrogen as hormone replacement therapy would reduce cardiovascular risk. The role of estrogen in cardiovascular protection remains controversial.

Several mechanisms that involve different systems have been proposed to explain the cardiovascular benefit induced by estrogen.[175] Some of these mechanisms include alterations in lipid metabolism and coagulation, as well as direct vascular effects. Oral estrogen increases HDL and lowers LDL cholesterol. This potential benefit appears to account for only 30 percent of the benefit seen. More recently, the effect of estrogen on coagulation has been investigated, and it has been shown that estrogen lowers levels of plasminogen activator inhibitor type I, thereby leading to more fibrinolysis. Estrogen causes vasodilation of both peripheral vessels and coronary arteries. Most of this effect appears to be mediated by the vascular endothelium and release of nitric oxide.

Observational studies have demonstrated a decrease in cardiac risk factors in postmenopausal women taking estrogen. The Rancho Bernado study of 1057 postmenopausal women showed that estrogen users were more likely than nonusers to have lower weight, diastolic blood pressure, fasting insulin, and total cholesterol, with higher HDL cholesterol.[176] A similar benefit in altering cardiovascular risk factors was seen in the Atherosclerosis Risk in Community study of 4958 postmenopausal women.[177]

Furthermore, observational studies have demonstrated a reduction in coronary heart disease in postmenopausal women who use estrogen. The Nurses Health Study of 48,470 postmenopausal women monitored for up to 10 years demonstrated that the use of estrogen was associated with a relative risk of 0.56 for major coronary disease and 0.72 for death from cardiovascular disease.[178]

Despite the mechanistic and epidemiological data supporting a cardiovascular benefit of estrogen, the only published randomized prospective study showed no benefit on coronary heart disease prevention. The Heart and Estrogen/Progestin Replacement Study (HERS) studied 2763 postmenopausal women with a prior history of coronary heart disease in a prospective secondary prevention trial. With an average follow-up of 4 years, no reduction in cardiovascular events was seen in the group of women receiving estrogen (0.625 mg conjugated equine estrogen) given in combination with medroxyprogesterone (2.5 mg).[179] Whether estrogen is beneficial as primary prevention should be answered by the ongoing Women's Health Initiative.[180] In addition, whether other estrogens or combinations with other progestins will provide a benefit remains to be determined.

Selective Estrogen Receptor Modulators

Because concern about an increased risk for breast cancer is a major deterrent to estrogen use, the class of drugs termed selective estrogen receptor modulators (SERMs) has been developed. These drugs do not bind well to the breast or uterine estrogen receptor. The effects that they will have on cardiovascular disease are not known as yet. The first drug of this class in common use was tamoxifen, which has been used primarily in the treatment of breast cancer. Several studies of tamoxifen in the treatment of breast cancer have shown a decrease in either fatal myocardial infarction or hospital admissions for cardiac disease.[181] [182] Caution must be used in viewing these results since the studies were not designed to look at heart disease as a primary endpoint. Tamoxifen has been shown to lower LDL cholesterol as a potential mechanism for its cardiovascular benefit.[183] The only other SERM now approved for use is raloxifene, which is indicated for the prevention and treatment for osteoporosis. Raloxifene lowers LDL cholesterol without increasing HDL cholesterol.[184] Whether raloxifene will have any benefit on cardiovascular morbidity or mortality is currently under investigation.

Oral Contraceptives

The literature on the association between oral contraceptive use and coronary heart disease is controversial. The controversy is due in large part to the decreasing estrogen content in oral contraceptives over the past 40 years, as well as the incorporation of varying progestins with different androgenic potencies. The changing spectrum of oral contraceptive composition also makes it difficult to extend data based on earlier agents to today's preparations. Several studies have shown an increased risk of myocardial infarction in oral contraceptive users.[185] However, prior oral contraceptive use does not confer an increased risk for cardiovascular disease. Studies of the effect of newer contraceptive agents are not available.[186]

BLOOD PRESSURE EFFECTS OF ORAL CONTRACEPTIVES AND HORMONAL REPLACEMENT THERAPY

Oral contraceptive use has been associated with a rise in blood pressure since their widespread use in the 1960s. When blood pressure rises, it usually remains within the normotensive range; rarely, it increases into the hypertensive (140/90 mm Hg) range. Even with the earlier-generation oral contraceptives, which used a higher estrogen dose and varied progestins, data were conflicting regarding whether whether blood pressure rises.[187] [188] [189] Differences in responses to oral contraceptives may depend on the quantity of estrogen, the type of progestin, and the race and genetic background of the user. Studies of the new generation of oral contraceptives, which contain no greater than 35 mug ethinyl estradiol and less androgenic progestins, are more limited. Available data on desogestrel-containing oral contraceptives include a multicenter trial of more than 1600 women monitored over 23,000 cycles. No significant change in mean blood pressure over a 2-year period of use was observed, and only a 0.3 percent incidence of hypertension was noted.[190] Other studies of this agent have revealed similar results.[191] [192] Although activation of the renin-angiotensin-aldosterone axis occurs in oral contraceptive users, the degree of activation may be greater in those who remain normotensive than those who became hypertensive. Thus, the etiology of oral contraceptive-induced hypertension remains unclear.

The belief that estrogens used for hormone replacement therapy induce hypertension is largely based on the older oral contraceptive literature. In fact, the use of estrogen in many trials is associated with no change in blood pressure. It is likely that estrogens differ in their effect on blood pressure. Estrone and estradiol, natural estrogens, may actually lead to a fall in blood pressure.

ANDROGENS AND THE HEART.

Similar to the view that women are protected against cardiovascular disease because of estrogen, it has been assumed that the increased incidence of cardiovascular disease in men is in part related to testosterone levels. However, studies designed to examine this link, although limited in number and size, have instead suggested that testosterone has a neutral or perhaps even beneficial effect on cardiovascular risk in men.

Observational studies have failed to show a positive relationship between testosterone levels and cardiovascular disease in men. Several studies of over 3000 men in different countries have shown no relationship between baseline testosterone levels and the future development of cardiovascular disease in men.[193] [194] Since these studies are cross-sectional, it is possible that the lower testosterone levels are a consequence of the coronary heart disease, not a cause.

Unfortunately, at this time, few intervention studies are available to help determine the cause-and-effect relationship. In a study of 62 men with a history of angina, men were randomized to receive placebo or oral testosterone. Of note, the serum testosterone levels of these men were normal, but significantly lower than controls at baseline. The group that received testosterone had a significant reduction in anginal symptoms and improvement in ST segment changes on electrocardiographic and Holter monitoring. [195] A more recent study evaluated the effect of acute intravenous testosterone on 14 men with a history of angina and angiographically proven coronary artery disease and low serum testosterone levels. In this study, the time to ST segment depression on exercise tolerance tests was prolonged by 20 percent in men receiving testosterone versus placebo.[196]

CARDIOVASCULAR CONSEQUENCES OF OBESITY

The prevalence of obesity is increasing in many developing countries and in the United States. Estimates based on the

National Health and Nutritional Examination Survey III study indicate that as of 1994, 33 percent of the U.S. population was obese,[197] and this percentage is predicted to steadily increase. Obesity is associated with higher levels of blood pressure, dyslipidemia, and type II diabetes mellitus, all contributors to cardiovascular disease. However, in addition, obesity appears to be an independent predictor of coronary artery disease in both men and women.[198] [199] Recent studies indicate that it is not just obesity that is associated with increased cardiovascular disease, but that upper body obesity further increases the risk.[200]

Evidence of circulatory dysfunction in the massively obese, in association with cardiac enlargement during life and at autopsy, was first described by Smith and Willius in 1933.[201] Cardiac changes in obesity may often be related to concomitant hypertension. The elevated leptin levels seen in obesity may be mediators of the hypertensive process.[201A] Left ventricular hypertrophy also may be present in the absence of systemic hypertension.[202] Right ventricular hypertrophy may also be seen, most commonly as a result of obesity-related obstructive sleep apnea and pulmonary hypertension. Much of the cardiovascular risk associated with obesity is probably associated with the concomitant insulin resistance (see Chap. 63) .

TREATMENT OF THE CARDIOVASCULAR MANIFESTATIONS OF OBESITY.

Although weight reduction would seem to be the most beneficial treatment of cardiovascular disease in obesity, conclusive longitudinal studies are lacking. However, with weight reduction often comes improvement in the hypertension, dyslipidemia, and insulin resistance seen in obesity. Weight reduction is also associated with regression of left ventricular hypertrophy independent of blood pressure changes,[203] as well as shortening of the prolonged QT_c seen in obese patients.[204]

CARDIAC COMPLICATIONS OF WEIGHT LOSS.

Rapid weight loss has been associated with cardiac arrhythmias and sudden death.[205] In some cases, these complications are probably secondary to inadequate electrolyte supplementation. In others, they may be related to a reduction in myocardial protein and cardiac atrophy. Although initially associated with a liquid protein diet, sudden death may occur under any circumstance associated with rapid weight loss.[206]

MALNUTRITION

Malnutrition, particularly protein-calorie deficiency, is prevalent in many underdeveloped areas of the world. However, in recent years, it has also become a concern in developed countries in individuals who have chronic diseases, in whom it exists as a result of both anorexia and hypermetabolism, and in otherwise healthy individuals with anorexia nervosa.

CARDIAC CHANGES IN MALNUTRITION.

The circulatory status of patients with severe nutritional depletion and electrolyte imbalance is precarious: Cardiac output, systolic pressure, and pulse pressure are abnormally low, and massive, generalized edema may be present; the PR interval may be shortened. Loss of subcutaneous fat may be observed, as well as general wasting and atrophy of most organs, including the heart, which is thin walled, pale, and flabby on gross examination. Histological study reveals atrophy of muscle fibers. Treatment of a dehydrated or severely anemic patient with protein-calorie malnutrition involves correction of hematological, fluid, and electrolyte imbalance. Congestive heart failure can be avoided if care is taken to avoid overloading with sodium, water, or blood.

ANOREXIA NERVOSA.

This common psychiatric condition, seen particularly in young women, is associated with significant cardiac morbidity and mortality. Many of the cardiac changes relate to protein-calorie malnutrition, including destruction of cardiac myofibrils.[207] Echocardiographic findings include small ventricular chamber size and mass, even when corrected for weight, reduced cardiac index, and abnormalities in mitral valve function.[208] Hypocalcemia and hypomagnesemia may contribute to arrhythmias, heart failure, and sudden death since bradycardia thought to be secondary to increased vagal tone is common. QT_c prolongation can also be seen and may indicate a predisposition to arrhythmias and sudden death. Predictors of QT_c prolongation are weight, body mass index, and rapidity of weight loss even in the absence of electrolyte disturbances.[209]

Chapter 65 - Pregnancy and Cardiovascular Disease

URI ELKAYAM

CARDIOVASCULAR PHYSIOLOGY DURING PREGNANCY AND THE PUERPERIUM

PREVALENCE.

Although heart disease is limited to only 0.5 to 1.0 percent of pregnant women, it remains an important cause of maternal morbidity and even mortality and has a significant effect on fetal outcome.[1] [2] [3] Pregnancy and the peripartum period are associated with important cardiocirculatory changes[4] that can lead to marked clinical deterioration in the woman with heart disease. Hemodynamic changes occurring during pregnancy are summarized in Table 65-1 .

BLOOD VOLUME.

Blood volume increases substantially during pregnancy, starting as early as the sixth week and rising rapidly until midpregnancy, when the rise continues but at a much slower rate[4] (Fig. 65-1) . The degree of maximum volume expansion varies considerably in the individual patient (20 to 100 percent) and averages 50 percent. This increase is reported to correlate with fetal weight, placental mass, weight of the products of conception, and maternal and neonatal weight.[4] A higher increment in blood volume is reported in multigravidas and in women with multiple pregnancies.[3]

Because increase in plasma volume is more rapid than increase in red blood cell mass (see Fig. 65-1) , hemoglobin concentration falls during pregnancy gradually until week 30, causing the "physiological anemia of pregnancy" with hematocrit levels that can be as low as 33 to 38 percent, a condition that can be partially corrected with iron therapy.[4] Changes in blood volume during pregnancy are attributable to estrogen-mediated stimulation of the renin-aldosterone system,[5] [6] which results in sodium and water retention. Changes in other hormones, including deoxycorticosterone, prostaglandins, estrogen, prolactin, placental lactogen, growth hormone, adrenocorticotropic hormone, and atrial natriuretic peptides, may also be involved in water retention during pregnancy.[4] [7]

CARDIAC OUTPUT, STROKE VOLUME, AND HEART RATE.

Cardiac output during pregnancy is estimated to increase by approximately 50 percent.[4] It begins to rise around the fifth week and increases rapidly until the 24th week, when it plateaus or continues to rise slightly[4] [8] [9] (Fig. 65-2 , Table 65-1) . During the third trimester, body position can substantially influence cardiac output, which increases in the lateral position and declines in the supine position, owing to caval compression by the gravid uterus and decreased venous return to the heart. The increase in cardiac output early in pregnancy is predominantly due to augmentation in stroke volume, whereas in the third trimester it is largely due to an accelerated heart rate and stroke volume does not change or even declines as a result of caval compression (see Fig. 65-2) . Increase in cardiac output seems to be enhanced in subsequent pregnancies.[9]

Heart rate peaks during the third trimester with an average increase of 10 to 20 beats/min[4] [9] (see Fig. 65-2) , although on occasion it may be markedly faster. Pregnancy with multiple fetuses is associated with an even higher heart rate.

BLOOD PRESSURE AND SYSTEMIC VASCULAR RESISTANCE.

Systemic arterial pressure begins to fall during the first trimester, reaches a nadir in mid pregnancy, and returns toward pregestational levels before term[4] [9] (see Table 65-1) . Because diastolic blood pressure decreases substantially more than systolic pressure, the pulse pressure widens.[4] Reduction in blood pressure is caused by a decline in systemic vascular resistance due to reduced vascular tone,[10] probably mediated by (1) gestational hormonal activity, increased levels of circulating prostaglandins, and atrial natriuretic peptides,[4] [11] as well as endothelial nitric oxide[12] ; (2) increased heat production by the developing fetus; and (3) the creation of low-resistance circulation in the pregnant uterus.

SUPINE HYPOTENSIVE SYNDROME OF PREGNANCY.

The supine hypotensive or the uterocaval syndrome of

Figure 65-1 Changes in plasma volume, erythrocyte volume, and hematocrit during pregnancy. Increase in plasma volume is more rapid than increase in erythrocyte volume, causing the "physiological anemia of pregnancy," which can be partially corrected with iron supplements. *(From Pitkin RM: Nutritional support in obstetrics and gynecology. Clin Obstet Gynecol 19:489, 1976.)*

pregnancy occurs with significant decreases in heart rate and blood pressure in up to 11 percent of pregnant women.[4] These hemodynamic changes are associated with weakness, lightheadedness, nausea, dizziness, and even syncope and are explained by acute occlusion of the inferior vena cava by the enlarged uterus (Fig. 65-3) (Figure Not Available) . When the supine position is abandoned, these hemodynamic effects and symptoms usually are promptly relieved.

HEMODYNAMIC CHANGES DURING LABOR AND DELIVERY.

Hemodynamics are altered substantially during labor and delivery secondary to anxiety, pain, and uterine contractions.[4] Oxygen consumption increases threefold; and cardiac output rises progressively during labor owing to increase in both stroke volume and heart rate, and it is higher in the lateral position. Both systolic and diastolic blood pressures increase markedly during contractions, with greater augmentation during the second stage.[4] [13] Hemodynamic changes during labor and delivery are greatly influenced by the form of anesthesia and analgesia.[4] [13] Reduction of pain and apprehension by local, caudal, and epidural anesthesia may limit hemodynamic changes and rise in oxygen consumption.[4] [13]

HEMODYNAMIC EFFECTS OF CESAREAN SECTION.

To avoid the hemodynamic changes associated with vaginal

Figure 65-2 Percent changes of heart rate, stroke volume, and cardiac output measured in the lateral position throughout pregnancy compared with prepregnancy values. *(Modified from Robson SC, Hunter S, Boys RJ, Dunlop W: Serial study of factors influencing changes in cardiac output during human pregnancy. Am J Physiol 256:H1060-H1065, 1989.)*

delivery, cesarean section is frequently recommended for women with cardiovascular disease. However, this form of delivery can also be associated with considerable hemodynamic fluctuations related largely to intubation, drugs used for anesthesia and analgesia,[14] larger extent of blood loss, the relief of caval compression, extubation, and postoperative awakening.[3]

HEMODYNAMIC CHANGES POST PARTUM.

A temporary increase in venous return may occur immediately after delivery due to relief of caval compression and, in addition, blood shifting from the contracting uterus into the systemic circulation (autotransfusion).[14] This change in effective blood volume occurs despite blood loss during delivery and can result in a substantial rise in ventricular filling pressure, stroke volume, and cardiac output and may lead to clinical deterioration. Both heart rate and cardiac output return to prelabor values by 1 hour after delivery and mean blood pressure and stroke volume by 24 hours after delivery.[4] [13] Hemodynamic adaptation to pregnancy persists post partum and

gradually returns to prepregnancy values within 12 to 24 weeks after delivery.[4]

Figure 65-3 (Figure Not Available) Venocaval compression of the inferior vena cava and abdominal aorta by the gravid uterus can lead to reduced venous return and thus to decreased cardiac output. *(From Lee W, Shah PK, Amin DK, et al: Hemodynamic monitoring of cardiac patients during pregnancy. In Elkayam U, Gleicher N: Cardiac Problems in Pregnancy. 2nd ed. New York, Alan R. Liss, 1990, p 61.)*

CARDIOVASCULAR EVALUATION DURING PREGNANCY

History and Physical Examination

Normal pregnancy is often accompanied by symptoms of fatigue, decreased exercise capacity, hyperventilation, dyspnea, palpitations, lightheadedness, and even syncope (Table 65-2) .[15] [16] In addition, augmentation of jugular venous pulsation due to increased blood volume, and leg edema (often observed in late pregnancy), could lead to an erroneous diagnosis of heart failure or overestimation of its severity. Systemic arterial pulses are full and collapsing and are similar to those palpated in patients with aortic regurgitation or hyperthyroidism. A left ventricular impulse is easily detected in most women in late pregnancy and is hyperactive and brisk. Right ventricular heave is usually present during the second and third trimester, and the pulmonary trunk and pulmonic valve closure are often palpable. This group of findings may result in difficulty in assessing the presence and/or severity of pulmonary hypertension.

CARDIAC AUSCULTATION (see Chap. 4) .

Especially after the first trimester, auscultation often reveals an increased first heart sound (S_1) with exaggerated splitting that may be misinterpreted as a fourth heart sound (S_4) or as a systolic click.[15] The second heart sound (S_2) is often increased in late pregnancy and may exhibit persistent splitting when the patient is examined in the lateral position. These changes in S_2 may be interpreted as signs of pulmonary hypertension (loud P_2) or atrial septal defect (systolic murmur and splitting of S_2). Auscultation of the third heart sound (S_3) and S_4 is uncommon in normal pregnancy.

Innocent Systolic Murmurs.

These can be heard in most pregnant women and are the result of the hyperkinetic circulation of pregnancy. Murmurs are usually midsystolic and soft, are heard best at the lower left sternal edge and over the pulmonic area, and radiate to the suprasternal notch and more to the left than to the right side of the neck.[15] Not uncommonly the benign murmur of pregnancy

TABLE 65-2 -- CARDIAC SYMPTOMS AND FINDINGS DURING NORMAL PREGNANCY

SYMPTOMS
Decreased exercise capacity
Tiredness
Dyspnea
Orthopnea
Palpitations
Lightheadedness
Syncope
PHYSICAL FINDINGS
Inspection
Hyperventilation
Peripheral edema
Distended neck veins with prominent a and v waves and brisk x and y descents
Capillary pulsation
Precordial Palpation
Brisk, diffuse, and displaced left ventricular impulse
Palpable right ventricular impulse
Palpable pulmonary trunk impulse
Auscultation
Pulmonary basilary rales
Increased first heart sound with exaggerated splitting
Exaggerated splitting of second heart sound
Midsystolic ejection-type murmurs at the lower left sternal edge and over the pulmonary area radiating to suprasternal notch and more to the left than right side of neck
Continuous murmurs (cervical venous hum, mammary souffle)
Diastolic murmurs (rare)

TABLE 65-3 -- ELECTROCARDIOGRAPHIC FINDINGS DURING NORMAL PREGNANCY

QRS axis deviation
Small Q wave and inverted P wave in lead III (abolished by inspiration)
ST segment and T wave changes (ritodrine tocolysis, cesarean section)
Frequent sinus tachycardia
Higher incidence of arrhythmias
Increase R/S ratio in leads V_2 and V_1

may be louder or longer and may sound like those associated with atrial septal defect or stenosis of one of the semilunar valves. In such cases an echocardiographic and Doppler evaluation is warranted to rule out an abnormal cardiac condition. Two benign continuous murmurs that may be heard during gestation are the cervical venous hum and mammary souffle. The venous hum is usually heard maximally over the right supraclavicular fossa but can radiate to the contralateral area and sometimes to the area below the clavicle. The mammary souffle may be either systolic or continuous, is heard over the breast late in gestation or in the lactating woman, and is caused by increased flow in the mammary vessels. Characteristically, the murmur decreases or vanishes when pressure is applied to the stethoscope or when the patient moves to the upright position.[15] Diastolic murmurs may be heard in normal pregnant women due to increased blood flow through the atrioventricular valve.[15] Such a finding, however, is infrequent in the healthy pregnant woman and therefore requires careful diagnostic work-up to rule out organic disease.

Laboratory Examinations

ELECTROCARDIOGRAPHY (see Chap. 5) .

In normal pregnancy, the QRS axis may shift to either the left or the right, but it usually stays within normal limits[15] (Table 65-3) . A small Q wave and an inverted P wave in lead III that vary with respiration as well as a greater r wave amplitude in lead V_2 may be present. A high incidence of ST segment depression mimicking myocardial ischemia but not associated with wall motion abnormalities has been described between induction of anesthesia and the end of surgery in patients undergoing cesarean section.[17] [18] Increased susceptibility to arrhythmias during pregnancy is manifested by the frequent finding of sinus tachycardia and atrial and/or ventricular premature beats.[16] There is an increased incidence of paroxysmal supraventricular tachycardia during normal pregnancy,[19] and several cases of ventricular tachycardia have been reported in healthy women.[20]

CHEST RADIOGRAPHY (see Chap. 8) .

Although the radiation dose associated with a routine chest radiograph is minimal, because of the potential for adverse biological effects from any amount of radiation the pelvic area should be shielded by protective lead material[21] (Table 65-4) .

Changes seen on chest films in normal pregnancy may simulate cardiac disease and should be interpreted with caution.[22] Straightening of the left upper cardiac border because of prominence of the pulmonary conus is often seen. The heart may seem enlarged because of its horizontal positioning secondary to the elevated diaphragm. In addition, an increase in lung markings may simulate a pattern of flow redistribution seen with increased pulmonary venous pressure. Pleural effusion is often found early post partum. It is usually small and resorbs 1 to 2 weeks after delivery.[15]

DOPPLER ECHOCARDIOGRAPHY (see Chap. 7) .

Gestational use of both maternal and fetal cardiac ultrasound is considered safe.[23] [23A] Transesophageal echocardiography has been increasingly used in pregnancy and seems to be well tolerated by both mother and fetus[24] (Table 65-5) .

TABLE 65-4 -- CHEST RADIOGRAPHIC FINDINGS DURING NORMAL PREGNANCY

Straightening of the left upper cardiac border
Horizontal position of the heart
Increased lung marking
Small plural effusion in early postpartum period

TABLE 65-5 -- DOPPLER AND ECHOCARDIOGRAPHIC FINDINGS DURING NORMAL PREGNANCY

Slightly increased systolic and diastolic left ventricular dimensions (when patient examined in the lateral position)
Unchanged or slightly improved left ventricular systolic function
Moderate increase in size of right atrium, right ventricle, and left atrium
Progressive dilation of pulmonary, tricuspid, and mitral valve annuli
Functional pulmonary, tricuspid, and mitral regurgitation
Small pericardial effusion

Pericardial effusion, usually small or minimal, has been noted in normal pregnant women late in pregnancy.[25] There is a progressive increase in all cardiac chamber dimensions with an approximately 20 percent increase in the size of the right atrium and the right ventricle, 12 percent in left atrial size, and 6 percent in left ventricular size.[26] [27] Post parturm these changes gradually return toward baseline but may remain different from prepregnancy values for several months.[9] In addition, there is early and progressive dilatation of mitral, tricuspid, and pulmonary annuli, which is associated with increase in valvular regurgitation.[28]

STRESS TESTING (see Chap. 6) .

An exercise test using bicycle ergometry or a treadmill can be carried out during pregnancy to help establish the diagnosis of ischemic heart disease and to assess functional capacity and cardiac reserve.[29] The safety of such testing in pregnancy has not been fully established. Because fetal bradycardia has been reported with maximal but not with submaximal exercise,[29] [30] a low-level exercise protocol allowing heart rate increase to 70 percent of maximal predicted heart rate with fetal monitoring is recommended when stress testing is indicated.[15]

RADIATION.

Exposure of the embryo to irradiation during the first 10 days post conception would most likely have either no effect or lead to resorption.[31] Irradiation during organ formation (days 10-50) may cause a teratogenic effect, whereas after completion of organogenesis, it may cause intrauterine growth retardation, central nervous system abnormalities, and possible increased incidence of childhood cancer or leukemia. Current recommendations related to intrauterine radiation exposure are

Less than 5 rads--patient can be reassured of very low likelihood of risk.

Five to 10 rads--patient should be counseled regarding low risk of problems.

Ten to 15 rads during first 6 weeks--individual considerations for termination of pregnancy should be made.

More than 15 rads--termination of pregnancy recommended.

Routine chest radiography is associated with radiation of 20 mrad to the chest. Standard fluoroscopy could deliver 1 to 2 rads/min to the chest and high level fluoroscopy or cine as much as 5 to 10 rads/min. The amount of radiation scattered to the uterus and absorbed by the embryo is less than 5 percent of radiation absorbed by the directly radiated tissue. Direct irradiation to the fetus should be avoided and can be prevented by covering the patient with a lead apron during radiographic procedures. The use of a lead apron, however, is of little help in reducing fetal irradiation due to Compton-scattered photons.[31]

Radiation to the fetus from nuclear medicine procedures is mainly due to distribution of radiopharmaceuticals to the bladder or the placenta or directly across the placental barrier. The expected radiation with thallium-201 or technetium-99m-labeled sestamibi diagnostic procedures is less than 1 rad per examination. Cardiac function studies with technetium-99m-labeled red blood cells is associated with fetal radiation of 1 to 2 rads, peripheral contrast radiographic venography of 0.5 rad or less, and pulmonary scintigraphy with technetium-macroaggregated albumin of 0.05 rad or less.[31]

MAGNETIC RESONANCE IMAGING (see Chap. 10) .

Although magnetic resonance imaging poses no known risks to the fetus, experience with this technique is limited and its safety has not been fully established.[32] Currently, the U.S. Food and Drug Administration recommends prudence in using magnetic resonance imaging during pregnancy.[32] This technique should therefore be used only when evaluation cannot be delayed until after pregnancy, and if possible after the first trimester.

PULMONARY ARTERY CATHETERIZATION.

Hemodynamic monitoring with the aid of a pulmonary artery catheter can be of great help in managing patients at high risk during pregnancy, labor, delivery, and the postpartum period.[33] The ability to insert and position the flotation catheter with pressure monitoring without the need for fluoroscopy makes it particularly attractive for use during pregnancy. Hemodynamic monitoring is recommended throughout labor and delivery for any patient with symptomatic cardiac disease during pregnancy or with the potential for deterioration due to valvular, myocardial, or ischemic heart disease. Because significant circulatory changes that may lead to hemodynamic deterioration occur in the early postpartum period,[4] hemodynamic monitoring should be continued for at least several hours after delivery to ensure stability.

CARDIAC CATHETERIZATION (see Chap. 11) .

Cardiac catheterization may be indicated in rare instances of cardiac decompensation when sufficient information cannot be obtained by noninvasive techniques, especially if cardiac surgery, coronary angioplasty, or balloon valvuloplasty is being considered. Although this technique provides high-quality images, it is associated with a relatively high dose of radiation. To minimize radiation to the pelvic and abdominal areas, the brachial rather than the femoral approach is preferred, fluoroscopy and cine time should be reduced to the minimum required, and direct irradiation to the fetus should be avoided.

PREGNANCY IN WOMEN WITH CONGENITAL HEART DISEASE (See Chap. 44)

Because of increased survival in children with congenital heart disease, pregnancy has become more common in this patient population.[34] [35] Preconception management should include careful history and assessment of risk for both the mother and the fetus.[35] [36] [37]

The patient should be counseled regarding contraceptive alternatives,[38] potential maternal and fetal risks of pregnancy,[39] [40] and, when appropriate, expected long-term maternal morbidity and survival as well as the risk of congenital malformations in the offspring.[41] In addition, guidance concerning anticoagulation and prophylactic antibiotics, if needed, should be provided.[42]

MATERNAL AND FETAL OUTCOME.

In general, a good maternal outcome can be expected in most cases with noncyanotic congenital heart disease. Maternal outcome is determined by the nature of the disease, surgical repair, presence and severity of cyanosis, increased pulmonary vascular resistance, maternal functional capacity, myocardial dysfunction, left ventricular obstruction, and history of arrhythmias[42A] [42B] or other prior cardiac events.[40] Unfavorable outcome, including development of congestive heart failure, arrhythmias, and hypertension, is commonly seen in patients with impaired functional status and those with cyanosis.[40] [41] [42] Other reported complications include angina, infective endocarditis, and thromboembolic phenomena.

Maternal functional capacity and cyanosis also determine fetal outcome.[43] [44] Fetal wastage was reported in 45 percent of cyanotic mothers compared with 20 percent in acyanotic mothers with congenital heart disease.[44] Low birth weight for gestational age and prematurity are common in cyanotic mothers and correlate with maternal hemoglobin and hematocrit values.[43] [44] Risk of congenital heart disease is increased for the offspring of mothers with congenital heart disease with a reported incidence of 4 to 8 percent.[45] [46] In addition, there are a greater number of noncardiac congenital malformations, as well as mental and physical impairments in children born to mothers with congenital heart disease.

LABOR AND DELIVERY.

Elective induction of labor when fetal maturity is confirmed may be used in high-risk patients for better planning of hemodynamic monitoring and availability of expert personnel[34] during labor and delivery. Vaginal delivery is preferred for most patients, and cesarean section is indicated in the stable patients only for obstetric reasons. Oxygen should be given to hypoxemic mothers, and hemodynamic as well as blood gas monitoring is recommended in most patients with impaired functional capacity, cardiac dysfunction, pulmonary hypertension, and cyanotic malformations. Blood volume loss must be anticipated and treated promptly.

ANTIBIOTIC PROPHYLAXIS.

Official recommendations by the American Heart Association suggest that antibiotic prophylaxis for an uncomplicated delivery is unnecessary except for cases with a prosthetic heart valve or a surgically constructed systemic-to-pulmonary shunt.[47] Because of difficulties in predicting complicated deliveries and potential devastating consequences of endocarditis,[48] antibiotic prophylaxis

for vaginal delivery in all patients with congenital heart disease (except those with an isolated secundum type of atrial septal defect and those 6 months or more after repair of septal defects or surgical ligation and division of patent ductus arteriosus) seems reasonable.

Specific Malformations

ATRIAL SEPTAL DEFECT (see also Chap. 44) .

Atrial septal defect is usually well tolerated in pregnancy even in patients with large left-to-right shunts. The development of pulmonary hypertension and atrial arrhythmias rarely occurs in the childbearing age. Because endocarditis is rare, antibiotic prophylaxis is not indicated in patients with secundum-type atrial septal defect. Recommendations concerning pregnancy in patients with atrial septal defect should be made on an individual basis, considering accompanying lesions, functional status, and the level of pulmonary vascular resistance.[34]

VENTRICULAR SEPTAL DEFECT (see also Chap. 44) .

Women with isolated ventricular septal defect usually tolerate pregnancy well, although congestive heart failure and arrhythmias have been reported.[34] The risk posed by pregnancy after closure of an uncomplicated ventricular septal defect should not differ from that in patients without heart disease. The incidence of ventricular septal defect in offspring has been reported to be 4 to 11 percent.[34] Marked reduction in blood pressure during or after delivery as a result of blood loss or anesthesia can lead to shunt reversal in patients with pulmonary hypertension. The use of vasopressors and volume replacement to stabilize blood pressure should prevent further complications.

PATENT DUCTUS ARTERIOSUS (see also Chap. 44) .

Maternal outcome in patients with patent ductus arteriosus with left-to-right shunt is usually favorable[34] [42] ; however, clinical deterioration and congestive heart failure can occur in some patients. There were no maternal deaths among a large number of patients with patent ductus arteriosus.[40] [48] The need for surgical intervention during pregnancy is rare. A fall in systemic vascular resistance during gestation and hypotension early post partum can lead to shunt reversal in women with pulmonary hypertension. Peripartum decrease in systemic blood pressure should be corrected by means of vasopressor agents.

CONGENITAL AORTIC VALVE DISEASE (see also Chap. 44) .

Most patients with mild aortic stenosis have favorable outcome of pregnancy provided that they receive early diagnosis and appropriate care, including hemodynamic monitoring during labor and delivery and appropriate anesthesia.[3] [34] [49] At the same time, however, moderate and severe aortic stenosis is likely to be associated with symptomatic deterioration during pregnancy and may lead to maternal morbidity and even mortality.[3]

Symptoms usually develop in the second or third trimester and may include exertional dyspnea, chest pain, lightheadedness, and syncope. Increased incidence of cardiac defects has been reported in liveborn infants of mothers with left ventricular outflow obstruction.[43] Because of the risk involved, patients with severe aortic stenosis (aortic valve area <1.0 cm^2) should consider undergoing valve replacement before becoming pregnant. Optional management strategies of a pregnant patient with severe aortic stenosis include (1) early abortion followed by valve replacement and repeat pregnancy and (2) continuation of pregnancy and plan for percutaneous balloon valvuloplasty or surgical intervention in patients who show clinical deterioration not controlled by medical therapy.[50] [51]

Both replacement of aortic valve and percutaneous balloon valvuloplasty have been performed successfully in pregnant women with aortic stenosis.[50] [51] [52] [53] These

procedures, however, are not free of complications. Although valvuloplasty obviates the general anesthesia and cardiopulmonary bypass required for surgery, it can be associated with prolonged radiation exposure and hemodynamic fluctuations that can lead to immediate and late fetal complications. Surgical replacement of the aortic valve during pregnancy can be associated with increased incidence of maternal complications and fetal loss.[53] These procedures should therefore be considered only in symptomatic patients with severe disease not manageable by medical therapy and should be avoided when possible during the first trimester.

COARCTATION OF THE AORTA (see also Chap. 44) .

Both maternal and fetal outcome is usually favorable in cases with aortic coarctation.[54] [55] [56] At the same time, however, cases of severe hypertension, congestive heart failure, and aortic dissection have been reported.[42] [56] A recent study reported congenital heart disease in 3 percent of newborns born to patients with corrected coarctation.[57] Because a higher incidence of infective endocarditis in the mother and of congenital heart disease in the fetus have been shown in cases with surgically uncorrected compared with corrected coarctation,[43] it seems advisable to correct aortic coarctation before pregnancy.[57]

Measures to reduce the incidence of aortic dissection and rupture of cerebral aneurysms during pregnancy consist of limiting physical activity and controlling blood pressure. Excessive blood pressure reduction, however, may compromise uteroplacental blood flow and should be avoided. Surgical correction of coarctation has been performed successfully during pregnancy[57] and may be indicated in patients with severe, uncontrollable systolic hypertension or heart failure.

PULMONIC STENOSIS (see also Chap. 44) .

Isolated pulmonic stenosis is usually well tolerated during pregnancy.[3] [34] [34A] When possible, however, severe stenosis should be corrected before conception. In the rare instance of progressive right ventricular failure or symptoms clearly related to the stenotic valve, or in a patient with intracardiac shunt at either the atrial or ventricular level with cyanosis, percutaneous balloon valvotomy should be considered during pregnancy.

TETRALOGY OF FALLOT (see also Chap. 44) .

Hemodynamic changes associated with pregnancy may become severe and cause clinical deterioration in women with surgically uncorrected or only partially corrected tetralogy of Fallot. Increase in blood volume and venous return to the right atrium raises right ventricular pressure, which combined with a fall in systemic vascular resistance can produce or exacerbate right-to-left shunt and cyanosis. Labor and delivery are particularly important because a fall in blood pressure can also increase right-to-left shunt and the degree of cyanosis. Maternal hematocrit above 60 percent, arterial oxygen saturation below 80 percent, right ventricular hypertension, and syncopal episodes are poor prognostic signs. Pregnancies in women with cyanosis are associated with high rate of spontaneous abortion, premature deliveries, and fetal growth retardation.[43] [44] [45] [58] [59]

Close monitoring of systemic blood pressure and blood gases during labor and delivery is recommended for cyanotic or symptomatic patients. Incidence of cardiac defects reported in born infants ranges between 3 and 17 percent.[40]

Patients who have undergone only palliative procedures or who have significant residual defects after repair, such as residual ventricular septal defect, pulmonic stenosis or regurgitation, and ventricular dysfunction, are still at higher risk during pregnancy. Patients who had undergone shunt procedures to improve cyanosis may develop pulmonary hypertension, which increases the risk of pregnancy. Because maternal and fetal outcomes seem to be markedly improved after surgical repair, this procedure should be performed before conception. Because revision of an incompletely repaired defect is recommended in patients with residual ventricular septal defect when the pulmonary/systemic flow ratio is greater than 1.5:1.0, in those

with right ventricular outflow obstruction (right ventricular systolic pressure >60 mm Hg), and in those with right ventricular failure due to pulmonic regurgitation, such revision should be performed before conception in a woman who plans to conceive.

EISENMENGER SYNDROME (see also Chap. 44) .

This condition continues to be associated with a high risk of maternal morbidity and mortality. A recent review of 55 women who had at least one pregnancy showed maternal mortality of 39 percent.[34] Similarly, a recent analysis of 65 published cases with Eisenmenger syndrome from more than 20 countries showed 43 percent maternal mortality.[60] Cause of maternal death is often unclear; it usually occurs in the first few days after delivery and is preceded by desaturation and hemodynamic deterioration. Eisenmenger syndrome is also associated with a poor fetal outcome, with a high incidence of fetal loss, prematurity, intrauterine growth retardation, and perinatal death.[34] [34A]

Because of the high risk of maternal mortality, patients with Eisenmenger syndrome should be advised against pregnancy and early abortion should be recommended for patients who are already pregnant. Management of a patient who decides to proceed to term must include close follow-up for early detection of clinical deterioration. Because of increased incidence of peripartum thromboembolism, anticoagulant therapy seems indicated in the third trimester of gestation and for 4 weeks post partum. Because premature delivery is common, women with Eisenmenger syndrome should be hospitalized for any sign of premature uterine activity. For this reason and to ensure restriction of activity and close follow-up, early elective hospitalization is recommended. Spontaneous labor is preferred to induction and should lower the chance of prematurity or the need for cesarean section. Blood pressure, electrocardiographic, and blood gas monitoring are essential during labor and delivery to ensure early detection and correction of problems; high concentrations of oxygen may be helpful. Most patients in stable condition will tolerate vaginal delivery; however, an attempt should be made to shorten the second stage of labor by the use of forceps or vacuum extraction. Because of the higher risk of fetal distress during vaginal delivery and potential need for emergency cesarean section, a planned cesarean section is often preferred. Insertion of a Swan-Ganz catheter may be difficult and associated with the development of arrhythmias, and its routine use is not recommended.[61] Inhaled nitric oxide has been used successfully to reduce pulmonary pressure and improve oxygenation during labor and the early postpartum period in two patients with Eisenmenger syndrome.[62] [63] Both patients gave birth to live infants but died 2 and 21 days post partum.

EBSTEIN ANOMALY.

Pregnancy in women with noncyanotic Ebstein anomaly is well tolerated. In cyanotic cases pregnancy is associated with increased risk of maternal heart failure, prematurity, and fetal loss.[64] [65] The approach to labor and delivery in symptomatic or cyanotic patients with Ebstein anomaly includes antibiotic prophylaxis, oxygen administration, hemodynamic and blood gas monitoring, and efforts to prevent a drop in systemic blood pressure in response to peripheral vasodilation or blood loss.

COMPLEX CYANOTIC CONGENITAL HEART DISEASE.

The more widespread use of palliative and corrective surgical procedures for complex cyanotic congenital cardiac anomalies has allowed more women who are so affected to reach childbearing age.[34] Although successful pregnancies have been reported in patients with partially corrected and uncorrected cyanotic heart disease, including pulmonary and tricuspid atresia,[44] [66] transposition of the great vessels,[64] [65] [66] [67] [68] [69] [70] truncus arteriosus,[71] single ventricle,[72] [73] [74] double-outlet right ventricle,[75] and double-inlet left ventricle, [76] pregnancy is associated with increased risk in these patients. A report[44] of 96 pregnancies in 44 patients with cyanotic heart disease without Eisenmenger reaction demonstrated cardiovascular complications in 32 percent of the patients. These complications included heart failure, thromboembolic events, supraventricular tachycardia, and peripartum bacterial endocarditis resulting in postpartum maternal death in one patient. In addition, a high incidence of fetal wastage (57 percent), premature deliveries, small-for-gestational-age newborns, and both cardiac and noncardiac congenital malformations have been reported.[34]

RHEUMATIC HEART DISEASE

Although the incidence of rheumatic heart disease is declining in the United States, the disease continues to be prevalent in many developing countries and may be associated with significant morbidity and even mortality.[3] [77]

ACUTE RHEUMATIC FEVER (see Chap. 66) .

This disease occurs most often in children, before puberty, and only rarely during pregnancy.[77] The management of acute rheumatic fever during pregnancy is similar to that of nonpregnant patients. Because heart failure is usually due to an incompetence of the mitral or aortic valve, diuretics and vasodilators should be the therapy of choice. Surgical repair of valvular incompetence should be performed in patients not responding to medical therapy. The results of mitral valve repair in patients with

acute rheumatic disease, however, are inferior to those seen in patients with other forms of valvular regurgitation. Mild cases of heart failure require only bed rest and treatment of streptococcal pharyngitis and comorbidity, including anemia and nutritional difficulty.[77]

CHRONIC RHEUMATIC VALVULAR DISEASE (see Chap. 46) .

Patients with chronic rheumatic valvular disease should be managed individually according to the site and severity of the lesion. However, certain general guidelines apply to the care of all patients. These include (1) restriction of physical activity in symptomatic patients to reduce cardiovascular load and prevent hemodynamic and symptomatic worsening and (2) prophylactic antibiotic treatment to prevent streptococcal infection and recurrence. Although antibiotic prophylaxis during labor and delivery has not been uniformly recommended,[47] it is commonly used for vaginal and abdominal deliveries. Hemodynamic monitoring is strongly recommended from the onset of labor to approximately 24 hours post partum in any patient who experiences symptoms of heart failure during pregnancy and for those with severe valvular disease, left ventricular dysfunction, or pulmonary hypertension.

MITRAL STENOSIS (see also Chap. 46) .

This condition is the most common rheumatic valvular lesion in pregnancy.[77] The majority of patients with moderate to severe mitral stenosis demonstrate a worsening of one or two classes in the New York Heart Association functional status during gestation.[3] [77] Although mitral stenosis is often accompanied by some degree of mitral regurgitation, hemodynamic problems are related predominantly to flow obstruction. The pressure gradient across the narrowed mitral valve may increase greatly secondary to the physiological increase in heart rate and blood volume of pregnancy.[3] Increased left atrial pressure can result in atrial flutter or fibrillation, substantially accelerating the ventricular rate and further elevating left atrial pressure. In addition, decreased serum colloid osmotic pressure during pregnancy and excessive peripartum intravenous fluid administration can both predispose to pulmonary edema. A recent study has demonstrated a high incidence of worsening of functional class and the development of heart failure, which led to the need for hospitalizations and either starting or increasing the dose of cardiac medications in patients with moderate to severe mitral stenosis. In addition, there was a marked increase in the rate of prematurity and fetal growth retardation in these cases. Despite marked increase in maternal morbidity, there was no mortality.[3]

Treatment.

The therapeutic approach to patients with significant mitral stenosis should aim to reduce the heart rate and decrease blood volume. Both heart rate and symptoms can be controlled effectively by restricting physical activity and administering beta-adrenergic receptor blockers.[77] [78] [79] In patients with atrial fibrillation, digoxin may also be useful for control of ventricular rate. Blood volume can be decreased through restriction of salt intake and the use of oral diuretics; aggressive use of diuretic agents should,

however, be avoided to prevent hypovolemia and reduction of uteroplacental perfusion.

Although careful medical therapy allows successful completion of pregnancy in the great majority of women,[77] repair or replacement of the valve during pregnancy may be indicated in some patients with severe symptoms in spite of adequate medical therapy.[80] [81] [82] In both mitral valve commissurotomy (open or closed) and replacement, the risk in pregnant patients is comparable to that in nonpregnant patients.[81] In contrast, however, open commissurotomy and valve replacement are likely to result in increased fetal loss.[81] [82] Closed mitral commissurotomy is associated with only minimal risk to the fetus; it is, therefore, preferable to the open technique.[83] However, it should be recommended only in centers where it is performed routinely.

Balloon Valvuloplasty (see also Chap. 46) .

The use of percutaneous mitral balloon valvuloplasty during pregnancy has been reported in an increasing number of pregnant patients with mitral stenosis.[84] [85] [86] [87] [88] [89] In the majority of cases, hemodynamic and symptomatic improvement has been achieved without apparent untoward maternal and fetal effects. At the same time, however, serious complications have occasionally been reported, including initiation of uterine contraction,[86] maternal arrhythmia leading to fetal distress,[87] cardiac tamponade requiring surgical intervention, and systemic embolization.[88] In addition, this procedure is associated with some risk to the fetus secondary to unavoidable ionizing radiation. This information suggests that percutaneous mitral balloon valvuloplasty is an attractive alternative to surgery during pregnancy, but it is limited by the exposure to radiation and possible complications that may result in fetal distress or require surgical intervention during pregnancy. The procedure should be avoided if possible during the first trimester[77] and should be performed by experienced operators with adequate abdominal and pelvic shielding with minimum radiation exposure or under echocardiographic guidance, if possible.

Mitral Valve Repair or Replacement (see also Chap. 46) .

For all of the aforementioned reasons, mitral valve repair or replacement during pregnancy should be considered only in cases with severe mitral stenosis (mitral valve area < 1.0 cm^2) refractory to optimal medical therapy or when close follow-up during pregnancy, labor, and delivery is not possible. When valve replacement is indicated, selection of the type of prosthesis should be based on its hemodynamic profile and durability and the need for anticoagulation.

Vaginal delivery can be permitted in most patients with mitral stenosis. In symptomatic patienvs, those with moderate or severe stenosis (mitral valve area <1.5 cm^2), hemodynamic monitoring is recommended during labor and delivery. Initiation of monitoring at onset of labor allows hemodynamic optimization by means of intravenous diuretics, digoxin (in case of atrial fibrillation), beta blockers, or nitroglycerin and prevention of a rise in left atrial pressure during labor and delivery. With delivery and thus relief of venocaval obstruction due to the gravid uterus, there is an immediate increase in venous return, which may lead to a substantial increase in pulmonary artery wedge pressure. For this reason, hemodynamic monitoring should be continued for at least several hours post partum.

Epidural anesthesia is the most appropriate form of analgesia in patients with mitral stenosis for both vaginal and abdominal delivery. This form of anesthesia is often associated with a significant fall in pulmonary arterial and left atrial pressures due to systemic vasodilation. With this approach, the great majority of patients with mitral stenosis, even if it is severe, can be delivered with few complications.

MITRAL REGURGITATION (see also Chap. 46) .

This condition is usually well tolerated in pregnancy, presumably because of left ventricular unloading secondary to the physiological fall in systemic vascular resistance. In symptomatic patients, drug therapy with diuretics is indicated, and digoxin may be useful in those with impaired left ventricular systolic function. Because hydralazine has been shown to be safe for use during pregnancy,[90] it may be used for further reduction of left ventricular afterload and prevention of hemodynamic worsening associated with isometric exercise during labor.[91]

AORTIC STENOSIS (see also Chap. 46) .

Rheumatic aortic stenosis is rare during pregnancy and occurs in conjunction with mitral valve disease in approximately 5 percent of pregnant patients with rheumatic valvular disease.[77] Although most patients with aortic stenosis and valve area greater than 1.0 cm^2 tolerate pregnancy well, patients with more severe stenosis may demonstrate clinical deterioration with exertional dyspnea, near-syncope, or syncope and pulmonary edema.[3] [92] Development of serious symptoms during pregnancy, especially if resistant to medical therapy, may require termination of pregnancy or repair of the valve either surgically (valve replacement) or by percutaneous balloon valvuloplasty.[81] [93]

AORTIC REGURGITATION (see also Chap. 46) .

Similar to mitral regurgitation, aortic regurgitation is also well tolerated during pregnancy, probably because of reduced systemic vascular resistance and increased heart rate, which results in shortening of diastole. In symptomatic patients, diuretics, digoxin, and hydralazine for left ventricular afterload reduction can be safely used.

Other Conditions Affecting the Valves, Aorta, and Myocardium

Mitral Valve Prolapse (see also Chap. 46)

The prevalence of mitral valve prolapse in the general population has been recently found to be 2.4 percent and was reported in approximately 1.2 percent of pregnant women. Because of high incidence of systolic functional murmurs and wide splitting of the first heart sound during pregnancy, mitral valve prolapse may be falsely diagnosed and needs to be confirmed by echocardiographic criteria.[94] At the same time, the incidence of prolapse-related auscultatory and echocardiographic findings may decrease during gestation as a result of an increase in left ventricular end-diastolic volume.[95]

For the few patients with mitral valve prolapse with chest pain or cardiac arrhythmias, the emphasis should be on reassurance and attempts to avoid the use of medications during pregnancy. Beta-adrenergic blocking agents are recommended when therapy is indicated. Patients with mitral valve prolapse, especially those with a thickened mitral valve and mitral regurgitation, are at increased risk for infective endocarditis. Although antibiotic prophylaxis for uncomplicated vaginal delivery has not been uniformly recommended, the development of bacteremia during vaginal delivery and cesarean section cannot always be predicted. For this reason, prophylaxis for labor and delivery in patients with mitral valve prolapse accompanied by valve thickening and/or regurgitation seems warranted.

Marfan Syndrome (See also Chap. 40)

Pregnancy in women with Marfan syndrome poses a twofold problem: (1) cardiovascular complications and (2) a high risk of having a child who will inherit the condition.[96] [97] Cardiovascular complications during pregnancy include dilatation of the ascending aorta, which may lead to the development of aortic regurgitation and congestive heart failure, and proximal and distal dissections of the aorta with occasional involvement of the iliac and coronary arteries (see Fig. 65-3) (Figure Not Available) . The risk of aortic dissection is significantly higher in patients with a dilated aorta or a history of previous dissection. Patients with Marfan syndrome who have only minor involvement of the cardiovascular system and aortic diameter less than 40 mm usually

Figure 65-4 Chest radiograph demonstrating severe dilatation of the thoracic aorta in a 23-year-old woman with Marfan syndrome who presented with sharp chest pain radiating to the back during her 16th week of gestation. The patient was found to have thoracoabdominal aortic aneurysm and descending aortic dissection and had an elective abortion at 19 weeks.

tolerate pregnancy well without subsequent worsening of their cardiovascular status attributable to pregnancy.[98] The majority of complications are developed in the later phase of pregnancy. Marfan syndrome may also be responsible for cervical incompetence, abnormal placental site, and postpartum hemorrhagic complications.[99]

The management of pregnancy in women with Marfan syndrome should include preconception counseling to discuss potential maternal and fetal risks.[96] Women with significant cardiac involvement--in particular, dilatation of the aorta and previous history of aortic dissection--are at high risk for complications during gestation and should be advised against conception or, if they are already pregnant, to have an early abortion (Fig. 65-4) . In contrast, the risk in patients without cardiac complications and with a normal aortic diameter is significantly lower. Still, a favorable outcome is not guaranteed, and aortic dissection can occur, albeit infrequently, in patients with a normal-sized aorta.[96] Preconception echocardiographic assessment of the aorta and periodic follow-up during pregnancy are highly recommended.[98] Because aneurysms and dissections of the aorta can occasionally involve the descending aorta, the use of transesophageal echocardiography seems preferred to transthoracic examination.[100] During pregnancy, vigorous physical activity should be avoided. Beta blockers, which have been shown to reduce the rate of aortic dilatation and the risk of complications in patients with Marfan syndrome, should be administered.[101] In case of substantial dilatation of the aorta during pregnancy, therapeutic abortion or surgical intervention should be considered.[96] In women with aortic dilatation, aortic dissection, or other cardiac complications, abdominal delivery by cesarean section should be the preferred mode of delivery to minimize hemodynamic changes associated with vaginal delivery.[96] [98]

Cardiomyopathies (See Chap. 48)

HYPERTROPHIC CARDIOMYOPATHY.

Reported experience in over 100 pregnancies in patients with hypertrophic cardiomyopathy reveals a favorable outcome in most cases but at the same time a potential for increased morbidity and even mortality.[102] [103] New onset or worsening of congestive heart failure has been reported in approximately 20 percent of cases, and a few patients experienced chest pain, palpitations, dizzy spells, and syncope. Poorly tolerated resistant supraventricular tachycardia with fetal distress[104] has also been reported as well as new-onset atrial fibrillation leading to hemodynamic deterioration and direct-current cardioversion.[105] Few patients had ventricular arrhythmias, which proved fatal in one,[102] and in one patient sudden death occurred at 28 weeks during moderate exertion.[106] Fetal outcome in most cases does not seem to be affected by maternal hypertropic cardiomyopathy. The risk of inheriting the disease may be as high as 50 percent in familial cases and less in sporadic cases.[102]

The therapeutic approach to the pregnant patient with hypertrophic cardiomyopathy depends on the presence of symptoms and left ventricular outflow obstruction. In the symptomatic patient with obstructive hypertrophic cardiomyopathy, an attempt should be made to avoid blood loss and use of drugs that can lead to vasodilation or sympathetic stimulation during labor and delivery. Indications for drug therapy during gestation include arrhythmias and symptoms other than those caused by normal pregnancy. Symptoms associated with elevated left ventricular filling pressure should be treated with beta-adrenergic blocking agents, with diuretics and calcium antagonists added if beta blockers alone are not sufficient.[102] Dual-chamber pacing may be considered before pregnancy in symptomatic patients.[107] Because of the potential arrhythmogenic effect of pregnancy, implantation of an automatic defibrillator before pregnancy should be considered in patients with hypertrophic cardiomyopathy with aborted syncope, or life-threatening arrhythmias.

Vaginal delivery has been shown to be safe in women with hypertrophic cardiomyopathy.[88] In those with symptoms or outflow obstruction, the second stage of labor may be shortened by the use of forceps. The use of prostaglandins to induce uterine contractions may be risky in a patient with obstructive hypertrophic cardiomyopathy, owing to their vasodilatory effect, whereas oxytocin should be well tolerated. Because tocolytic agents with beta-adrenergic receptor activity may aggravate left ventricular outflow tract obstruction, other medications such as magnesium sulfate are preferred. Similarly, spinal and epidural anesthetics should be used with caution in obstructive hypertrophic cardiomyopathy because of their vasodilatory effect, and excessive blood loss should be avoided or replaced promptly with intravenous fluid or blood.[102] [103]

Because the risk for infective endocarditis is increased in hypertrophic cardiomyopathy, especially the obstructive form, and in patients with mitral valve abnormalities, antibiotic prophylaxis should be considered for labor and delivery.

PERIPARTUM CARDIOMYOPATHY.

Peripartum cardiomyopathy is a form of dilated cardiomyopathy with left ventricular systolic dysfunction that results in signs and symptoms of heart failure. Symptoms usually occur during the last trimester of gestation, and diagnosis is usually made in the early peripartum period.[108] [108A] Because there is no specific test available for the diagnosis of peripartum cardiomyopathy, it is established by exclusion of other causes of left ventricular dilatation and systolic dysfunction (Table 65-6) . The reported incidence of the disease in the United States is approximately 1 in 15,000 with a higher incidence (up to 1 in 1,000) in certain parts of Africa.[108]

Common symptoms and signs are shortness of breath, fatigue, chest pain, palpitations, weight gain, peripheral edema, peripheral or pulmonary embolization, and arrhythmias. Physical examination often reveals an enlarged heart, S_3 , and murmurs of mitral and tricuspid regurgitation. The electrocardiogram may show tachycardia, ST-T wave

TABLE 65-6 -- MODIFIED CRITERIA FOR DIAGNOSIS OF PERIPARTUM CARDIOMYOPATHY

Development of cardiac failure during pregnancy or within 6 months of delivery
Absence of a determinable cause for cardiac failure
Demonstrable impairment in left ventricular systolic function

changes, conduction abnormalities, and arrhythmias. Chest radiography usually shows cardiomegaly, pulmonary venous congestion with interstitial or alveolar edema,

and occasionally pleural effusion. Doppler echocardiography commonly shows enlargement of all four cardiac chambers, with marked reduction in left ventricular systolic function. Small-to-moderate pericardial effusion and mitral, tricuspid, and pulmonic regurgitation may be evident. The clinical presentation and hemodynamic changes are indistinguishable from those found in other forms of dilated cardiomyopathy. [109] A few patients with high-output heart failure have been reported.[110]

The incidence of peripartum cardiomyopathy is greater in multiparous women and in those with preeclampsia and twin pregnancies, as well as in women older than 30 years of age.[111] Although the etiology of peripartum cardiomyopathy is still unknown, the unique nature of this syndrome is suggested by its relation to pregnancy, its occurrence at a relatively young age when compared with other forms of dilated cardiomyopathy, the relatively rapid recovery of cardiac size and function in a large number of patients, and the recurrence of left ventricular depression with subsequent pregnancies.[108] Association between myocarditis and peripartum cardiomyopathy was suggested by some investigators who reported a high incidence of myocarditis documented by endomyocardial biopsy.[112] Later reports, however, have indicated a low incidence of myocarditis in patients with peripartum cardiomyopathy that was comparable to that found in an age- and sex-matched nonpregnant, control population with idiopathic dilated cardiomyopathy.[108] [113]

The clinical course of peripartum cardiomyopathy varies, with 50 to 60 percent of patients showing complete or near-complete recovery of clinical status and cardiac function, usually within the first 6 months postpartum[111] ; the rest of the patients demonstrate either further clinical deterioration, leading to cardiac transplantation or early death, or persistent left ventricular dysfunction and chronic heart failure.

Management.

Acute heart failure should be treated vigorously with oxygen, diuretics, digitalis, and vasodilator agents. The use of hydralazine as an afterload-reducing agent is safe during pregnancy.[90] The use of organic nitrates, dopamine, dobutamine, or milrinone has been reported in pregnancy in a limited number of cases. Nitroprusside has been used successfully during pregnancy, but experiments in animals have shown the potential for fetal toxicity.[90] Angiotensin-converting enzyme inhibitors have a teratogenic effect, may cause fetal renal dysfunction, and should therefore not be used during pregnancy.[114] Because of the increased incidence of thromboembolic events in peripartum cardiomyopathy, anticoagulant therapy is recommended. Because the disease may be reversible, the temporary use of an intraaortic balloon pump or left ventricular assist device may help stabilize the patient's condition pending improvement.[115] [116] A small retrospective study of intravenous immune globulin showed a favorable effect on recovery of left ventricular dysfunction in patients with peripartum cardiomyopathy.[117] Further evaluation of this therapy seems warranted. The presence of preeclampsia may be associated with greater improvement in left ventricular dysfunction post partum.[111] Because of the high risk of mortality, patients with severe heart failure, who do not recover early, should be considered for cardiac transplantation. Two reports comparing results of cardiac transplantation in age-matched females with peripartum cardiomyopathy and idiopathic cardiomyopathy showed favorable and comparable long-term survival in both groups.[118] [119] Although mortality from peripartum cardiomyopathy was reported to be over 40 percent in early studies,[108] two recent studies reported incidence of death or cardiac transplantation to be in the range of 12 to 18 percent.[111] [112]

Subsequent pregnancies in women with peripartum cardiomyopathy are often associated with relapse, leading to left ventricular dysfunction, symptomatic deterioration, and even to death. Although the likelihood of such relapse is greater in patients with persistently abnormal cardiac function, it has also been reported in women in whom left ventricular function is restored after the first episode.[120] Two recent surveys on the risk of subsequent pregnancy in women with history of peripartum cardiomyopathy reported mortality of 0 to 2 percent in patients with normal left ventricular ejection fraction before the subsequent pregnancy and 8 to 17 percent in patients with depressed left ventricular ejection fraction (Table 65-7) .[120] [121] For these reasons, subsequent pregnancies should be discouraged in patients with peripartum cardiomyopathy who have persistent cardiac dysfunction; women with recovered cardiac function cannot be guaranteed an event-free pregnancy, and recurrence of the disease is possible. The risk of mortality in such cases, however, seems to be small.

Hypertension in Pregnancy (See Chap. 28)

Hypertensive disorders are the most common medical complications of pregnancy and are a major cause of maternal and perinatal morbidity and mortality.[2] [122] In general, hypertension in pregnancy is defined as blood pressure greater than 140 mm Hg systolic and 90 mm Hg diastolic on at least two occasions 6 hours apart.[123] Hypertension complicates 8 to 10 percent of all pregnancies and is an important cause of maternal mortality and morbidity, including abruptio placentae, pulmonary edema, respiratory failure, disseminated intravascular coagulation, cerebral hemorrhage,

Superimposed preeclampsia
Superimposed eclampsia
Coincidental Hypertension
Chronic hypertension that antecedes pregnancy or persists post partum

hepatic failure, and acute renal failure.[123] Fetal complications include prematurity, intrauterine growth retardation, stillbirth, and neonatal death. Hypertensive disorders in pregnancy can be divided into three broad categories: chronic hypertension, gestational hypertension,[124] and preeclampsia (Table 65-8) .

CHRONIC HYPERTENSION.

Chronic hypertension is defined as hypertension that precedes pregnancy, hypertension that occurs before the 20th gestational week, and hypertension that persists beyond the 6th postpartum week.[123] It occurs in 1 to 5 percent of pregnancies and is associated with increased complications (15 percent), such as fetal growth retardation, premature delivery, abruptio placentae, acute renal failure, and hypertensive crisis; most of these complications occur in patients older than age 30 years with a longer duration of hypertension or those who develop superimposed preeclampsia. Drug therapy is recommended for patients with high-risk characteristics. Therapy options for patients with high-risk chronic hypertension are shown in Table 65-9 .

GESTATIONAL HYPERTENSION.

This is defined as hypertension induced by pregnancy beginning after 20 weeks of gestation and resolving by the sixth postpartum week.[123] Gestational hypertension is further classified as transient hypertension (hypertension without proteinuria) and preeclampsia (hypertension with proteinuria). Transient hypertension usually presents in the late third trimester with return of blood pressure to normal by the 10th postpartum day. It should be noted that the presence of proteinuria can occur late in the course of preeclampsia and the distinction between transient hypertension and preeclampsia can be difficult and made retrospectively. For this reason, in uncertain situations, preeclampsia should be considered and seizure prophylaxis should be instituted empirically in patients with blood pressure greater than 160/110 mm Hg. Pregnancy outcome is usually favorable, and use of antihypertensive therapy should be reserved for patients with blood pressure greater than 160/110 mm Hg. Recommended drugs include parenteral hydralazine, parenteral labetolol, and oral nifedipine.[124]

PREECLAMPSIA-ECLAMPSIA.

Preeclampsia usually occurs after 20 weeks' gestation in the first pregnancy and near term in multiparous women. Preeclampsia can be subclassified into mild and severe.[123] In mild preeclampsia, systolic blood pressure is greater than 140 mm Hg but less than 160 mm Hg, and diastolic blood pressure is greater than 90 mm Hg but less than 110 mm Hg, and mild proteinuria (<5.0 g/24 hr) is the only laboratory abnormality. In severe preeclampsia, blood pressure is greater than 160 mm Hg systolic or more than 110 mm Hg diastolic, proteinuria is greater than 5.0 g/24 hr, platelet count is less than 100.000/ml, and there is evidence for microangiopathic hemolytic anemia or elevated levels of hepatic enzymes. Other symptoms consistent with severe disease are persistent headache, visual disturbance, pulmonary edema, and epigastric pain. Preeclampsia is always associated with increased risk to both mother and fetus and can progress to eclampsia, a life-threatening convulsive phase. Preeclampsia usually regresses within 24 to 48 hours post partum. In the minority of cases, postpartum eclampsia with hypertension, proteinuria, and convulsions occurs within 10 days after delivery.[123]

Patients with stable, mild preeclampsia may be followed until fetal pulmonary maturity is verified or until after 37 weeks of gestation with cervical ripening.[124] There is no evidence for need or benefit of antihypertensive drug therapy in this subgroup of patients. Severe preeclampsia can be rapidly progressive, leading to sudden deterioration of the status of both mother and fetus. Patients with severe preeclampsia who are at or past 34 weeks' gestation should be delivered promptly. Patients with severe preeclampsia who are at 24 to 34 weeks' gestation may receive expectant management that includes admission, bed rest, 24 hours of intravenous magnesium sulfate for seizure prophylaxis, blood pressure control, fetal assessment, and corticosteroids for acceleration of fetal lung maturity. Indicators for delivery

TABLE 65-9 -- ANTIHYPERTENSIVE DRUGS IN PREGNANCY

CLASS	DRUG	STARTING DOSE	MAXIMUM DOSE
Drugs for Long-Term Treatment of Hypertension			
Central $alpha_2$ - agonist	Methyldopa	250 mg tid	4 g/d
	Clonidine	0.1-0.3 mg bid	1.2 mg/d
$Alpha_1$ -adrenergic blocker	Prazosin	1 mg bid	20 mg/d
Calcium channel blocker	Nifedipine	10 mg qid	120 mg/d
Beta-adrenergic blocker	Atenolol	100 mg qd	100 mg/bid
Alpha/beta-adrenergic blocker	Labetalol	100 mg tid	2400 mg/d
Diuretics	Hydrochlorothiazide	25 mg qd	50 mg/d

CLASS	DRUG	DOSE
Drugs for Acute Treatment of Severe Hypertension		
Arterial dilator	Hydralazine	5-10 mg IV q 15-30 min
	Diazoxide	30-60 mg IV q 10-15 min
Calcium channel blocker	Nifedipine	10-20 mg PO q 30 min
Alpha/beta-adrenergic blocker	Labetalol	20-40-80 mg IV q 10-20 min (up to 300 mg)
Arterial/venous dilator	Sodium nitroprusside	(50 mg/250 mL saline): 0.5-5.0 mug/kg/min

include eclampsia, resistant, severe hypertension (refractory to maximum doses of three antihypertensive drugs), completion of 34 weeks of gestation, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), and fetal testing suggesting a problem is present.[123] Because of potential risks to the mother and fetus, conservative management of severe preeclampsia has been recommended only at tertiary perinatal centers under a very close maternal and fetal monitoring. The primary goal of treatment is to prevent cerebral complications. Recommended goal of therapy is reduction of mean blood pressure below 126 mm Hg but not less than 105 mm Hg and diastolic blood pressure between 90 and 105 mm Hg. Use of intravenous hydralazine is recommended as initial therapy, given intravenously in 5-mg bolus doses at intervals of 20 minutes up to cumulative dose of 20 mg. If not effective or associated with maternal side effect (tachycardia, headache, nausea), labetalol (20 mg intravenously) or nifedipine (10 mg orally) should be given.

PREGNANCY AFTER CARDIAC TRANSPLANTATION (SeeChap. 20)

A recent study conducted to determine the outcome of pregnancy in cardiac allograft recipients identified 47 pregnancies in 35 heart transplant recipients, which resulted in 35 (74 percent) live births.[125] Therapeutic abortion was performed in five cases owing to a short interval between transplantation and conception. Maternal hemodynamic changes during gestation seemed well tolerated, and rejection episodes were rare. At the same time, however, a higher incidence of maternal complications was reported, including chronic hypertension, preeclampsia, worsening kidney failure, premature rupture of membranes, and infections.[126] Although fetal loss does not seem to be increased, an increased incidence of preterm deliveries and fetal growth retardation and cesarean sections were reported. No maternal deaths were reported during pregnancy. The incidence of late death, however, was high compared with age-matched healthy women. None of the newborns was found to have congenital malformations, supporting a lack of teratogenic effect of immunosuppressive agents.[126] This limited information suggests, therefore, that pregnancy in women after cardiac transplantation is not associated with increased maternal mortality; however, it results in increased maternal morbidity, preterm deliveries, and fetal growth retardation. In addition, the patients and their families should be informed regarding risk of shorter life span after delivery in patients after heart transplantation.

CORONARY ARTERY DISEASE (See Chaps. 35 , 36 , and 37)

PATHOGENESIS.

Although coronary artery disease is encountered during pregnancy with increasing frequency because of increasing maternal age and fertility,[127] it is still rare among women of childbearing age; and the occurrence of peripartum acute myocardial infarction is anecdotal.[128]

Risk factors for coronary artery disease in women younger than the age of 50 years include cigarette smoking, high levels of total plasma cholesterol, low levels of high-density lipoproteins, diabetes mellitus, hypertension, a family history of coronary artery disease, toxemia of pregnancy, and the use of oral contraceptives.[127] [128] [129] [130] The combination of heavy smoking or hypertension and concurrent use of oral contraceptives has been shown to be a powerful predictor of acute myocardial infarction.[130]

In the assessment of risk factors for coronary artery disease during pregnancy it should be noted that total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels are significantly increased during pregnancy.[131]

ACUTE MYOCARDIAL INFARCTION (see alsoChap. 35) .

Peripartum acute myocardial infarction has been reported at any stage of pregnancy and at ages between 16 and 45. The highest incidence, however, occurs in the third trimester and in women older than age 33 years. In addition, acute myocardial infarction has been noted to occur more commonly in multigravidas and its location

to be more commonly in the anterolateral wall. Most maternal death occurred either at the time of infarction or within 2 weeks.[128] To reduce the risk for acute myocardial infarction, oral contraceptives should be avoided or formulations with lower effective doses of estrogen should be used in cigarette smokers and in women with hypertension.

Although atherosclerotic disease seems to be the primary cause of acute myocardial infarction[128] [132] [133] [134] peripartum acute myocardial infarction is often associated with normal coronary angiograms and has been suggested as being due to a decrease in coronary perfusion caused by spasm or in situ thrombosis. Although the presence of spasm has not been documented and its cause is not clear, it has been suggested as a cause of myocardial infarction in some instances with pregnancy-induced hypertension and with the administration of ergot derivatives, bromocriptine,[135] oxytocin, and prostaglandin[136] used to suppress lactation or uterine bleeding and in patients with pheochromocytoma.[137] Coronary arterial dissection mostly in the immediate postpartum period has been commonly associated with peripartum acute myocardial infarction.[128] [135] [138] [139] The dissection involves the left anterior descending artery in approximately 80 percent of cases and the right coronary artery in most other cases. Other potential causes of acute myocardial infarction during pregnancy have been collagen vascular disease, Kawasaki disease, sickle cell anemia, and hemostatic abnormalities.[128] [135] [140]

DIAGNOSIS.

The diagnostic approach to ischemic myocardial disease in pregnancy is influenced to some extent by whether a diagnostic procedure could harm the fetus and by normal changes seen during pregnancy that may mimic pathological changes. T wave inversion, Q wave in lead III, and increased R/S ratio in leads V_1 and V_2 are commonly seen in normal pregnancy. ST segment depression, not associated with chest pain or echocardiographic wall motion abnormalities, has been described during elective cesarean section and can mimic myocardial ischemia. Because fetal bradycardia has been reported during maximal exercise in normal women, a submaximal exercise protocol with fetal monitoring is recommended for the evaluation of ischemic myocardial disease during pregnancy.

Radionuclide myocardial perfusion scans and radionuclide ventriculography expose the fetus to some radiation and should be used only when the potential benefits seem to outweigh fetal risk. For similar reasons, cardiac catheterization involving fluoroscopy and cineangiography should be used only when relevant information cannot be obtained by other, noninvasive methods. The diagnosis of myocardial ischemia and infarction has been reported to be delayed during pregnancy because of the low level of suspicion.[128] Concentrations of myoglobin, creatine kinase, and creatine kinase MB were found to be increased twofold 30 minutes after delivery, whereas level of troponin I remained below the cutoff value for discriminating myocardial infarction. For this reason, troponin should be used to diagnose myocardial infarction after delivery.[141]

MANAGEMENT.

Both maternal and fetal considerations should influence the therapeutic approach to ischemic heart disease during pregnancy. Morphine sulfate does not cause congenital defects. Because it crosses the placenta, it can cause neonatal respiratory depression when given shortly before delivery.[128] Available reports on the use of thrombolytic therapy during pregnancy do not support a teratogenic effect, and the majority of reported cases resulted in favorable maternal and fetal outcome.[128] [133] [142] This therapy, however, is associated with risk of maternal hemorrhage, especially when given at the time of delivery. Because of their safety in pregnancy, beta blockers appear to be the drugs of choice. The use of organic nitrates and calcium antagonists in patients with acute myocardial ischemia or infarction has been described in a limited number of patients. These drugs should be given cautiously to prevent maternal hypotension and potential fetal distress. Use of high-dose aspirin during pregnancy is debatable, because it has been reported to cause fetal growth retardation and bleeding in the neonate and in the mother.[143] Use of low-dose aspirin, however, is safe during pregnancy.[143] [144]

Coronary reperfusion by means of percutaneous transluminal coronary angioplasty[133] [145] [146] or coronary artery bypass graft surgery[134] [139] [147] has been reported to be successful during pregnancy although experience is still limited. Such procedures should be avoided during the first trimester, if possible, owing to the potential deleterious fetal effects due to ionizing radiation as well as cardiopulmonary bypass.

Risk stratification after acute myocardial infarction during pregnancy should be determined by noninvasive methods. Total cholesterol, low density lipoprotein cholesterol, and triglyceride levels are significantly increased during pregnancy.[131] Coronary angiography should be done only in cases in which coronary angioplasty or bypass surgery seems indicated during pregnancy.

Management of the Pregnancy.

Management should focus on reducing cardiovascular stress during pregnancy and the peripartum period. Termination of pregnancy may be required in patients with intractable ischemia or heart failure in the early phase of gestation. During labor, adequate analgesia and supplemental oxygen should be given; and, if desired, cardiac output can be increased by placing the patient in the left lateral decubitus position. Labor in the supine position, however, may decrease venous return and thus reduce right and left ventricular filling pressures. Low forceps can be used to shorten the second stage of labor. Pulmonary artery catheterization with hemodynamic monitoring can help in the early detection and correction of hemodynamic abnormalities during labor and delivery.[148] Although elective cesarean section is not indicated in every case, it should be used in patients with active ischemia or hemodynamic instability despite adequate medical therapy.[149] Continued hemodynamic monitoring is advisable for several hours post partum to detect hemodynamic worsening associated with postpartum hemodynamic changes described earlier.

ARRHYTHMIAS (See Chap. 25)

Pregnancy is associated with an increased incidence of arrhythmias in women both with and without structural heart disease.[16] [150] [151] [152] [153] In healthy women, multiple and even frequent atrial and ventricular premature complexes may occur, usually without effect on either the mother or the fetus.[16] There is also a strong suggestion for an increased frequency of paroxysmal supraventricular tachycardia during pregnancy.[152] [153]

ATRIAL FLUTTER AND ATRIAL FIBRILLATION.

Atrial flutter and fibrillation are rare during normal pregnancy and are usually associated with rheumatic mitral valve disease.[3] Recent reports have described atrial fibrillation during gestation accompanied by treatment with magnesium sulfate[154] and in a patient with preexcitation.[155] Ventricular tachycardia is a rare occurrence in pregnancy. It has been reported in women without structural disease,[156] [157] but it is usually associated with structural heart disease, drugs,[158] [159] [160] electrolyte abnormalities,[161] or eclampsia. [162]

Although palpitations, dizziness, and even syncope are relatively common symptoms in normal pregnancy, these are rarely associated with cardiac arrhythmias.[16] Cardiac arrhythmias, however, when they occur, can be hemodynamically significant even in patients with a normal heart during gestation.[19] Reduction in blood pressure occasionally associated with such arrhythmias can result in fetal bradycardia and the need for immediate treatment with antiarrhythmic drugs, electric cardioversion, or urgent cesarean section. The effect of pregnancy on women with the hereditary long QT syndrome has been reported.[163] The postpartum interval was associated with a significant increase in the risk for cardiac events, including death, aborted cardiac arrest, and syncope. Treatment with beta-adrenergic blockers was independently associated with a decrease in the risk for cardiac events.

Synchronized electrical cardioversion has been performed safely during all stages of pregnancy[157] [164] [165] and can be used in patients with tachyarrhythmias unresponsive to drug therapy that are associated with hemodynamic decompensation. Insertion of an implantable cardioverter-defibrillator has not been reported during pregnancy; however, pregnancies in women with an implantable cardioverter-defibrillator have been reported to be uneventful.[166]

COMPLETE HEART BLOCK.

This condition has been described during pregnancy and is usually congenital.[167] [168] [169] Patients with complete heart block may remain asymptomatic during pregnancy and have an uncomplicated labor and delivery without treatment.[167] Improvement of atrioventricular nodal conduction during two successive uncomplicated pregnancies in a patient with congenital heart block has been reported.[170] Symptomatic patients with conduction abnormalities, including bifascicular block,[171] second-degree atrioventricular block,[172] and complete heart block,[173] have been treated during pregnancy with either temporary or permanent pacemakers; and numerous pregnancies have been reported in patients after pacemaker implantation. In an attempt to reduce exposure to ionizing radiation, placement of a pacemaker during pregnancy has been done with electrocardiographic and echocardiographic guidance in some cases.[172] [174] Skin irritation and ulceration at the implant site due to enlargement of the breast and abdomen during pregnancy have been reported.

MANAGEMENT OF ARRHYTHMIAS.

A complete evaluation is indicated in patients with arrhythmias during pregnancy to rule out a treatable cause such as electrolyte imbalance, thyroid disease, and arrhythmogenic effects of drugs, alcohol, caffeine, and cigarette smoking. An identified cause should be treated and antiarrhythmic drug therapy initiated only if the arrhythmia persists and is symptomatic, hemodynamically important, or life threatening. When drug therapy seems necessary, the smallest therapeutic dose of drugs known to be safe for the fetus should be used (Table 65-10) . Therapeutic blood levels and the indication for continuous drug therapy should be reevaluated periodically. Electrophysiological evaluation is usually postponed until the postpartum period but can be performed under echocardiographic guidance if indicated during pregnancy.[174] Because of the unpredictable exposure to ionizing radiation, catheter ablation procedures should be performed, if possible, after delivery.

OTHER CARDIOVASCULAR DISORDERS

Aortic Dissection (See also Chap. 40)

A predisposition to aortic dissection during gestation has been suggested.[175] [176] Over the past 50 years, approximately 200 cases of aortic dissection in association with pregnancy have been reported. The incidence is increased among multiparous women older than age 30 years with coarctation of the aorta and Marfan syndrome. Pregnancy-related aortic dissection may be due to alterations in the structure of the vascular wall[175] [177] and seems to occur most often during the third trimester and peripartum period.

Transesophageal echocardiography provides a powerful and safe tool for establishing the diagnosis of aortic dissection during pregnancy.[178] This method is preferable to computed tomography, which involves radiation exposure, and to magnetic resonance imaging, the safety of which during gestation has not been fully established.[32]

The combination of intravenous nitroprusside and beta-adrenergic blocking agents is currently recommended to control hypertension in nonpregnant patients with aortic dissection. Because nitroprusside can result in fetal toxicity, it should be used only post partum or in patients refractory to other drugs during pregnancy and can be substituted by hydralazine or nitroglycerin.[90] To avoid blood pressure elevation associated with labor and vaginal delivery in women with aortic dissection, cesarean section using epidural anesthesia is recommended.[179] [180]

Takayasu Arteritis (See Chap. 67)

Because Takayasu arteritis often occurs in young women, there is a high likelihood of pregnancy in patients with this condition.[181] Review of the literature revealed information on pregnancies in over 50 women with Takayasu disease.[182] The majority of more recently published cases have reported favorable maternal outcome, although increase in blood pressure during pregnancy and the development of heart failure have been described.[183] [184] Although fetal growth retardation and premature labor and delivery are common,[185] [186] [187] favorable fetal outcome has been reported in most cases. Mode of delivery in the majority of cases was vaginal, and forceps were often used to expedite the second stage of labor. Cesarean section delivery has been performed mainly for obstetrical indications or maternal hypertension and vascular disorders. In the great majority of patients, abdominal delivery has been performed under epidural anesthesia with

TABLE 65-10 -- CARDIOVASCULAR DRUGS IN PREGNANCY

DRUG	USE IN PREGNANCY	POTENTIAL SIDE EFFECTS	SAFETY	BREASTFEEDING[213]	RISK FACTORS[219] *
Adenosine[19]	Maternal and fetal arrhythmias	No side effects reported in >30 cases treated for maternal arrhythmia; data on use during first trimester, however, are limited to few patients.	Safe	NA	C
Amiodarone[215]	Maternal and fetal arrhythmias	IUGR, prematurity, hypothyroidism	Unsafe	Not recommended	C
Angiotensin-converting enzyme inhibitors[216]	Hypertension	Oligohydramnios, IUGR, prematurity, neonatal hypotension, renal failure, anemia, and death. Skull ossification defect, limb contractures, patent ductus arteriosus	Unsafe	Compatible	D
Beta-adrenergic blocking agents[217]	Hypertension, maternal arrhythmias, myocardial ischemia, mitral stenosis, hypertrophic cardiomyopathy, hyperthyroidism, Marfan syndrome	Fetal bradycardia, low placental weight, prolonged labor, low birth weight, hypoglycemia, respiratory dysfunction	Safe	Compatible; monitoring of infant's heart rate recommended	B
Digoxin[218]	Maternal and fetal arrhythmias, heart failure	Low birth weight, prematurity	Safe	Compatible	C
Disopyramide[215]	Maternal arrhythmias	May induce uterine contraction and delivery	Limited data	Compatible	C
Diuretics[219]	Hypertension, congestive heart failure	Reduced uteroplacental perfusion	Potentially unsafe	Compatible	C-D
Flecainide[215]	Maternal and fetal arrhythmias	Two cases of fetal death after successful maternal treatment for fetal supraventricular tachycardia reported. Neither death could be attributed with certainty to flecainide.	Limited data	Compatible	C
Lidocaine[215]	Local anesthesia, maternal arrhythmias	May cause infants central nervous depression at birth with high dose	Safe	Compatible	C
Mexiletine[215]	Maternal arrhythmias	Fetal bradycardia, IUGR, low Apgar score, and neonatal hypoglycemia have been reported	Limited data	Compatible	C
Nifedipine[90]	Hypertension	Fetal distress due to maternal hypotension reported	Safe	Compatible	C
Organic nitrates[90]	Myocardial infarction and ischemia, hypertension, pulmonary edema, tocolysis	Fetal heart rate deceleration and bradycardia	Limited data	NA	C
Procainamide[215]	Maternal and fetal arrhythmias	None reported	Probably safe	Compatible	C
Propafenone[215]	Maternal and fetal arrhythmias	Fetal death reported after direct intrauterine administration in fetuses with nonimmune fetal hydrops	Limited data	NA	C
Quinidine[215]	Maternal and fetal arrhythmias	Minimal oxytoxic activity, high doses may cause premature labor and abortion. Transient neonatal thrombocytopenia and damage to eighth nerve reported	Safe	Compatible	C

Sodium nitroprusside[90]	Hypertension, aortic dissection	Potential thiocyanate toxicity with high-dose, fetal mortality reported in animals	Potentially unsafe	NA	C
Sotalol[217]	Maternal arrhythmias, hypertension, fetal tachycardia	Fetal bradycardia, IUGR	Limited data	Compatible; significant quantities in breast milk, careful monitoring of infants recommended	B

Category A: Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.

Catetory B: Either animal-reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).

Category C: Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal, or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).

IUGR=intrauterine growth retardation; NA=no data available.

*Risk factors have been assigned based on level of risk to the fetus[214] :

favorable results. A study of C-reactive protein scores and digital plethysmography showed improvement rather than deterioration of Takayasu arteritis with pregnancy.

Primary Pulmonary Hypertension (See Chap. 53)

Primary pulmonary hypertension is one of the few cardiovascular conditions in which pregnancy can be associated with a high maternal mortality. Review of the literature has revealed maternal mortality of 30 to 40 percent.[188] [189] Clinical deterioration during pregnancy or death cannot be predicted on the basis of the patient's preconceptual clinical status. Symptomatic deterioration usually occurs in the second trimester and is manifested by fatigue, exertional dyspnea, syncope, chest pain, palpitations, nonproductive cough, hemoptysis, and leg edema. Worsening of symptoms during pregnancy led to early hospitalization in many reported cases. Death has occurred a few hours to several days post partum, usually due to sudden death or progressive right ventricular failure. Although the exact cause of death in patients with primary pulmonary hypertension is not clear, right ventricular ischemia and failure, cardiac arrhythmias, and pulmonary embolism are likely mechanisms. In addition to high maternal risk, primary pulmonary hypertension is associated with poor fetal outcome with high incidence of fetal loss, prematurity, and fetal growth retardation.[188]

Because of the potential deleterious effect of pregnancy on both mothers with primary pulmonary hypertension and their fetuses, pregnancy should be avoided in these patients and tubal ligation should be recommended. Because an etiological link between pulmonary hypertension and estrogen-containing oral contraceptives has been suggested, this form of birth control is not recommended for women with primary pulmonary hypertension. Early abortion is indicated in patients with primary pulmonary hypertension who become pregnant. If the patient elects to continue the pregnancy, physical exertion should be restricted to reduce the circulatory load. The incidence of premature deliveries is increased in patients with primary pulmonary hypertension and should be anticipated. Because of the beneficial effect of anticoagulation in patients with primary pulmonary hypertension[190] [191] and the increased incidence of thromboembolism during pregnancy, such therapy is recommended throughout gestation or at least during the third trimester and early postpartum phase. Hemodynamic monitoring and blood gas measurements should be performed continuously during labor and delivery. Oxygen should be provided to prevent hypoxemia, and every effort should be made to prevent or immediately correct blood loss during delivery.[188]

Most patients can tolerate vaginal delivery, and spontaneous labor is preferable to induction. Because of the high rate of early postpartum maternal death, close monitoring is recommended for several days post partum. Successful short-term use of calcium antagonists has been reported in patients with primary pulmonary hypertension during pregnancy.[192] Prostaglandins have also been used to lower pulmonary pressure for a short period during pregnancy.[192] The safety of these drugs, when used chronically, however, is not known.

Cardiac Surgery During Pregnancy

Because heart disease that requires surgery is usually diagnosed and treated before pregnancy, cardiac surgery during gestation is uncommon; and the experience continues to be anecdotal.[193] [194] The effects of anesthesia and the surgical procedure, especially cardiopulmonary bypass, on the uteroplacental circulation and fetal outcome are still not well understood. Recent review of the literature published between 1984 and 1996[194] identified 161 cases of various cardiovascular operations, 137 with and 24 without cardiopulmonary bypass.[195] Surgery during pregnancy resulted in high fetal-neonatal mortality of 30 percent. Week of gestation at time of surgery, surgery with cardiopulmonary bypass, longer duration, and temperature of cardiopulmonary bypass did not influence fetal-neonatal outcome. Operations performed during pregnancy resulted in a moderately high maternal mortality at 6 percent, and surgery performed immediately after delivery was associated with even higher mortality at 12 percent. Hospitalization after the 27th gestational week and emergency surgery were associated with poor maternal outcome. Nine percent maternal mortality was reported in cases that involved valvular surgery and 22 percent in cases of aortic or arterial dissection repairs and pulmonary embolectomies. Maternal risk associated with peripartum cardiovascular surgery seems therefore higher than risk of similar surgery in nonpregnant patients.

Because of high incidence of fetal wastage and moderate increase in maternal risk, surgery should be recommended only for patients who do not respond to medical therapy. To minimize the risk of teratogenicity, surgery should be avoided during the first trimester. Because heart surgery is indicated after failure of medical therapy, many of these patients will be hemodynamically unstable and will require hemodynamic evaluation and optimization before operation and monitoring during surgery. Anesthetic agents should be selected on the basis of their hemodynamic effects and fetal safety. When the patient is at or near term, abdominal delivery by cesarean section can be performed before cardiac surgery, once fetal maturity has been confirmed. Fetal heart monitoring should be performed continuously during surgery by experienced personnel.

Pregnancy in Patients with Prosthetic Heart Valves (See Chap. 46)

VALVE SELECTION.

The selection of a prosthetic heart valve for women of childbearing age remains difficult.[195] [196] New-generation mechanical valves offer excellent durability, low risk of reoperation, and superior hemodynamic profile. However, the need for anticoagulation is associated with an increased risk of maternal bleeding and fetal loss. Tissue valves have a high incidence of deterioration in young patients, which is further accelerated during pregnancy,[197] [198] [199] [200] with a 30 percent expected rate of valve replacement within 10 years, and an inferior hemodynamic profile, especially with small valve sizes in the aortic position.[201] Although homograft valves and new pericardial valves appear to have better hemodynamics, information regarding pregnancy in women with these valves is limited.[202] [203] Because of their durability and hemodynamic advantage, and, with careful anticoagulation, only a small risk of thromboembolic as well as bleeding complications, second-generation mechanical prostheses seem to be the preferred choice in all women of childbearing age who need valve replacement and who can be closely monitored.

Risks associated with pregnancy in women with prosthetic valves are related mainly to the increased hemodynamic burden and incidence of thromboembolic events as well as to fetal untoward effects caused by cardiovascular drugs and anticoagulation. Experience in more than 1000 pregnancies indicates that most asymptomatic or mildly symptomatic patients before gestation tolerate the hemodynamic burden of pregnancy, although decreased functional capacity and need to start or increase drug therapy are not uncommon.[197] [198] [199] [200] [201] [202] [203] [204]

Increased thromboembolic events have been reported, with an incidence as high as 10 to 15 percent. Approximately two thirds of these patients present with valve thrombosis, leading to death in 40 percent of them.[197] [198] [199] [200] Thromboembolism, however, has been reported mostly with older-generation mechanical prostheses in the mitral position.[197] [198] [199] [200] [204] Heparin has been considered the anticoagulant of choice during pregnancy because of its proven safety for both the patient and the fetus.[205] Oral anticoagulant

Figure 65-5 Suggested algorithm for the management of anticoagulation in patients with mechanical prosthetic heart valves during pregnancy.

agents have been considered contraindicated in pregnancy because of their teratogenic effect, increased fetal bleeding complications, and risk of central nervous system damage during gestation. Reports of increased incidence of mechanical valve thrombosis during use of subcutaneous heparin during pregnancy[198] [199] [204] have raised concern regarding the effectiveness of heparin in pregnant women with mechanical heart valves.[206] This has led to recommendations for the use of warfarin as an anticoagulant of choice for the first 35 weeks of pregnancy in patients with a mechanical prosthetic valves.[198] [204] [207] [208] These recommendations have been problematic and have not been adopted by both patients and physicians, especially in the United States.[209] [210] The concern regarding use of warfarin during pregnancy is related to the risk of warfarin-induced embryopathy (depressed nasal bridge, nasal hypoplasia, small nasal bones, hypoplastic alae nasi, telacanthus, upper airway obstruction due to choanal stenosis, and punctate epiphyseal dysplasia of the long bones and the cervical and lumbar vertebral plates) and increased risk of intracranial bleeding.[205] The incidence of warfarin-induced embryopathy is 5 to 9 percent and is dose related.[206] [211] Limited information indicates that in patients with new-generation mechanical prosthetic valves the use of adjusted-dose heparin either throughout pregnancy or during the first trimester and after the 35th to 36th week of gestation is safe.[195]

ANTICOAGULATION (see also Chap. 46) .

Our recommendations for anticoagulation during pregnancy in patients with mechanical valve prosthesis are shown in Figure 65-5 . Thromboembolic prophylaxis of women seems to be best achieved with oral anticoagulation with first-generation prosthetic valves in the mitral position, especially in those patients who can achieve therapeutic anticoagulation with less than 5 mg/d of warfarin (international normalized ratio of 3.0-4.5) for the first 35 weeks. An alternative therapy for patients electing to avoid warfarin in the first gestational trimester is intravenous or subcutaneous heparin with aggressive monitoring and appropriate dose adjustment[206] for the first trimester, followed by warfarin between 13 and 36 weeks and then intravenous or subcutaneous heparin until delivery. High heparin intensity should be used in patients at high risk, aiming at antifactor Xa levels of 0.55 to 0.8 U/ml or an activated partial thromboplastin time of 2.5 to 3.5.

Because of a high incidence of premature labor in patients with prosthetic heart valves,[204] [209] warfarin should be substituted for heparin at the 35th or 36th week to avoid onset of labor during warfarin therapy. The switch from warfarin to heparin should be performed in the hospital. In lower-risk patients, including those with an aortic prosthetic valve and second-generation prosthesis in the mitral position, subcutaneous heparin therapy is advocated throughout pregnancy (activated partial thromboplastin time of 2.0-3.0).[195] [196] [205] Use of warfarin during weeks 13 to 35 or 36 is an alternative regimen in cases in which self-injection of heparin is not desirable by the patient or is associated with side effects. A higher level of anticoagulation seems justified in patients with mechanical prostheses in the mitral position, in patients with more than one mechanical prosthesis, in patients with atrial fibrillation, and/or in patients with a history of systemic embolization. The intensity of anticoagulation should be frequently monitored and immediately corrected if needed. Because a small dose of aspirin is safe during pregnancy[143] and can reduce the incidence of systemic embolization or death when added to oral anticoagulation,[212] 80 mg of aspirin may be added to maximize the antithrombolic effect.

Safe use of low-molecular-weight heparin has been reported in few patients with prosthetic heart valve.[195] Low-molecular-weight heparin provides a better effect, owing to its superior bioavailability and longer half-life, and may reduce the risk of bleeding and osteoporosis. This drug, however, is less readily reversible by protamine sulfate and may be more difficult to handle during labor and delivery. More information is therefore required before low-molecular-weight heparin can be routinely recommended for anticoagulation in a patient with a prosthetic valve during gestation. For more information on cardiovascular drugs, see Table 65-10 . [213] [214] [215] [216] [217] [218] [219]

GUIDELINES
MANAGEMENT OF VALVULAR DISEASE IN PREGNANCY

Thomas H. Lee

Recommendations for management of valvular heart disease in pregnancy are included in the 1998 ACC/AHA guidelines on valvular disease.[1] These guidelines do not recommend routine antibiotic prophylaxis in patients with valvular heart disease undergoing uncomplicated vaginal delivery or cesarean section unless infection is suggested. For high-risk patients, such as those with prosthetic heart valves or prior histories of endocarditis, antibiotics are considered optional.

Complex guidelines are offered on anticoagulation for patients with mechanical prosthetic heart valves (Table 65-G-1) . These guidelines reflect high complication rates in pregnant women managed with subcutaneous heparin and support the use of intravenous heparin during the first trimester. After the 36th week of pregnancy, transition from warfarin to heparin is recommended in anticipation of labor. Data on low-molecular-weight heparin in this setting were too sparse for the development of recommendations.

TABLE 65--G-1 -- GUIDELINES FOR ANTICOAGULATION DURING PREGNANCY IN PATIENTS WITH MECHANICAL PROSTHETIC VALVES

Indication	Class I	Class IIa	Class IIb	Class III
Anticoagulation during pregnancy in patients with mechanical prosthetic valves: weeks 1 through 35	The decision whether to use heparin during the first trimester or to continue oral anticoagulation throughout pregnancy should be made after full discussion with the patient and her partner; if she chooses to change to heparin for the first trimester, she should be made aware that heparin is less safe for her, with a higher risk of both thrombosis and bleeding, and that any risk to the mother also jeopardizes the baby.[2] High-risk women (a history of thromboembolism or an older-generation mechanical prosthesis in the mitral position) who choose *not* to take warfarin during the first trimester should receive continuous unfractionated heparin intravenously in a dose to prolong the midinterval (6 hours after dosing) aPTT to two to three times control. Transition to warfarin can occur thereafter.	In patients receiving warfarin, INR should be maintained between 2.0 and 3.0 with the lowest possible dose of warfarin, and low-dose aspirin should be added.	Women at low risk (no history of thromboembolism, newer low-profile prosthesis) may be managed with adjusted-dose subcutaneous heparin (17,500 to 20,000 U b.i.d.) to prolong the mid-interval (6 hours after dosing) aPTT to two to three times control.	
Anticoagulation during pregnancy in patients with mechanical prosthetic valves: after the 36th week		Warfarin should be stopped no later than week 36 and heparin substituted in anticipation of labor. If labor begins during treatment with warfarin, a cesarean section should be performed. In the absence of significant bleeding, heparin can be resumed 4 to 6 hours after delivery and warfarin begun orally.		

aPTT = activated partial thromboplastin time; INR = international normalized ratio.

Chapter 66 - Rheumatic Fever

ADNAN S. DAJANI

Rheumatic fever (RF) is generally classified as a connective tissue disease or collagen-vascular disease. Its anatomical hallmark is damage to collagen fibrils and to the ground substance of connective tissue. The rheumatic process is expressed as an inflammatory reaction that involves many organs, primarily the heart, the joints, and the central nervous system. The clinical manifestations of acute RF follow a group A streptococcal (GAS) infection of the tonsillopharynx after a latent period of approximately 3 weeks. The major importance of acute RF is its ability to cause fibrosis of heart valves, leading to crippling hemodynamics of chronic heart disease.

RF is the most common cause of acquired heart disease in children and young adults worldwide. Although the incidence of RF declined sharply in many developed countries, the disease remains a major problem in many developing countries. The precise reasons for the fluctuations in the incidence of the disease remain only partly understood. Although RF has been studied extensively, the pathogenesis of the disease is not well defined.

Epidemiology

The incidence of RF and prevalence of rheumatic heart disease are markedly variable in different countries.[1] [2] At the beginning of the 20th century, the incidence of RF in the United States exceeded 100 per 100,000 population, ranged between 40 and 65 per 100,000 between 1935 and 1960, and is currently estimated at less than 2 per 100,000. Beginning in 1984, several outbreaks of acute RF were reported from a number of geographically distinct areas in the United States.[2] These focal outbreaks were not associated with a national increase in the incidence of RF.[3] The decline in the incidence of RF in industrialized countries is in sharp contrast to the persistent high incidence of the disease in nonindustrialized countries.

In many developing countries, the incidence of acute RF approaches or exceeds 100 per 100,000.[1] In keeping with the falling incidence of RF in industrialized countries, the prevalence of rheumatic heart disease has declined. Table 66-1 compares the prevalence of rheumatic heart disease in school-age children in different regions of the world.

The decline in incidence of RF and prevalence of rheumatic heart disease has been attributed to several factors. Although the decline preceded the introduction of antimicrobial agents for the treatment of streptococcal pharyngitis, some reports suggest that the use of these agents may have enhanced the rate of this decline.[4] Improved economic standards, better housing conditions, decreased crowding in homes and schools, and access to medical care are often credited, at least in part, for the marked decline in RF.[1] Epidemiological observations in the United States[5] and the United Kingdom[6] show periodic shifts in the appearance and disappearance of specific M types in a particular geographical location. Such shifts may be another explanation for the decline and resurgence of RF in some parts of the world.

Because of the causal relationship between RF and GAS pharyngitis, the epidemiologies of the two illnesses are very similar. Initial attacks of RF occur most commonly between the ages of 6 and 15 years, and RF rarely occurs before the age of 5 years.[7] The risk of RF is increased in populations at high risk for streptococcal pharyngitis, such as military recruits, persons living in crowded conditions, and those in close contact with school-age children. The incidence of RF is equal in male and female patients. The seasonal incidence of RF also parallels that of streptococcal pharyngitis. The peak incidence of RF in Europe and the United States is in spring. Although RF used to be considered a disease of temperate climates, it is now more common in warm tropical climates, particularly in developing countries.

Pathogenesis

The evidence that GAS is the agent causing initial and recurrent attacks of RF is strong but indirect. It is based on clinical, epidemiological, and immunological observations. Factors that contribute to the pathogenesis of RF are related to both the putative causative agent and the host (Table 66-2) .

THE ETIOLOGICAL AGENT.

An untreated GAS tonsillopharyngitis is the antecedent event that precipitates RF.[8] RF does not follow streptococcal skin infection (impetigo). Proper antimicrobial treatment of streptococcal pharyngitis with eradication of the organism virtually eliminates the risk of RF.[8] In situations conducive to epidemic streptococcal pharyngitis (such as the military population, crowding), as many as 3 percent of untreated acute streptococcal sore throats may be followed by RF.[9] Endemic infections result in much lower attack rates. It has been well documented that about one-third of all cases of acute RF follow mild, almost asymptomatic pharyngitis. The lack of symptomatic pharyngitis was particularly striking in most of the recent outbreaks of acute RF in which the majority of patients (58 percent) had no history of pharyngitis.[2] This is an alarming observation, because primary prevention of acute RF relies on identification and proper treatment of streptococcal pharyngitis.

The major factors that are related to the risk of RF are the magnitude of the immune response to the antecedent streptococcal pharyngitis and persistence of the organism during convalescence.[9] Variations in the rheumatogenicity of GAS strains are a factor influencing the attack rate of RF.[10] The concept that RF is associated with infections due to virulent encapsulated (mucoid) strains capable of inducing strong type-specific immune responses to M protein and other streptococcal antigens[11] has been strengthened by observations made during the outbreaks of acute RF in the

Resistance to phagocytosis
Does not produce opacity factor
SUSCEPTIBLE HOST
Genetic predisposition
Presence of specific B-cell alloantigen
High incidence of class II HLA antigens

mid-1980's. The streptococci isolated from patients with RF and their sibling contacts during these outbreaks were primarily strains belonging to M types 1, 3, 5, 6, and 18.[12] M proteins of rheumatogenic streptococci show distinct structural characteristics: They share a long terminal antigenic domain[13] and contain epitopes that are shared with human heart tissue, particularly sarcolemmal membrane proteins and cardiac myosin.[14] [15]

THE HOST.

Although only a small proportion of individuals with untreated streptococcal pharyngitis may develop RF (3 percent), the incidence of the disease after streptococcal pharyngitis in patients who have had a previous episode of RF is substantially greater (about 50 percent). Numerous epidemiological studies also indicate familial predisposition to the disease. These observations and more recent studies strongly suggest a genetic basis for susceptibility to RF. A specific B-cell alloantigen, identified by monoclonal antibodies, has been described in almost all patients (99 percent) with RF but in only a small number (14 percent) of controls.[16] Furthermore, susceptibility to RF has been linked with HLA-DR 1, 2, 3, and 4 haplotypes in various ethnic groups.[17]

Pathology

The acute phase of RF is characterized by exudative and proliferative inflammatory reactions involving connective or collagen tissue. Although the disease process is diffuse, it affects primarily the heart, joints, brain, and cutaneous and subcutaneous tissues. A generalized vasculitis affecting small blood vessels is commonly noted, but unlike the vasculitis of some other connective tissue disorders, thrombotic lesions are not seen in RF.

The basic structural change in collagen is fibrinoid degeneration. The interstitial connective tissue becomes edematous and eosinophilic, with fraying, fragmentation, and disintegration of collagen fibers. This is associated with infiltration of mononuclear cells including large modified fibrohistiocytic cells (Aschoff's cells). Some of the histiocytes are multinucleated and form Aschoff's giant cells.

The Aschoff's nodule in the proliferative stage is considered pathognomonic of rheumatic carditis. These nodules have been found almost invariably in the autopsies of patients who died of rheumatic carditis; however, more recent observations indicate that Aschoff's nodules are observed in only 30 to 40 percent of biopsy specimens from patients with primary or recurrent episodes of RF.[18] Aschoff's bodies may be seen in any area of the myocardium but not in other affected organs such as joints or brain. They are most often noted in the interventricular septum, the wall of the left ventricle, or the left atrial appendage. Aschoff's nodules persist for many years after a rheumatic attack, even in patients with no evidence of recent or active inflammation.

Inflammation of valvular tissue accounts for the more commonly recognized clinical manifestations of rheumatic carditis. Initial inflammation leads to valvular insufficiency. The histological findings in endocarditis consist of edema and cellular infiltration of the valvular tissue and the chordae tendineae. Hyaline degeneration of the affected valve leads to the formation of verrucae at its edge, preventing total approximation of the leaflets. Fibrosis and calcification of the valve occur if inflammation persists. This process may eventually lead to valvular stenosis.

DIAGNOSIS

No specific clinical, laboratory, or other test establishes the diagnosis of RF.[18A] In 1944, T. Duckett Jones formulated his criteria for the diagnosis of RF[19] ; these criteria are still valuable. They have been modified, revised, edited, and updated by the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young (American Heart Association).[20] The most recent guidelines (Table 66-3) emphasize the diagnosis of *initial attacks* of RF. Dividing clinical and laboratory findings into major and minor manifestations is based on the diagnostic importance of a particular finding. If supported by evidence of preceding GAS infection, the presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute RF.

Major Clinical Manifestations

CARDITIS.

Rheumatic carditis is a pancarditis affecting the endocardium, myocardium, and pericardium to various degrees. Clinically, rheumatic carditis is almost always associated with a murmur of valvulitis. The severity of carditis is variable. In its most severe form, death due to cardiac failure may occur. More commonly, carditis is less intense, and the predominant effect is subsequent scarring of the heart valves. Evidence of carditis may be very subtle; signs of valvular involvement may be mild and transient and may be easily missed on auscultation. Baseline studies, including electrocardiographs and echocardiographs, should be obtained in patients in whom RF is suspected. Patients who show no clear evidence of carditis on initial examination should be closely monitored for a few weeks to assess cardiac involvement.

Carditis is often regarded as the most specific manifestation

TABLE 66-3 -- GUIDELINES FOR THE DIAGNOSIS OF INITIAL ATTACKS OF RHEUMATIC FEVER (JONES CRITERIA, UPDATED 1992)

MAJOR MANIFESTATIONS	**MINOR MANIFESTATIONS**
Carditis	Clinical findings
Polyarthritis	Arthralgia
Chorea	Fever

Subcutaneous nodules	Elevated acute phase reactants
	Erythrocyte sedimentation rate
	C-reactive protein

	Prolonged PR interval

SUPPORTING EVIDENCE OF ANTECEDENT A STREPTOCOCCAL INFECTION

Positive throat culture or rapid streptococcal antigen test
Elevated or rising streptococcal antibody titer

From Dajani AS, Ayoub EM, Bierman FZ, et al: Guidelines for the diagnosis of rheumatic fever: Jones Criteria, updated 1992. JAMA 268:2069, 1992. Copyright 1992 American Medical Association.

Figure 66-1 Relative frequency of major manifestations of rheumatic fever in earlier (dark bars) and more recent (light bars) reports in the 1980s

of RF. It is noted in at least 50 percent of patients with acute RF (Fig. 66-1) . Recent outbreaks in the United States suggested that the frequency of carditis was somewhat higher than traditionally reported and may be in part due to more sophisticated diagnostic methods.[2] In one report, carditis was diagnosed in 72 percent of cases by auscultation and in 91 percent of cases by Doppler ultrasonography. The risk of overdiagnosing valvular incompetence by echocardiography should be emphasized, and overreliance on this tool in diagnosing rheumatic carditis should be avoided.

Valvulitis (endocarditis) involving mitral and aortic valves and the chordae of the mitral valve is the most characteristic component of rheumatic carditis. Mitral regurgitation is the hallmark of rheumatic carditis. Aortic regurgitation is less common and usually associated with mitral regurgitation. The pulmonic and tricuspid valves are rarely involved. Residual valvular damage is a major concern in patients with RF and may lead to intractable cardiac failure requiring surgical intervention.

Myocarditis or pericarditis in the *absence* of valvulitis is *not* likely to be due to RF. Tachycardia is an early sign of myocarditis but may also be due to fever or cardiac failure. Transient arrhythmias may occur in patients with myocarditis. Severe myocarditis or valvular regurgitation may lead to cardiac failure. Cardiac enlargement occurs when severe hemodynamic changes result from valvular, myocardial, or pericardial disease. Inflammation of the visceral and parietal surfaces of the pericardium occurs, resulting in pericarditis and the accumulation of pericardial fluid.

ARTHRITIS.

Polyarthritis is the most common major manifestation of RF (see Fig. 66-1) but the least specific. It is almost always asymmetric and migratory and involves larger joints (knees, ankles, elbows, and wrists). Swelling, redness, heat, severe pain, limitation of motion, and tenderness to touch are characteristic. The arthritis of RF is benign and does not result in permanent joint deformity. Joint fluid shows findings characteristic of inflammation (not infection). In untreated cases, arthritis usually lasts 2 to 3 weeks. A striking feature of rheumatic arthritis is its dramatic response to salicylates. Indeed, if a patient does not improve substantially after 48 hours of adequate salicylate treatment, the diagnosis of RF should be in doubt.

Some patients may develop arthritis and other multisystem manifestations after acute streptococcal pharyngitis that do not fulfill the Jones criteria for the diagnosis of acute RF. This "syndrome" has been referred to as poststreptococcal reactive arthritis (PSRA). The arthritis of PSRA does not respond dramatically to antiinflammatory agents. Some patients with PSRA may have silent or delayed-onset carditis[21] ; therefore, these patients should be carefully observed for several months for the subsequent development of carditis.

CHOREA.

Sydenham's chorea, St. Vitus' dance, or chorea minor occurs in about 20 percent of patients with RF (see Fig. 66-1) . The rheumatic inflammatory process in the central nervous system specifically involves the basal ganglia and caudate nuclei. Chorea is a *delayed* manifestation of RF, usually appearing 3 months or longer after the onset of the precipitating streptococcal infection. This is in sharp contrast to the latent period of carditis or arthritis, which is usually 3 weeks. As such, chorea is frequently the only manifestation of RF. Furthermore, evidence of a recent GAS infection may be difficult to document, and other supporting historical, clinical, or laboratory findings to fulfill the Jones criteria may be lacking. The diagnosis of RF can be made in a patient with chorea without strictly adhering to the Jones criteria.

Sydenham's chorea is characterized clinically by purposeless and involuntary movements, muscle incoordination and weakness, and emotional lability. The manifestations are more evident when a patient is awake and under stress and may disappear during sleep. All muscles may be involved, but primarily muscles of the face and extremities. Speech may be affected, being explosive and halting. Handwriting deteriorates, and patients become uncoordinated and easily frustrated. The symptoms of Sydenham's chorea must be distinguished from tics, athetosis, conversion reactions, hyperkinesis, and behavior problems. Symptoms usually resolve in 1 to 2 weeks, even without treatment.

ERYTHEMA MARGINATUM.

This distinctive rash is a rare manifestation of RF, occurring in less than 5 percent of patients. It is an evanescent, erythematous, macular, nonpruritic rash with pale centers and rounded or serpiginous margins. Lesions vary greatly in size and occur mainly on the trunk and proximal extremities, not on the face. The rash may be induced by application of heat.

SUBCUTANEOUS NODULES.

These are firm, painless, freely movable nodules that measure 0.5 to 2 cm. They are rarely seen in patients with RF (about 3 percent); when present, they are most often seen in patients with carditis. They are usually located over extensor surfaces of the joints (particularly elbows, knees, and wrists), in the occipital portion of the scalp, or over spinous processes. The overlying skin is freely movable, shows no discoloration, and is not inflamed.

Minor Manifestations

CLINICAL FINDINGS.

Fever and arthralgia are nonspecific, common findings in patients with acute RF. Their diagnostic value is limited because they are encountered commonly in various other diseases. They are used to support the diagnosis of RF when only a single major manifestation is present. Fever is noted during the acute stages of the disease and has no characteristic pattern. Arthralgia is pain in one or more large joints without objective findings on examination and must not be considered a minor manifestation if arthritis is present. Epistaxis and abdominal pain may also occur but are not included as minor diagnostic criteria for RF.

LABORATORY FINDINGS.

Elevated acute phase reactants offer objective but nonspecific indications of tissue inflammation. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level are almost always elevated during the acute stages of the disease in patients with carditis or polyarthritis but are usually normal in patients with chorea. The ESR is useful in monitoring the course of the disease; it usually returns to normal as the rheumatic activity subsides. The ESR may be elevated in patients with anemia and may be suppressed to normal levels in patients with congestive cardiac failure. Unlike the ESR, the CRP level is unaffected by anemia or cardiac failure.

A common finding in patients with acute RF is a prolonged PR interval for age and rate on electrocardiography. This finding alone is not diagnostic of carditis and does not

correlate with the ultimate development of chronic rheumatic cardiac disease. Other findings on electrocardiography include tachycardia, atrioventricular block, and QRS-T changes suggestive of myocarditis; these changes are not considered minor manifestations.

Leukocytosis may be observed in the acute stages of RF, but the leukocyte count is variable and not dependable. Anemia is usually mild or moderate and normocytic normochromatic in morphology (anemia of chronic inflammation). Chest roentgenograms are useful in assessing cardiac size; however, normal findings on a chest roentgenogram do not preclude the presence of carditis. Pericarditis, pulmonary edema, and increased pulmonary vascularity are also detected by this examination. Echocardiography may be helpful in detecting endocardial, myocardial, and pericardial involvement. Antimyosin antibody imaging has been reported to be useful in the detection of rheumatic carditis.[21A]

Antecedent Group A Streptococcal Infection

A number of illnesses mimic acute RF, and no laboratory test or tests establish a specific diagnosis of RF. It is therefore important to establish an antecedent streptococcal infection by demonstrating GAS in the tonsillopharynx or an elevated or rising streptococcal antibody titer. *Evidence of an antecedent streptococcal infection is required for confirmation of the initial diagnosis of acute RF.*

At the time of diagnosis of acute RF, only about 11 percent of patients have throat cultures positive for GAS.[2] The paucity of positive cultures is due, in part, to elimination of the organism by host defense mechanisms during the latent period between the onset of the infection and the subsequent development of RF. Several rapid GAS antigen detection tests are commercially available. These tests vary in method. Most have a high degree of specificity but a low sensitivity in a clinical setting. A negative test result does not preclude the presence of GAS in the pharynx. A positive throat culture result or rapid antigen test does not distinguish between a recent infection that can be associated with acute RF and chronic pharyngeal carriage of the organism.

Because the presence of GAS in the pharynx may not represent active infection, elevated or rising antistreptococcal antibody titers provide more reliable evidence of a recent streptococcal infection than does a positive culture or a positive rapid antigen test result. The most commonly used antibody tests are the antistreptolysin O (ASO) and antideoxyribonuclease B (anti-DNase B). The ASO test is usually performed first, and if results are not elevated, the anti-DNase B test is done. Elevated titers for both tests may persist for several weeks or months. ASO titers rise and fall more rapidly than anti-DNase B. A commercially available slide agglutination test measures antibodies to several streptococcal antigens. It is simple to perform, rapid, and widely available; however, the test is not well standardized and not very reproducible and is not recommended as a definitive test for evidence of a preceding GAS infection.

TREATMENT

GENERAL.

Whenever possible, patients should be admitted to a hospital for close observation and appropriate work-up. Bed rest is generally considered important because it lessens joint pain. The duration of bed rest may be variable and individually determined. Ambulation may be attempted once fever abates and acute phase reactants return to normal. Patients should be allowed to return to a reasonably active life with normal physical activity. Strenuous physical exercise should be avoided, however, particularly if carditis was present. Although throat cultures are rarely positive for GAS at the time of onset of RF, patients should receive a 10-day course of penicillin therapy. Patients allergic to penicillin should be treated with erythromycin.

If heart failure intervenes, patients should receive diuretics, oxygen, and digitalis and be on a restricted sodium diet. Digitalis preparations should be used cautiously because cardiac toxicity may occur with conventional dosages.

ANTIRHEUMATIC THERAPY.

There is no specific treatment for the inflammatory reactions initiated by RF. Supportive therapy is aimed at reducing constitutional symptoms, controlling toxic manifestations, and improving cardiac function.

Patients with mild or no carditis usually respond well to salicylates. Salicylates are particularly effective in relieving joint pain; such pain usually abates within 24 hours of starting salicylates. Indeed, if joint pain persists after salicylate treatment, the diagnosis of RF may be questionable and patients should be reevaluated. Because no specific diagnostic tests for RF exist, antiinflammatory therapy should be withheld until the clinical picture has become sufficiently clear to allow for a diagnosis. Early administration of antiinflammatory agents may suppress clinical manifestations and prevent appropriate diagnosis. For optimal antiinflammatory effect, serum salicylate levels around 20 mg percent are required. Aspirin, at doses of 100 mg/kg/d, given four to five times daily, usually results in adequate serum levels to achieve a clinical response. Optimal salicylate therapy must be individualized, however, to ensure adequate response and avoid toxicity. Tinnitus, nausea, vomiting, and anorexia are common dose-related toxicities associated with salicylism. Side effects may subside after a few days of treatment despite continuation of the medication.

Patients with significant cardiac involvement--particularly those with pericarditis or congestive heart failure--respond more promptly to corticosteroids than to salicylates. Indeed, steroids may be life saving in very ill patients. Patients who do not respond to adequate doses of salicylates may occasionally benefit from a trial course of corticosteroids. Prednisone, 1 to 2 mg/kg/d, is the usual dose.

There is no evidence that salicylate or corticosteroid therapy affects the course of carditis or diminishes the incidence of residual heart disease. Therefore, the duration of therapy with antiinflammatory agents is arbitrarily based on an estimate of the severity of the episode and the promptness of the clinical response.

Mild attacks with little or no cardiac involvement may be treated with salicylates for about 1 month or until there is sufficient clinical and laboratory evidence of inflammatory inactivity. In more severe cases, therapy with corticosteroids may be continued for 2 to 3 months. The medication is then gradually reduced over the next 2 weeks. Even with prolonged therapy, some patients (approximately 5 percent) continue to demonstrate evidence of rheumatic activity for 6 months or more. A "rebound," manifested by reappearance of mild symptoms or of acute phase reactants, may occur in some patients after antiinflammatory medications have been discontinued, usually within 2 weeks. Modest symptoms usually subside without treatment; more severe symptoms may require treatment with salicylates. Some physicians recommend the use of salicylates (aspirin, 75 mg/kg/d) during the period when corticosteroids are being tapered and believe that such an approach may reduce the likelihood of a rebound.

Information about the use of salicylates other than aspirin is very limited. No evidence shows that other nonsteroidal antiinflammatory agents are more effective than aspirin. In patients who cannot tolerate aspirin or who are allergic to it, a trial of other nonsteroidal agents may be warranted. Aspirin preparations that are coated or that contain alkali or buffers may also be tried; however, little evidence shows that such preparations are better tolerated, and some may have undesirable side effects.

PREVENTION

Primary Prevention

Prevention of primary attacks of RF depends on prompt recognition and proper treatment of GAS tonsillopharyngitis. Eradication of GAS from the throat is essential. Although appropriate antimicrobial therapy started up to 9 days after the onset of acute streptococcal pharyngitis is effective in preventing primary attacks of rheumatic fever,[8] early therapy is advisable because it reduces both morbidity and the period of infectivity. In selecting a regimen for the treatment of GAS pharyngitis, various factors should be considered, including bacteriological and clinical efficacy; ease of adherence to the recommended regimen (frequency of daily administration, duration of therapy, palatability); cost; spectrum of activity of the selected agent; and potential side effects.[22]

Penicillin is the antimicrobial agent of choice for the treatment of GAS, except in patients with history of allergy to penicillin.[23] [24] Penicillin has a narrow spectrum of activity, has a longstanding proven efficacy, and is the least expensive regimen. GAS resistant to penicillin has not been documented.[25] Penicillin may be administered intramuscularly or orally (Table 66-4) , depending on the patient's likely adherence to an oral regimen.

Intramuscular benzathine penicillin G is preferred, particularly for patients who are unlikely to complete a 10-day course of oral therapy and for patients with a personal or family history of RF or rheumatic heart disease. Benzathine penicillin G injections should be given as a single dose in a large muscle mass. This formulation is painful; injections that contain procaine penicillin in addition to benzathine penicillin G are less painful. Less discomfort is associated with intramuscular benzathine penicillin G if the medication is warmed to room temperature before administration.

The oral antibiotic of choice is penicillin V (phenoxymethyl penicillin). Patients should take oral penicillin regularly for an entire 10-day period, although they are likely to

be asymptomatic after the first few days. Although the broader-spectrum amoxicillin is often used for treatment of GAS pharyngitis, it offers no microbiological advantage over penicillin.

Oral erythromycin is acceptable for patients allergic to penicillin. Treatment should also be prescribed for 10 days. Erythromycin estolate (20 to 40 mg/kg/d in two to four divided doses), or erythromycin ethyl succinate (40 mg/kg/d in two to four divided doses) is effective in treating streptococcal pharyngitis; however, efficacy of a twice-daily regimen in adults requires further study. The maximal dose of erythromycin is 1 gm/d. Although strains of GAS resistant to erythromycin are prevalent in some areas of the world and have resulted in treatment failures,[26] they are uncommon in most parts of the United States.[25]

The macrolide azithromycin has similar susceptibility to that of erythromycin against GAS but may cause fewer gastrointestinal side effects. Azithromycin can be administered once daily and produces high tonsillar tissue concentrations. A 5-day course of azithromycin is approved by the Food and Drug Administration as a second-line therapy for the treatment of patients 16 years of age or older with GAS pharyngitis. The recommended dosage is 500 mg as a single dose on the first day followed by 250 mg once daily for 4 days.[27]

A 10-day course of an oral cephalosporin is an acceptable alternative, particularly for penicillin-allergic patients. Narrower-spectrum cephalosporins, such as cefadroxil or

TABLE 66-4 -- PREVENTION OF RHEUMATIC FEVER

AGENT	DOSE	ROUTE	DURATION
	Primary Prevention		
Benzathine penicillin G	600,000 units for patients kg 1,200,000 units for patients >27 kg	IM	Once
	or		
Pencillin V	Children: 250 mg 2-3 times daily Adolescents and adults: 500 mg 2-3 times daily	PO	10 days
For patients allergic to penicillin:			
Erythromycin	40 mg/kg/d 2-4 times daily (maximum 1 gm/d)	PO	10 days
	Secondary Prevention		
Benzathine penicillin G	1,200,00 units every 3-4 wk	IM	See Table 66-5
	or		
Penicillin V	250 mg b.i.d.	PO	See Table 66-5
	or		
Sulfadiazine	0.5 gm once daily for patients 10104;27 kg (60 lb) 1.0 gm once daily for patients >27 kg (60 lb)	PO	See Table 66-5

Erythromycin	250 mg b.i.d.	PO	See Table 66-5

IM=intramuscularly; PO=orally.*Modified from Dajani AS, Taubert K, Ferrieri P, et al: Treatment of streptococcal pharyngitis and prevention of rheumatic fever. Pediatrics 96:758, 1995. Reproducted by permission of Pediatrics.*

cephalexin, are probably preferable to the broader-spectrum cephalosporins such as cefaclor, cefuroxime, cefixime, and cefpodoxime. Some penicillin-allergic persons (<15 percent) are also allergic to cephalosporins, and these agents should not be used by patients with immediate (anaphylactic-type) hypersensitivity to penicillin.

Several reports indicate that a 10-day course with an oral cephalosporin is superior to 10 days of oral penicillin in eradicating GAS from the pharynx.[28] [29] [30] [31] Reports suggest that a 5-day course with selected oral cephalosporins is comparable to a 10-day course of oral penicillin in eradicating GAS from the pharynx.[32] [33] [34]

Certain antimicrobials are not recommended for treatment of streptococcal upper respiratory tract infections.[24] Tetracyclines should not be used because of the high prevalence of resistant strains. Sulfonamides and trimethoprimsulfamethoxazole will not eradicate GAS in patients with pharyngitis and should not be used to treat active infections. Chloramphenicol is not recommended because of unpredictable efficacy and potential serious toxicity.

Secondary Prevention

Patients who have suffered a previous attack of RF and who develop streptococcal pharyngitis are at high risk for a recurrent attack of RF. A GAS infection need not be symptomatic to trigger a recurrence. Furthermore, RF can recur even when a symptomatic infection is optimally treated. For these reasons, prevention of recurrent RF requires continuous antimicrobial prophylaxis rather than recognition and treatment of acute episodes of streptococcal pharyngitis.

Continuous prophylaxis is recommended for patients with a well-documented history of RF (including cases manifested solely by Sydenham's chorea) end those with definite evidence of rheumatic heart disease. Such prophylaxis should be initiated as soon as acute RF or rheumatic heart disease is diagnosed. A full therapeutic course of penicillin (as outlined in Table 66-4) should first be given to patients with acute RF to eradicate residual GAS even if a throat culture is negative at that time. Streptococcal infections occurring in family members of rheumatic patients should be treated promptly.

CONTINUOUS ANTIMICROBIAL PROPHYLAXIS.

This provides the most effective protection from RF recurrences. Risk of recurrence depends on several factors. Risk increases with several previous attacks, whereas the risk decreases as the interval since the most recent attack lengthens. The likelihood of acquiring a streptococcal upper respiratory tract infection is an important consideration. Patients with increased exposure to streptococcal infections include children and adolescents; parents of young children; teachers, physicians, nurses, and allied health personnel in contact with children; military recruits; and others in crowded housing. A higher risk of recurrences in economically disadvantaged populations has been demonstrated.

Physicians must consider each individual situation when determining appropriate duration of prophylaxis. Patients who have had rheumatic carditis are at a relatively high risk for recurrences of carditis and are likely to sustain increasingly severe cardiac involvement with each recurrence. Therefore, patients who have had rheumatic carditis should receive long-term antibiotic prophylaxis, perhaps for life. Duration of prophylaxis depends on whether residual valvular disease is present or absent (Table 66-5) . Prophylaxis should continue even after valve surgery, including prosthetic valve replacement. Patients who have had RF without carditis are at considerably less risk of cardiac involvement with a recurrence. Therefore, prophylaxis may be discontinued in these individuals after several years.[35] In general, prophylaxis should continue until 5 years have elapsed since the last RF attack or age 21 years, whichever is longer. The decision to discontinue prophylaxis or reinstate it should be made after discussion with the patient of potential risks and benefits and careful consideration of the epidemiological risk factors enumerated earlier.

An injection of 1,200,000 units of long-acting penicillin preparation every 4 weeks is the recommended regimen for secondary prevention in most circumstances in the United States (see Table 66-4) . In countries where the incidence of RF is particularly high, in special circumstances, or in certain high-risk individuals, such as patients with residual rheumatic carditis, the administration of benzathine penicillin G every 3 weeks is recommended.[36] Long-acting penicillin is of particular value in patients with a high risk of

TABLE 66-5 -- DURATION OF SECONDARY PROPHYLAXIS IN PATIENTS WITH RHEUMATIC FEVER

CATEGORY	DURATION
Rheumatic fever with carditis and residual valvular disease	At least 10 yr after last episode and at least until age 40 Sometimes lifelong prophylaxis
Rheumatic fever with carditis but no residual valvular disease	10 yr or well into adulthood, whichever is longer
Rheumatic fever without carditis	5 yr or until age 21, whichever is longer

From Dajani AS, Taubert K, Ferrieri P, et al: Treatment of streptococcal pharyngitis and prevention of rheumatic fever. Pediatrics 96:758, 1995; with permission.

recurrence of RF. The advantages of benzathine penicillin G must be weighed against inconvenience to patients and pain of injection, which cause some patients to discontinue prophylaxis.

Successful oral prophylaxis depends primarily on patients' adherence to prescribed regimens. Patients need careful and repeated instructions about the importance of continuing prophylaxis. Most failures of prophylaxis occur in nonadherent patients. Even with optimal patient adherence, risk or recurrence is higher in individuals receiving oral prophylaxis compared with those receiving intramuscular benzathine penicillin G.[22] Oral agents are more appropriate for patients at lower risk for rheumatic recurrence. Accordingly, some physicians switch patients to oral prophylaxis when they have reached late adolescence or young adulthood and have remained free of rheumatic attacks for at least 5 years.

Penicillin V is the preferred oral agent (see Table 66-4) . There are no published data about the use of other penicillins, macrolides, or cephalosporins for secondary prevention of RF. Although sulfonamides are not effective in eradication of GAS, they do prevent infection. Sulfadiazine and sulfisoxazole appear to be equivalent; the use of sulfisoxazole is acceptable on the basis of extrapolation from data demonstrating that sufladiazine has proven effectiveness in secondary prophylaxis. The recommended dose of sulfisoxazole is the same as that for sulfadiazine. Sulfonamide prophylaxis is contraindicated in late pregnancy because of transplacental passage of the drugs and potential competition with bilirubin for albumin-binding sites. Erythromycin is recommended for patients who are allergic to penicillin and sulfisoxazole.

Infective Endocarditis Prophylaxis (See also Chap. 47)

Patients with rheumatic valvular heart disease also require additional short-term antibiotic prophylaxis before certain surgical and dental procedures to prevent possible development of infective endocarditis. Patients with prosthetic valves or previous endocarditis are at particularly high risk. *Antibiotic regimens used to prevent recurrences of acute RF are inadequate for prevention of bacterial endocarditis.* The current recommendations of the American Heart Association concerning prevention of bacterial endocarditis should be followed.[37] Because alpha-hemolytic streptococci in the oropharynx may have developed resistance to oral penicillin being used for secondary prevention of RF, the agent selected to prevent endocarditis should not be a penicillin. Patients who have had RF but who do not have evidence of rheumatic heart disease do not need endocarditis prophylaxis.

Chapter 67 - Rheumatic Diseases and the Cardiovascular System

BRIAN F. MANDELL
GARY S. HOFFMAN

Systemic rheumatologic conditions are pleomorphic and often involve the cardiovascular system. Patients may present because of musculoskeletal disease, fever of uncertain origin, regional or visceral ischemia, organ failure (e.g., uremia, hypoxemia, dementia, congestive heart failure), or inflammation (e.g., pericarditis, pleurisy). The cardiologist is usually not the initial source of care but becomes involved through the consultative process. However, in certain circumstances, cardiologists or cardiothoracic surgeons may be the first to recognize clinical "outliers" for which systemic autoimmune disease should be part of the differential diagnosis. Several examples include young patients with ischemic heart disease, aortic aneurysms and valvular regurgitation, claudication, or multifocal thrombi or any patient in whom cardiovascular abnormalities occur in the setting of systemic illness. The varied presentations and treatments of rheumatic illnesses and their cardiovascular manifestations are the subjects of this chapter.

Vasculitis

Vasculitis is the common denominator of rheumatic diseases that affect the cardiovascular system, although each of the many forms of systemic vasculitis is uncommon. This fact alone makes it a challenge for the clinician. Additionally, all forms of vasculitis are readily confused with other systemic illnesses for which immunosuppressive therapy may have adverse or lethal consequences. Processes that may be confused with vasculitis include sepsis (particularly bacterial endocarditis), drug toxicities and poisonings (especially with agents that are likely to produce vasospasm, e.g., cocaine, amphetamines), coagulopathies, malignancies, cardiac myxomas, and multifocal emboli from large vessel aneurysms[1] (Table 67-1) . The most certain diagnosis of vasculitis lies in the identification of compatible clinical features and pathologic proof of vasculitis. In some instances, vasculitis may present as a characteristic constellation of findings within systemic illness. For example, the presence of upper and lower airway inflammation and red blood cell casts in the urine sediment, with or without renal insufficiency, would suggest Wegener granulomatosis. Hypertension and upper extremity claudication in a young individual, especially if female, should suggest Takayasu arteritis. Unfortunately, many patients with vasculitis do not present with such readily recognizable features. Instead, one may have to rely on combinations of less typical clues. A patient with fever, active urinary sediment, and peripheral neuropathy is likely to have vasculitis, especially if the previously noted competing diagnoses have already been ruled out. The presence of a purpuric rash, particularly if it is palpable, furthers the probability of this diagnosis, which can be confirmed by a simple skin biopsy. When such features occur in a patient with an already established autoimmune disease (e.g., rheumatoid arthritis, systemic lupus erythematosus, Sjogren syndrome, or relapsing polychondritis), the likelihood of vasculitis being present increases.

The incidence of vasculitis appears to be on the rise, with aging of the population.[1A] [1B] [1C] The considerable social and economic costs of the vasculitides may have been underestimated in the past.[1D] A recent bibliography provides an update on the literature of the vasculitic syndromes.[1E]

PROOF OF DIAGNOSIS.

Definitive proof depends on visualizing vasculitic lesions in affected tissue, and the greatest success in achieving a tissue diagnosis comes from biopsy of abnormal or symptomatic sites. In patients with proven vasculitis, the yield from biopsies of clinically normal sites is considerably less than 20 percent. Therefore, a biopsy of apparently normal tissue is not recommended.[2] [3] Biopsies of abnormal organs provide diagnostically useful information in over 65 percent of cases. Yield is less than 100 percent because uniform involvement of vessels in vasculitis is uncommon.

A biopsy may not be practical in an illness with symptoms of visceral ischemia, carotidynia, or findings of unequal pulses or blood pressures. Biopsies of large vessels and diagnostic laparotomy, in the absence of an acute abdomen, are usually impractical. In this setting, angiography may be helpful. Evidence of vascular injury may be apparent from areas of vascular stenosis and/or aneurysm formation that cannot be explained on the basis of atherosclerosis. Angiography is particularly useful for patients with diseases that involve large (Takayasu arteritis, giant cell

TABLE 67-1 -- DIAGNOSIS OF VASCULITIS: DISEASES THAT CAN MIMIC PRIMARY SYSTEMIC VASCULITIS

arteritis of the elderly [GIA]) and medium-sized vessels (e.g., polyarteritis nodosa). Serological tests may provide additional information.[3A] [3B]

Once the diagnosis of vasculitis is clearly established and based on the strongest of circumstantial evidence or biopsy proof of vascular inflammatory injury, one must still consider whether such lesions are due to *secondary vasculitis* from bacterial, fungal, and viral infections (e.g., hepatitis B or C and, in immunologically compromised patients, human immunodeficiency virus or cytomegalovirus) or malignancies. Paraneoplastic vasculitis should be considered on the basis of a suspicious history or laboratory finding, or in patients who fail to respond to usually effective aggressive immunosuppressive therapy.

Takayasu Arteritis

Takayasu arteritis (TA), an idiopathic large-vessel vasculitis in young individuals, affects the aorta and its major branches (Fig. 67-1 *A* and *B*). Histologically, TA is characterized by intense mononuclear leukocyte infiltration and the presence of giant cells (see Fig. 67-1 *C*). Women are affected about 10 times more often than men. Morbidity results from arterial stenosis and organ ischemia, as well as aneurysm formation, especially of the aortic root, where it may produce aortic regurgitation.

Hypertensive or primary cardiac, renal, and central nervous system vascular disease account for most deaths. Estimates of mortality range from 3 percent at 8 years[4] to 35 percent at 5 years follow-up.[5]

Symptoms of large-vessel abnormalities or the finding of hypertension, especially in young patients, necessitate careful examination of extremity pulses and blood pressures for asymmetry as well as a search for vascular bruits. Other indications of active disease include increasing extremity or visceral ischemia, malaise, myalgias, arthralgias, night sweats, and fever. Occurrence of such symptoms that take place in the presence of an elevated erythrocyte sedimentation rate suggests active disease. However, a significant number of patients may not have any constitutional or new vascular symptoms, and as many as 50 percent may have normal sedimentation rates and still experience progressive disease.[6] [7] [8] The occurrence of active TA in this setting has been documented by the finding of (1) new vascular abnormalities on sequential angiographic studies in patients who were thought to be in remission and (2) inflammatory changes in bypass specimens from patients in whom surgery was performed because of critical flow abnormalities, in the setting of clinically "quiescent" disease.[7] [8] [9] Until we are able to judge more accurately the degree of disease activity in TA, outcomes will be compromised. Studies using refinements in magnetic resonance imaging techniques may enable the clinician to detect qualitative abnormalities in the vessel wall that imply inflammatory change.[10] These abnormalities may then be followed sequentially to determine response to therapy.

The cardiac sequelae of TA are far more commonly due to aortic regurgitation and inadequately treated hypertension than arteritis affecting the coronary vessels.[6] [11] When coronary artery vasculitis occurs, it is most frequent in the ostial regions. However, more distal involvement can also occur and both types of lesions may coexist in the same patient. These observations underscore the importance of considering vasculitis in the differential diagnosis of young patients with ischemic syndromes.[12]

TREATMENT.

Approximately 60 percent of patients with TA respond to corticosteroid therapy (e.g., prednisone, 1 mg/kg/d), with subsequent resolution of symptoms and stabilization of arteriographically demonstrable abnormalities. However, progressive tapering of corticosteroid therapy has been associated with disease relapse in over 40 percent of patients. Corticosteroid-resistant or relapsing patients may

Figure 67-1 Takayasu arteritis. *A,* The arrows in this aortic arch angiogram show the characteristic narrowing that occurs in the brachiocephalic, carotid, and subclavian arteries. *B,* Gross photography of the same patient at autopsy shows two cross sections of the right carotid artery with pronounced intimal thickening and minimal residual lumen. *C,* This histologic section illustrates arterial media destruction by mononuclear inflammation with giant cells that takes place in active Takayasu aortitis. (From Schoen FJ, Cotran RS: Blood vessels. *In* Cotran RS, Kuman V, Collins T [eds]: Robbins Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, pp 493-541.)

respond to the addition of daily therapy with cyclophosphamide (~2 mg/kg) or weekly therapy with methotrexate (~20 mg).[7] [9] [13] About 40 percent of patients who are treated with a cytotoxic agent and a corticosteroid will achieve remission, but over time about half of these patients will also experience relapse, leading to the requirement for chronic immunosuppressive therapy in approximately 25 percent of all patients with TA.

A discussion of pharmacological therapy for TA addresses only one important aspect of care. Other important

Figure 67-2 Takayasu arteritis. Standard Takayasu arteritis diagram used by the Cleveland Clinic Center for Vasculitis Care and Research. In this young man, occlusion of both subclavian arteries has led to leg pressures being the only reliable measure of central aortic pressure. He has also had a left renal artery bypass for a stenotic lesion, which was responsible for severe hypertension. Also note bilateral common carotid stenosis.

issues include treatment of the anatomic effects of vascular lesions. Patients with TA may have signs of clinical deterioration caused by fixed critical stenoses or aneurysms. Hypertension affects 21 to 90 percent of patients.[7] [9] [14] [15] [16] In Asia and Mexico, TA is one of the most common causes of hypertension in the adolescent and young adult population. Inadequately treated hypertension may lead to cerebral, cardiac, and renal injury. One of the most common errors in clinical management occurs when the physician does not know whether blood pressure recordings in an extremity are representative of aortic root pressure. Because over 90 percent of patients have stenotic lesions and the most common site of stenosis is the subclavian artery(s), blood pressure in one or both arms may underestimate pressure in the aorta. Elevated aortic root pressure, unrecognized and untreated, enhances the risks of hypertensive complications. This potential pitfall can best be avoided by recording arterial pressures when performing angiography (Fig. 67-2) . These observations emphasize the importance of knowing the distribution and severity of all vascular lesions. In the setting of renal insufficiency, the potential contrast agents to cause further renal impairment may limit exploration of the extent of all potential vascular lesions. However, in the absence of contraindications, the entire aorta and its primary branches should be included in vascular imaging studies. Magnetic resonance angiography lacks the ability to measure intravascular pressures. If the clinical examination does not suggest the presence of extremity lesions or show unequal extremity pressures, a magnetic resonance study may be sufficient to delineate other vascular lesions without resorting to invasive contrast angiography. Whenever feasible, anatomic correction of clinically significant lesions should be considered, especially when renal artery stenosis and hypertension are present.

Aortic root involvement may lead to valvular insufficiency, angina, and congestive heart failure in about 20 percent of patients.[7] [16] Severe or progressive changes may require aortic surgery, with or without valve replacement. Because determining disease activity based solely on clinical and laboratory parameters may be difficult, *all* such surgeries should include histopathological evaluation of vascular specimens.[7] [8] [9] It is always preferable to operate on patients with TA when their disease is in apparent remission. Pathology findings from surgical specimens should guide the need for postoperative immunosuppressive treatment.

The care of patients with TA requires a team approach that includes clinicians familiar with the proper use of immunosuppressive therapies, vascular imaging/intervention specialists, and, in the setting of critical stenoses or aneurysms, cardiovascular physicians and surgeons. For most patients, medical and surgical therapies are palliative.

Giant Cell Arteritis of the Elderly

Giant cell arteritis (GCA) and Takayasu arteritis are the principal diseases associated with sterile granulomatous inflammation

Figure 67-3 Temporal (giant cell) arteritis: Active aortitis with perivascular lymphoplasmacytic infiltrate in the adventitia, unorganized periadventitial fibrin and secondary infarcts and patchy scarring involving approximately 50 per cent of the media in giant cell arteritis. (Courtesy of F. J. Schoen.)

of large and medium-sized vessels (Fig. 67-3). GCA affects people 50 years of age and older (mean=70 years). Although women are more often affected (2-3:1), this gender difference is not as striking as in TA (6-10:1). The demographic characteristics of GCA are the same as for patients with polymyalgia rheumatica and, in fact, 30 to 50 percent of patients with GCA may concurrently present features of polymyalgia rheumatica. The most characteristic features of GCA include new onset of atypical and often severe headaches, scalp and temporal artery tenderness, acute visual loss, and pain within the muscles of mastication (Table 67-2) .[17] When such abnormalities occur in conjunction with an elevated erythrocyte sedimentation rate, a clinical diagnosis of GCA can be presumed and treatment initiated even without the benefit of a temporal artery biopsy.

TABLE 67-2 -- GIANT CELL ARTERITIS: CLINICAL PROFILE

ABNORMALITY	FREQUENCY (%)
Atypical headache	60-90
Tender temporal artery	40-70
Systemic symptoms not attributable to other diseases	20-50
Fever	20-50
Polymyalgia rheumatica	30-50

Acute visual abnormalities	12-40
Transient ischemic attacks or stroke	5-10
Claudication	
"Jaw"	30-70
Extremities	5-15
Aortic aneurysm	15-20
Dramatic response to corticosteroid	~100
Positive temporal artery biopsy	~50+

(From Hoffman GS: Textbook of Rheumatology, Systemic Vasculitis. Update 28. Philadelphia, WB Saunders, 1998.)

The diagnosis is doubtful if dramatic improvement does not occur within 24 to 72 hours. The specific findings of a positive biopsy would be helpful in guiding treatment when typical features are not present, but the diagnosis is suggested because of vague systemic symptoms, atypical headache in the setting of normal or elevated sedimentation rate, and exclusion of all other reasonable diagnoses have been ruled out. The yield of positive temporal artery biopsies in patients clinically diagnosed with GCA has been estimated to be 50 to 80 percent, depending in part on the size of the biopsy and whether bilateral samples have been obtained.

GCA may produce aortitis in at least 15 percent of cases and involve the primary branches of the aorta in a similar number of individuals.[1A] [1B] [1C] [1D] [1E] [18] [19] [20] [21] Consequently, some patients with GCA may present with features that resemble those of TA. The same considerations and precautions must be applied in GCA among the elderly with large vessel inflammatory diseases in patients with TA (e.g., the need to identify an extremity that provides a reliable blood pressure equivalent to aortic root pressure; follow-up should include careful observation for new bruits, pulse and blood pressure asymmetry, and the possible development of aortic aneurysms). Recent studies have demonstrated that patients with GCA were more than 17 times more likely than age-matched controls to have thoracic aortic aneurysms and about two times more likely than aged-matched controls to have abdominal aortic aneurysms.[19] [20] Fifty-five percent of patients with thoracic aortic aneurysms died as a result of those lesions. Because aneurysms were found either in the course of routine care or at postmortem, these may be conservative estimates. The finding of large vessel disease, including aortic aneurysms, in elderly persons with GCA should not merely be assumed to be secondary to atheromatous disease.

It is not surprising that objective features of cardiac disease would be present in about half of all patients with GCA.[22] However, it appears that myocardial infarction due to GCA is rare[23] or rarely appreciated because histopathological findings in coronary arteries are infrequently sought in patients with a mean age of 70 years.

Corticosteroids continue to be the most effective therapy for GCA. Prednisone (~0.7-1 mg/kg/d) will reduce symptoms within 1 to 2 days and often eliminates symptoms within a week. Tapering of corticosteroids can begin about 1 month after clinical and laboratory parameters (particularly the erythrocyte sedimentation rate) have normalized. Unfortunately, the erythrocyte sedimentation rate does not always normalize even with disease control, so it should not be relied on as the only measure of disease activity. Occasional patients may either not achieve complete remission or not respond to tapered-off corticosteroids. Some authors have recommended cytotoxic or immunosuppressive agents for such individuals, but the utility of these agents has not been proven, as demonstrated in controlled comparative trials.

Idiopathic Aortitis

Aortitis, a recognized feature of TA and GCA, may also occur in uncommon diseases such as Behcet disease and Cogan syndrome and as a complication of Kawasaki disease in children. Occasionally, it is an unanticipated finding in patients undergoing surgery for aortic valve regurgitation, aneurysm resection, or coarctation. Little is known about the frequency and clinical characteristics of idiopathic aortitis.

A recent 20-year review of pathological specimens from consecutive aortic surgeries at the Cleveland Clinic Foundation revealed that 52 of 1204 specimens (4.3 percent) were classified as idiopathic aortitis, a designation that required

exclusion of vasculitis associated with postoperative infections, atherosclerosis, or inflammation occurring around surgical materials from prior operations. Sixty-seven percent of patients with idiopathic aortitis were women. In 96 percent of cases, aortitis was present in the thoracic aorta. If one considered only thoracic aortic aneurysms, 12 percent of 386 thoracic specimens had idiopathic inflammatory features. In 96 percent of cases, symptoms of systemic illness had not been present at the time of surgery. In 69 percent of cases, idiopathic aortitis was not related to a current or past history of systemic disease. In 31 percent (16/52), aortitis was associated with a past history of giant cell arteritis, Takayasu arteritis, systemic lupus, Wegener granulomatosis, and a variety of other disorders. Over a mean follow-up period of 42 months, new aneurysms were identified among 6 of 25 patients who were not treated with glucocorticosteroids and none of 11 patients who were treated with glucocorticosteroids. Although the observations on nonrandomized patients could indicate a benefit of such therapy in this setting, marked variation of dose and duration of therapy raises uncertainty about the efficacy of therapy. Because 17 percent of patients subsequently developed new aneurysms, it is prudent for patients with idiopathic aortitis, identified at the time of surgery, to be periodically evaluated for recurrent or persistent disease. If proof of recurrent disease is present, treatment should be pursued, as recommended for Takayasu arteritis and GCA.

The broad spectrum of aortitis includes patients who may have systemic illnesses known to affect large vessels. However, in the setting of a cardiovascular surgery practice, aortitis may first become apparent only after pathological evaluation of excised specimens.

KAWASAKI DISEASE (See also Chap. 45)

Kawasaki disease (KD) is an acute febrile illness that primarily affects children younger than 4 years of age and almost never affects children older than 8 years (mean age in Japan is 12 months, and in the United States it is 2.8 years).[24] The most prominent features are included in the Centers for Disease Control and Prevention case definition guidelines (Table 67-3) . KD is usually self-limiting within 4 to 8 weeks; its mortality rate is 2 percent. Deaths usually result from acute thrombosis of coronary artery aneurysms, the result of prior vasculitis. Case studies using noninvasive techniques find coronary artery aneurysms in 20 percent of patients, compared with 60 percent discovered by angiography. Data from postmortem studies have also demonstrated vasculitis of the aorta and celiac, carotid, subclavian, and pulmonary arteries. Rare case reports of gut vasculitis in KD exist.[25] [26] Gastrointestinal morbidity may depend more on small-vessel than large-vessel disease. Treatment with high doses of aspirin (30 mg/kg/d) or intravenous gamma globulin may prevent aneurysms or hasten their regression.

VASCULITIS OF SMALL/MEDIUM-SIZED VESSELS THAT MAY AFFECT THE CARDIOVASCULAR SYSTEM

Hypersensitivity vasculitis, Henoch-Schonlein purpura, Wegener granulomatosis, microscopic polyangiitis, polyarteritis nodosa, and Churg-Strauss syndrome (CSS) may all have cardiac consequences.[26A] Surveys of the literature and the original observations of Churg and Strauss indicate that CSS (asthma, eosinophilia, and vasculitis) may be complicated by congestive heart failure (25-50 percent), acute or constrictive

TABLE 67-3 -- CDC CASE DEFINITION OF KAWASAKI DISEASE

Fever 5 days, without other explanation, plus at least four of the following:
1. Bilateral conjunctival injection
2. Mucous membrane changes: injected or fissured lips; injected pharynx or "strawberry" tongue
3. Extremity abnormality: erythema of palms/soles, edema of hands/feet or generalized or peripheral desquamation
4. Rash
5. Cervical lymphadenopathy
Note: 80% of cases occur in children younger than 4 years old; it is rare in children older than 8 years old.

pericarditis (10-30 percent), hypertension (30-75 percent), myocarditis, and, rarely, myocardial infarction. The majority of deaths in CSS relate to cardiovascular disease.[27] [28] [29] [30] Cardiac involvement is associated with an increased relative risk of death in CSS, polyarteritis nodosa, and related vasculitides of small and medium-sized vessels.[31] [32] Patients with cardiac involvement almost always have an established diagnosis based on prior recognition of more specific disease

manifestations. Treatment of active inflammatory lesions of the heart is the same as would be applied to other sites of vasculitis. Because vasculitis usually involves small vessels, opportunities for invasive therapeutic measures are limited.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the most common form of chronic inflammatory polyarthritis. Present in approximately 70 percent of patients, rheumatoid factor does not confirm the diagnosis of RA, and it is frequently present in other diseases, including chronic viral hepatitis and bacterial endocarditis. Systemic complications of RA include pericarditis, pleuritis, systemic necrotizing arteritis, compressive neuropathies, interstitial lung disease, and Sjogren and Felty syndromes.

PERICARDIAL DISEASE (see also Chap. 50) .

RA affects the pericardium in approximately 50 percent of patients, as indicated by echocardiographic and necropsy studies (see Chap. 50) . Chronic, asymptomatic effusive pericardial disease is more common than acute pericarditis.[33] [34] [35] Although the frequency of symptomatic pericarditis among outpatients with RA has been estimated as less than 0.5 percent, in a series of 41 selected patients with severe RA, 75 percent had symptoms compatible with acute pericarditis.[33] Patients with rheumatoid pericardial disease are generally older and have long-standing RA. Although it may show characteristic changes in acute pericarditis, the electrocardiogram is usually normal in patients with chronic pericardial disease. Coexistent small pleural effusions are common and may reflect rheumatoid serositis or hemodynamic effects of the pericarditis. Pericardial calcification has been reported,[36] mimicking tuberculous pericarditis. Limited data have been published on the nature of pericardial fluid in RA. Fluid is frequently blood tinged, and leukocyte counts range from scant to more than 30,000/mm[3] , generally with a neutrophil predominance. The glucose level may be quite low when compared with serum glucose values, similar to markedly depressed glucose levels reported in rheumatoid pleural effusions. The presence of rheumatoid factor in the fluid does not confirm the diagnosis of RA pericarditis. Infection must be excluded. Constrictive pericarditis has been reported, and it must be distinguished from restrictive cardiomyopathy, a rare complication of secondary amyloidosis in patients with long-standing RA. Treatment of clinical pericarditis includes the use of nonsteroidal antiinflammatory drugs, intensified systemic immunosuppressive therapy, pericardial steroid injections, and surgical decompression. A pericardial window may be required if systemic therapy is ineffective or already at an intense level. The pressure of pericardial constriction usually requires surgical treatment. Chest pain due to costochondritis is far more common than pericarditis. The use of aggressive medical therapy early in the course of rheumatoid disease may decrease the frequency of pericardial involvement.

OTHER CARDIOVASCULAR INVOLVEMENT.

Patients with RA have a decreased life expectancy, and their leading cause of death is cardiovascular disease.[37] Potential risk factors for coronary artery disease (CAD) in patients with RA include the systemic inflammatory state, the use of corticosteroids, which may accelerate atherosclerosis, and possibly the use of methotrexate, which can elevate levels of circulating homocysteine, although the relative contributions of these factors to acceleration of CAD are not clear.[38] [39] Significant ischemic disease may be clinically silent owing to the relative physical inactivity of patients

Figure 67-4 Aortic valve in a patient with rheumatoid arthritis with florid chronic active inflammation including numerous plasma cells, lymphocytes, and polymorphonuclear leukocytes. (Courtesy of F. J. Schoen.)

with severe rheumatoid disease. Coronary arteritis is a rarely reported complication of RA.[40] Treatment of CAD does not differ from that of patients without RA. Coronary arteritis, occurring along with systemic arteritis, is treated with combination immunosuppressive therapy, including corticosteroids plus cyclophosphamide or other agents.

RA is not usually associated with clinically significant myocarditis or congestive heart failure. Secondary amyloidosis is rare in rheumatoid disease, but it can cause cardiomyopathy and atrioventricular conduction abnormalities. Tachyarrhythmias can occur as a result of rheumatoid pericarditis. Focal myocardial involvement with rheumatoid disease has been well described and may result in conduction system abnormalities. Rheumatoid nodules involving the conduction system have been reported.[41] All levels of conduction block have been described and, once established, do not generally respond to antiinflammatory therapy.

Autopsy studies have indicated frequent involvement of the cardiac valves (Fig. 67-4) and aorta, but these abnormalities are rarely of clinical significance. Slowly progressive granulomatous valvulitis may be difficult, if not impossible, to distinguish from disease unrelated to RA. A rapidly progressive inflammatory aortic valvulitis of the aortic valve, advancing to need for valve replacement over less than 5 years has been described previously. [42] Rheumatoid aortitis, with involvement of the aortic valve, has been reported,[43] but aortitis is not frequently recognized ante mortem. RA does not cause primary pulmonary hypertension, but secondary pulmonary hypertension may result from rheumatoid lung disease.

HLA-B27-Associated Spondyloarthropathies

The rheumatoid factor-negative spondyloarthropathies share several features that distinguish them from rheumatoid arthritis. Unlike rheumatoid arthritis, the entire spine, not just the cervical region, may be involved. Involvement of the sacroiliac joint occurs frequently, and it may be the only musculoskeletal manifestation. Large peripheral joints are commonly involved. Inflammation of the tendon sheaths and bone insertions (enthesitis) occurs frequently. Diffuse tendon sheath involvement may produce "sausage digits." There is an increased frequency of the HLA-B27 gene in these disorders. Although approximately 10 percent of healthy American whites have the HLA-B27 gene, it is present in 90 percent of American whites with ankylosing spondylitis and approximately 60 percent of patients with inflammatory bowel-related spondylitis. These percentages are much lower in African Americans and Asians. Presence of the gene predisposes to anterior uveitis, cardiac conduction disease, and proximal aortitis. Thus, some patients with psoriatic arthritis, enteropathic arthritis, reactive arthritis including Reiter syndrome, and ankylosing spondylitis are predisposed to these complications. Patients may express extraskeletal HLA-B27-related complications without overt rheumatic disease.

Pericarditis, although reported,[44] is not characteristic of these diseases (see also Chap. 50) . CAD does not occur at an increased rate, and arteritis is not expected. Diastolic dysfunction has been reported[45] in patients who have the HLA-B27 gene but is rarely of clinical significance. Cardiac conduction disease has been well described in patients with ankylosing spondylitis as well as Reiter syndrome. It has been estimated that up to one third of patients with ankylosing spondylitis develop conduction disease.[46] Initially, the atrioventricular conduction block may be intermittent, but it tends to progress. Conduction disease occurs more commonly in males, and as many as 20 percent of males with permanent pacemakers carry the HLA-B27 gene.[47] Conduction disease may be the only abnormality associated with the HLA-B27 gene. Electrophysiological studies indicate that the level of block is usually at the atrioventricular node, not fascicular.[48] [49] It has been suggested that atrial fibrillation occurs more commonly than expected in patients who carry the HLA-B27 gene.

AORTIC ROOT DISEASE (see also Chap. 40) .

This condition, with involvement of the aortic valve, has been reported in up to 100 percent of patients in autopsy series and 30 percent in echocardiographic studies. Characteristic findings have included thickening of the aortic root with subsequent dilatation. Aortic cusp nodularity with proximal thickening comprises the "subaortic bump."[50] Transesophageal echocardiography located the subaortic bump in 74 percent of 44 patients with ankylosing spondylitis.[51] In this study, aortic regurgitation developed in 50 percent of patients and 20 percent of patients developed congestive heart failure, underwent valve replacement, suffered a stroke, or died as compared with only 3 percent of age- and sex-matched volunteers. The aortic lesions progressed in 24 percent of patients and resolved in an additional 20 percent of patients over approximately a 2-year follow-up. The severity of aortic root disease was associated with the patients' age and duration of spondylitis. Because dilatation and stiffening of the aortic root contributes to the aortic regurgitation, the regurgitant murmur may be best heard along the right sternal border. Inflammatory aortic disease can occasionally extend to the mitral valve, causing mitral regurgitation.

Systemic Lupus Erythematosus (See also Chap. 51)

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the presence of immune complexes and a constellation of clinical features that may include serositis, arthritis, glomerulonephritis, central nervous system dysfunction, hemolytic anemia, thrombocytopenia, leukopenia, and autoantibodies. Histologically, the arteritis of SLE can include fibrinoid necrosis as well as intense perivascular

Figure 67-5 Systemic lupus erythematosus. Vasculitis with fibrinoid necrosis. (From Schoen FJ, Cotran RS: Blood vessels. *In* Cotran RS, Kuman V, Collins T [eds]: Robbins Pathologic Basis of Disease. 6th ed. Philadelphia, WB Saunders, 1999, pp 493-541.)

cuffing by leukocytes (Fig. 67-5). Antiphospholipid antibodies (APLAs) are present in more than 20 percent of lupus patients. The disease is more common in women, and it can occur at any age. Idiopathic and drug-induced lupus have cardiac manifestations. Drug-induced lupus is well recognized after treatment with various cardiac medications, including procainamide, quinidine, and hydralazine. Over 90 percent of patients with SLE have antinuclear antibodies, although the presence of even high titers of antinuclear antibodies is *not* diagnostic of SLE. Anti-double-stranded DNA is present in 50 to 70 percent of patients with idiopathic SLE and is most common in those with glomerulonephritis.

PERICARDIAL DISEASE (see also Chap. 50) .

Imaging and autopsy series demonstrate pericardial involvement in more than 60 percent of patients, and clinically significant pericarditis occurs in less than 30 percent,[52] making pericarditis the most common cardiac problem among patients with SLE.[53] Although unexplained chest pain is common in these patients, it is more likely caused by causes other than pericarditis. Pericarditis may occur as the initial manifestation of SLE, but it may also appear at any point during the disease course or as a complication of chronic renal disease. Pericardial fluid, when obtained, has generally demonstrated a high neutrophil predominance,[53] an elevated protein level, and a low or normal glucose level. Complement levels in the fluid tend to be low, but this is not a characteristic unique to SLE. Indeed, the fluid is indistinguishable from that obtained from patients with bacterial pericarditis. Pericardial tamponade may occur at any point in the course of SLE, including the initial presentation.[54] When effusions occur in the setting of chronic renal failure, it is difficult to distinguish uremic from lupus pericarditis. Patients with mild pericarditis without hemodynamic compromise are generally treated with NSAID therapy, unless there is a contraindication to such therapy, such as renal insufficiency. If corticosteroid therapy does not engender a prompt response, large sterile pericardial effusions, particularly those accompanied by fever and/or hemodynamic compromise, are best treated with drainage and consideration of a pericardial window. Pericarditis, as well as tamponade, can occur with drug-induced lupus. Constrictive pericarditis, presumably as a sequela of lupus pericarditis, has been reported. Pericardial thickening has been described in approximately 30 percent of patients with SLE.

CORONARY ARTERY DISEASE.

Coronary arteritis that results in ischemic syndromes occurs in patients with SLE. The distinction between CAD and coronary arteritis may require sequential angiographic studies, with documentation of more rapid change in luminal images than is usually seen with CAD. Despite the young age of many patients with lupus, atherosclerosis remains the most common cause of ischemic cardiac disease. The prevalence of subclinical CAD is quite high, as measured by thallium exercise testing and autopsy studies, and angina or myocardial infarction occurs in less than 20 percent of patients. As patients live longer with their disease, the prevalence of clinical events will increase.

Cardiovascular disease is the most common cause of death in patients with long-standing SLE. There are reports of young patients with SLE who suffer myocardial infarction as the initial manifestation of their CAD. Middle-aged women with lupus are more than 50 times more likely to experience myocardial infarction[55] than other women of similar age. Risk factors include disease duration, period of time treated with corticosteroids, postmenopausal status, and hypercholesterolemia. Additional causes of acute coronary syndromes include thrombosis, often related to the presence of APLAs, and embolism from nonbacterial vegetative endocarditis (Libman-Sacks). The presence of APLAs predisposes to thrombosis in some patients and has been associated with valvular thickening and nonbacterial endocarditis. Antiendothelial antibodies may accelerate atherogenesis. In this regard, APLAs were an independent predictor of CAD in a subset analysis of the Helsinki heart study.[56] Treatment of ischemic disease in patients with SLE is similar to those patients with "routine" atherosclerotic disease. Exceptions include the rare patients with coronary arteritis, who should be treated aggressively with high doses of corticosteroids, and those patients with thrombotic disease related to APLAs. These latter patients should be treated with long-term high-dose anticoagulation. Aspirin is *not* sufficient. Thrombocytopenia is common in patients with APLAs and may complicate therapy.

MYOCARDIAL DISEASE.

Myocardial dysfunction in lupus is usually multifactorial and may result from immunologic injury, ischemia, valvular disease, or coexistent problems such as hypertension. Acute myocarditis is infrequent, but it can be the initial presentation of SLE. Patients with peripheral skeletal myositis are reportedly at increased risk for myocarditis.[57] Measurement of cardiotroponin-I may be of value in documenting cardiac involvement, but the MB fraction of CPK may be elevated in the presence of skeletal myositis, even in the absence of myocarditis. Echocardiographic and systolic time interval studies have demonstrated abnormal cardiac function in patients with active SLE. These changes usually reverse with control of disease

activity. In the absence of other contributing factors,[58] acute or chronic congestive heart failure due to SLE is not common. Findings on endomyocardial biopsy specimens are not specific, generally revealing patches of myocardial fibrosis, sparse interstitial mononuclear cell infiltrates, and occasional myocyte necrosis.[59] If acute left ventricular failure occurs in patients with active SLE in the absence of CAD or valve disease, a trial of corticosteroid therapy is indicated.

ARRHYTHMIAS.

Tachyarrhythmias can occur in patients with SLE secondary to pericarditis or ischemia. Sinus tachycardia may be the earliest manifestation of myocarditis. A gallium scan may be abnormal in lupus myocarditis.[60] Abnormal heart rate variability has been described and may be due to autonomic dysfunction or to occult myocarditis. Abnormal heart rate variability and abnormal myocardial single-photon emission computed tomography have been described, including some patients with normal resting echocardiograms.[61] Unexplained sinus tachycardia that resolves with treatment of SLE can occur in the presence of active SLE even without demonstrable cardiac dysfunction. Occult pulmonary embolism should always be considered as a cause of tachycardia in patients with SLE, especially in the presence of antiphospholipid antibodies.

Infants born to mothers with SLE and other systemic autoimmune diseases have an increased incidence of congenital complete heart block. The pathogenic mechanism is the transmission of maternal anti-Ro and anti-La antibodies in utero, which causes myocardial inflammation and fibrosis of the conduction system.[62] [63] The risk for development of third-degree atrioventricular block in infants born to mothers carrying this antibody is quite low. However, women with systemic autoimmune diseases should be screened for antibody presence before pregnancy. If they are present, the patients should be examined with fetal ultrasound studies throughout pregnancy to detect complete heart block or hydrops. Heart block usually appears after the first trimester of pregnancy; it is almost always irreversible. If recognized early, dexamethasone in utero may be successful in reversing myocarditis.[64] Plasmapheresis and intravenous gamma-globulin therapy may also be tried. It is frequently necessary to place a pacemaker in the infant shortly after delivery.[65]

VALVULAR DISEASE.

Valvular involvement in SLE is common. Recognized 50 years ago as noninfectious vegetations (Libman-Sacks endocarditis), transesophageal studies have shown valvular abnormalities in over 50 percent of patients with SLE.[66] Valvular thickening is the most striking finding, followed by vegetations and valvular insufficiency. The vegetations are generally located on the atrial side of the mitral valve and the arterial side of the aortic valve; they are usually immobile. Over time, the lesions may either resolve or worsen, and fibrosis may cause retraction of the valve, causing insufficiency. Less commonly, the vegetations on the valve may occlude the orifice causing stenosis.[67] Valvulitis, with valve fenestrations and rapidly progressing dysfunction, may occur. There are descriptions of mitral and aortic valve replacement in patients with SLE.[68] Valve repair has also been described.[69] Recurrence of valve disease, particularly thrombosis, may affect prosthetic valves. The nonbacterial vegetations rarely embolize and cause stroke syndromes. Several studies have demonstrated an increased prevalence of cardiac valve dysfunction in the presence of APLA, with or without SLE.[70] Because vegetations may occur in APLA-negative patients with SLE,[71] there appear to be multiple mechanisms that affect heart valves in lupus patients. Because of the high prevalence of valvular abnormalities in SLE patients, these patients should receive consideration for antibiotic prophylaxis for endocarditis. However, at present no adequate studies to evaluate this intervention have been performed.

Pulmonary artery hypertension is common in patients with SLE as assessed noninvasively.[72] Clinically significant pulmonary hypertension is less common. Causes for development of pulmonary hypertension include thromboembolic disease due to APLA, intimal proliferation of the pulmonary artery, chronic vasospastic disease associated with peripheral Raynaud disease, and, very rarely, arteritis of the pulmonary vessels. Successful heart-lung transplantation has been reported in a patient with SLE and progressive pulmonary hypertension.[73] Aortitis rarely occurs in patients with SLE.[74]

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (APLAS) is defined as the presence of either APLA or a lupus anticoagulant *and* a history of otherwise unexplained recurrent venous or arterial thrombosis, or frequent second- or third-trimester miscarriages. Mild thrombocytopenia and livedo reticularis are also common. APLAs are quite common in patients with SLE, although not all of these patients will exhibit the clinical syndrome. Low to moderate levels of APLA can also be found in association with a number of infectious and other autoimmune diseases, usually without clinical consequence. In the absence of another systemic disease, APLAS is termed *primary.*

Primary APLAS is not associated with pericarditis, myocarditis, or conduction disease. Cardiac manifestations include thrombotic CAD, intracardiac thrombi,[75] and nonbacterial endocarditis.[76] Heart valve abnormalities can be found in approximately 30 percent of patients with primary APLAS. Valvular involvement can include thrombotic masses extending from the valve ring or leaflets, vegetations, or thickening. The mitral valve is affected more frequently than aortic valve; regurgitation is far more common than stenosis. Most valvular involvement is clinically silent. The first manifestation of valvular involvement with APLAS may be a thromboembolic event such as stroke. The incidence of superimposed bacterial endocarditis is not known.

Thrombosis in the setting of APLAs is treated with full-dose anticoagulation with warfarin (Coumadin) using a target international normalized ratio of 3.0. Treatment of clinically significant valvular or intracardiac masses is high-dose anticoagulation with warfarin,[77] with or without the addition of aspirin. Patients likely can also be treated with full therapeutic doses of heparin. Management of heparin dosing, in the setting of a lupus anticoagulant that prolongs the baseline PTT, may require consultation with the coagulation laboratory.[78] The lack of prospective controlled trials with matched patients precludes making any firm recommendations about the long- and short-term utility of adding acetylsalicylic acid to either anticoagulation regimen, although this is often done in patients with recurrent thrombosis despite anticoagulation. Treatment needs to be tailored to the unique clinical circumstances that are present in each patient. There are no data to direct decisions regarding anticoagulation in the setting of APLAS and valvular disease, without thrombosis. Vegetations may resolve with anticoagulation therapy over several months.[79] Patients with APLAS are at risk for myocardial infarction and reocclusion after angioplasty or bypass grafting. Aggressive prophylactic anticoagulation should be employed perioperatively in patients with APLAS and previous thrombosis.[80] Pulmonary hypertension can occur in patients with APLAS secondary to chronic thromboembolic disease. It has also been proposed that APLAs can directly stimulate pulmonary artery intimal proliferation.

Scleroderma

Scleroderma (progressive systemic sclerosis [PSS]/CREST syndrome) and its variants are characterized by the presence

of microvascular disease and various patterns of cutaneous and parenchymal fibrosis; antinuclear antibodies are present in more than 90 percent of patients. Generalized scleroderma (PSS) includes proximal cutaneous fibrosis; Raynaud phenomenon, which occurs in 90 percent of patients and is often severe; gastrointestinal dysmotility; pulmonary fibrosis; and cardiac disease. These patients are at risk to develop scleroderma renal crisis.[81] Most of the manifestations of scleroderma are due to fibrosis, not to acute inflammation. Corticosteroids are not the mainstay of treatment.

The more limited CREST variant includes calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia. Patients with CREST syndrome may develop isolated pulmonary hypertension and cardiac conduction disease, but they are not prone to pulmonary fibrosis or renal crisis.

Pericardial involvement is common in scleroderma and includes fibrinous pericarditis in up to 70 percent of patients at autopsy (see also Chap. 50) .[82] Small pericardial effusions are demonstrated at echocardiography in 40 percent or less of patients. Acute pericarditis syndromes, including significant effusions, also occur.[83] The presence of moderate or large pericardial effusions is an independent risk factor for mortality.[84] Pericarditis with effusions may require corticosteroid therapy, but there is concern over the risk of inducing scleroderma renal crisis with the use of corticosteroids.

Necropsy and endomyocardial biopsy demonstrate the presence of patchy myocardial fibrosis, occasionally with contraction band necrosis. The latter finding has been attributed to intermittent and intense ischemia produced by microvascular occlusion, perhaps due to vasospasm.[85] Extramural coronary arteries are generally normal. However, approximately 80 percent of PSS and 65 percent of CREST patients have fixed perfusion defects on thallium imaging.[86] Myocardial infarctions have been documented in PSS patients with angiographically normal coronary arteries.[85] Ventricular conduction abnormalities are common and, along with a septal pseudoinfarct pattern, correlate with reduced myocardial function with exercise.[87] Electrical abnormalities can be found throughout the conduction system, and ventricular ectopy is present in more than 60 percent of patients. Patients with scleroderma, especially those with a history of palpitations or syncope, are prone to sudden death, a risk that is further increased in patients with coexistent skeletal myositis.[88] Primary valvular disease is not common. Renal crisis may be associated with variable degree of hypertension, rapidly rising creatinine levels, microangiopathy, and left ventricular failure. Treatment is with angiotensin-converting enzyme inhibitors, not corticosteroids.

Pulmonary hypertension is a major clinical problem that occurs in both limited scleroderma and PSS. In PSS, it may be due to intrinsic pulmonary artery disease or be secondary to interstitial fibrosis.[89] Patients with CREST and PSS should have periodic echocardiograms to screen for asymptomatic pulmonary hypertension, [90] which may respond to vasodilator therapy.[91]

Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are characterized by inflammation and resultant weakness of proximal greater than distal skeletal muscles; both can be associated with fever and interstitial lung disease. Respiratory muscles may be involved in severe cases. Other visceral organ involvement is uncommon in adults. Dermatomyositis has characteristic skin lesions that include extensor tendon erythema; Gottron papules overlying knuckles, elbows, and knees; edema of the eyelids; and a photosensitive diffuse papular eruption with scale. In a minority of cases, dermatomyositis may be a paraneoplastic syndrome. Both polymyositis and dermatomyositis are associated with progressive proximal muscle weakness. Acute disease may be associated with intense myalgia as well as weakness.

Although pericarditis is uncommon, it can be seen when polymyositis occurs as part of an overlap syndrome with other autoimmune diseases such as SLE or PSS (see also Chap. 50) . Coronary arteritis and ischemic CAD would be rare as part of these syndromes. Localized or generalized myocardial dysfunction is common by echocardiographic assessment but infrequently causes clinical failure.[92] The cardiomyopathy may be corticosteroid responsive. Corticosteroid myopathy generally affects skeletal, but not respiratory or cardiac, muscle.

Polymyositis and dermatomyositis frequently affect the conduction system. In an electrocardiographic study of 77 patients, 23 percent had conduction block,[93] which can occur in the absence of cardiomyopathy and may be progressive. Pulmonary hypertension can occur but is usually secondary to interstitial lung disease.

Sarcoidosis (See also Chap. 48)

Sarcoidosis is a granulomatous inflammatory disease of unknown etiology that primarily affects the lung parenchyma. It can also cause significant adenopathy, arthropathy, myositis, fever, and renal, liver, skin, and cardiac disease.

Pericarditis has been frequently described, and necropsy studies have documented cardiac involvement in 27 percent of patients.[94] This granulomatous, infiltrative disease of the myocardium is often

Figure 67-6 Sarcoid vasculitis. Aortogram from a 20-year-old African-American male who presented with chronic polyarthritis, uveitis, Bell palsy, and upper extremity claudication. He has had occlusion of both the subclavian and innominate vessels, which led to claudication, and also has aneurysmal dilatation of the entire aorta.

TABLE 67-4 -- RELATIVE FREQUENCIES OF CARDIAC INVOLVEMENT IN SELECTED SYSTEMIC AUTOIMMUNE DISORDERS

+=reported; ++=rare; +++=well described; ++++=frequently reported.

*Congenital complete heart block.

asymptomatic, but it can cause arrhythmias, conduction disease, and, rarely, otherwise unexplained congestive heart failure.[95] Granulomatous infiltration may be patchy, and there is a predilection toward involvement of the left ventricle, particularly the upper septal area. This distribution may influence the results of diagnostic right-sided endomyocardial biopsy. Use of gallium imaging may be helpful in determining the need and duration of immunosuppressive therapy.[96] Sarcoid dilated cardiomyopathy may be difficult to distinguish from idiopathic cardiomyopathy or giant cell myocarditis. Conduction disease is more common in patients with sarcoidosis,[97] and thallium perfusion defects tend to preferentially affect the anterior septal and apical regions. Biopsy may help to distinguish sarcoidosis from giant cell myocarditis,[98] but the diagnostic yield of endomyocardial biopsy is low.[99] Sarcoidosis is at least somewhat steroid responsive. Pulmonary artery hypertension can occur in sarcoidosis, generally as a result of pulmonary fibrosis.

Systemic vasculitis is an uncommon complication of sarcoidosis. Its precise frequency remains unknown. Sarcoid vasculitis can affect small- to large-caliber vessels, including the aorta. The latter presentation can be easily confused with Takayasu arteritis (Figure 67-6) . African-American patients appear predisposed to the development of large vessel involvement. Although corticosteroid therapy may be palliative for all forms of sarcoid vasculitis, relapses of the disease are common and often preclude withdrawal of treatment. Morbidity from disease and treatment is common. Deaths from sarcoid vasculitis occur in a minority of reported cases.[100]

Summary

The different rheumatic diseases can affect the heart in distinct patterns (Table 67-4) . Occasionally, cardiac involvement represents the initial manifestation of a systemic autoimmune disease. The clinical pattern of involvement may provide a clue as to the underlying diagnosis. Cardiologists will encounter patients with these diseases and their cardiac and extracardiac complications and should remain vigilant to recognize these patterns when they occur.

Chapter 68 - Cardiovascular Abnormalities in HIV-Infected Individuals

STACY D. FISHER
STEVEN E. LIPSHULTZ

Infection with the human immunodeficiency virus (HIV) is one of the leading causes of acquired heart disease and specifically of symptomatic heart failure (Table 68-1) . The cardiac complications of HIV infection tend to occur late in the disease and are therefore becoming more prevalent in our society as therapy and longevity improve. Mean annual incidence is estimated at 15.9 cases of cardiac disease per 1000 HIV-infected patients.[1]

The Joint United Nations Program on HIV/AIDS estimated that, worldwide, 33.4 million people were living with HIV infection or acquired immunodeficiency syndrome (AIDS) in 1998.[2] The incidence of new HIV infection in the United States has decreased substantially over the past 5 years. Deaths related to HIV infection decreased 42 percent in 1996-1997 and 20 percent in 1997-1998 because of improved antiretroviral therapies and better identification and treatment of opportunistic infections. By the end of 1998, about 300,000 people in the United States were living with AIDS and the number of long-term survivors was increasing.[3] Early in the epidemic, HIV infections were chiefly found in homosexual males; however, now most new cases occur in injection drug users and heterosexual partners of infected persons. Minority groups are overrepresented.[3]

The range of cardiac abnormalities caused by HIV infection is suggested in one recent autopsy study of 440 patients. Eighty-two had cardiac involvement: the conditions, in order of frequency, were pericardial effusion, lymphocytic interstitial myocarditis, dilated cardiomyopathy (frequently with myocarditis), infective endocarditis, and malignancy (myocardial Kaposi's sarcoma and B-cell immunoblastic lymphoma).[4]

Left Ventricular Systolic Dysfunction

CLINICAL PRESENTATION.

In HIV-infected patients, concurrent pulmonary infections, pulmonary hypertension, anemia, portal hypertension, malnutrition, or malignancy may alter or confuse the characteristic signs that define heart failure in other populations. Thus, patients with left ventricular systolic dysfunction may be asymptomatic or may present with New York Heart Association Class III or IV heart failure.

Echocardiography is a useful test to assess left ventricular systolic function in this population and, in addition to left ventricular dysfunction, often reveals either low-tonormal wall thickness or left ventricular hypertrophy and a dilated left ventricular chamber. Electrocardiography (ECG) may reveal nonspecific conduction defects or repolarization changes. In one multicenter trial, 57 percent of asymptomatic HIV-infected individuals had baseline ECG abnormalities, including supraventricular and ventricular ectopic beats.[5] The chest radiograph has low sensitivity and specificity for congestive heart failure in patients with HIV infection.

Encephalopathy is associated with symptomatic heart failure in HIV-infected individuals, suggesting that it may be comorbid with cardiac dysfunction in late-stage HIV infection.[6]

INCIDENCE.

One prospective study of asymptomatic HIV-infected adults with initial CD4 counts of more than 400 cells/ml found that 76 of 952 (8 percent) had significant left ventricular dysfunction (diffuse left ventricular hypokinesis with an ejection fraction less than 45 percent and left ventricular end-diastolic volume index greater than 80 ml/m[2]) over 60 months follow-up.[1] Almost all had fewer than 400 CD4-positive cells/ml at the time of diagnosis of cardiomyopathy. The mean annual incidence for asymptomatic patients was calculated at 15.9 cases of dilated cardiomyopathy per 1000 patients. Cardiomyopathy was diagnosed 28 ± 10 (mean standard deviation) months after enrollment.[1]

A 4-year observational study of 296 patients with a spectrum of HIV-related disease found 44 (15 percent) with dilated cardiomyopathy (fractional shortening less than 28 percent, with global left ventricular hypokinesis), 13 (4 percent) patients with isolated right ventricular dysfunction (right ventricle larger than left ventricle on standard two-dimensional views), and 12 (4 percent) patients with borderline left ventricular dysfunction (left ventricular end-systolic diameter greater than 58 mm, but fractional shortening greater than 28 percent, or global dysfunction reported by one or two, but not all three observers) (Fig. 68-1) .[7] Dilated cardiomyopathy was strongly associated with a CD4 count of less than 100 cells/ml.[7]

Left ventricular dysfunction is a common consequence of HIV infection in children. In a study of 205 vertically (mother to child) HIV-infected children (enrolled at a median age of 22 months and followed with echocardiography every 4 to 6 months and ECG, Holter monitoring, and chest radiography every year), the prevalence of decreased left ventricular function (fractional shortening <28 percent)

TABLE 68-1 -- CARDIOVASCULAR ABNORMALITIES IN HIV-INFECTED PATIENTS

TYPE	POSSIBLE ETIOLOGIES AND ASSOCIATIONS	INCIDENCE
Dilated cardiomyopathy	Infectious	Estimated 15.9 patients/1000 asymptomatic HIV-infected persons[1]
	HIV documented in mycocytes	
	Toxoplasma gondii	
	Coxsackievirus group B	
	Epstein-Barr virus	
	Cytomegalovirus	

	Adenovirus	
	Autoimmune response to infection	
	Drug-related	
	Cocaine	
	Possibly nucleoside analogues

TABLE 68-1 -- CARDIOVASCULAR ABNORMALITIES IN HIV-INFECTED PATIENTS *Continued*

TYPE	POSSIBLE ETIOLOGIES AND ASSOCIATIONS	INCIDENCE
Nonbacterial thrombotic endocarditis (generally tricuspid valve)	Underlying valvular endothelial damage, vitamin C deficiency, valvular injury secondary to catheters or injected impurities (intravenous drug use), disseminated intravascular coagulation, hypercoagulable state, malnutrition, wasting, prolonged acquired immunodeficiency	Rare (<3-5%) incidence[29] [32]
Malignancy	Prolonged immunodeficiency, low CD4 count	1% incidence (3/440) [33]
(Kaposi's sarcoma, non-Hodgkin's lymphoma, leiomyosarcoma)	Viral Associations	
	Human herpesvirus-8	
	Epstein-Barr virus	
Isolated right ventricular and pulmonary disease	Recurrent bronchopulmonary infections, pulmonary arteritis, microvascular pulmonary emboli due to thrombus or drug injection	
Primary pulmonary hypertension	Plexogenic pulmonary arteriopathy Mediator release from endothelium	0.5% incidence[38]
Vasculitis		
Systemic necrotizing	Drug therapy (antibiotic and antiretroviral)	Case reports becoming more common
Hypersensitivity		
Henoch-Schonlein purpura		
Lymphomatoid granulomatosis		
Primary central nervous system angiitis		
Accelerated atherosclerosis		
Coronary artery disease	Protease inhibitor therapy, atherogenesis by virus-infected macrophages, chronic inflammation	Up to 8% prevalence by autopsy and case reports[42] [44]
Cerebrovascular disease		
Autonomic dysfunction	Associated nervous system disease	Common in late-stage disease[47]
	Drug therapy side effects Prolonged immunodeficiency Malnutrition	
Arrhythmias	Drug therapy	Unknown
	Pentamidine Autonomic dysfunction	

was 5.7 percent. The 2-year cumulative incidence was 15.3 percent.[8] The cumulative incidence of symptomatic congestive heart failure and/or the use of cardiac medications was 10 percent over 2 years.[8]

Global estimates of HIV-infected people range from 33.4 to 120 million people worldwide between the years 1998 and 2000.[2] If there is a 10 percent incidence of symptomatic congestive heart failure over the 2 years,[8] then there would be 3.34 to 12 million cases of congestive heart failure during a 2-year interval.

PATHOGENESIS.

A wide variety of possible etiological agents have been postulated in HIV-related cardiomyopathy (see Table 68-1) , including myocardial infection with HIV itself, opportunistic infections, viral infections, autoimmune response to viral infection, cardiotoxicity from therapeutic or illicit drugs, nutritional deficiencies, cytokine overexpression, and many others.[9]

Myocarditis (see Chap. 48) .

Myocarditis is perhaps the best studied of the possible causes. Dilated cardiomyopathy may be related to a direct action of HIV on the myocardial tissue or to an autoimmune process induced by HIV alone or in conjunction with co-infecting viruses.[1] , [9A] *Toxoplasma gondii,* coxsackievirus group B, Epstein-Barr virus, cytomegalovirus, adenovirus, and HIV in myocytes have been found in biopsy specimens.[10] Postmortem biopsy samples of children with HIV revealed histological evidence of myocarditis in 11 of 32 and borderline myocarditis in another 13 cases, possibly relating to the development of cardiomyopathy and to rapid progression of HIV disease.[10A]

Right ventricular biopsy performed on 76 patients within 1 month of the diagnosis of cardiomyopathy revealed evidence of myocarditis in 63, HIV nucleic acid sequences in cardiac myocytes in 58, and active myocarditis in 36.[1] In the 36 patients with active myocarditis, 9 had coexisting viral infections (coxsackievirus group B [n=6], cytomegalovirus [n=2], or Epstein-Barr virus [n=1]).[1]

Autopsy and biopsy results have revealed only scant and patchy inflammatory cell infiltrates in the myocardium.[11] HIV virions appear to infect myocardiocytes in patchy distributions. The infected cells are not surrounded by an inflammatory response, and no clear association has been made between the infection and functional disability. Nevertheless, myocardial biopsy may be clinically helpful, because it may reveal lymphocytic infiltrates suggesting myocarditis or treatable opportunistic infections (by special stains), permitting aggressive therapy for an underlying pathogen.

Notably, HIV-related cardiomyopathy is often not associated with any specific opportunistic infection, and approximately 40 percent of patients have not experienced any opportunistic infection before the onset of cardiac symptoms.[12]

Cytokine Alterations.

HIV infection increases the production of tumor necrosis factor-alpha, which alters intracellular calcium homeostasis and increases nitric oxide (NO) production, tumor growth factor-beta, and endothelin-1 upregulation.[12] [13] NO induced in high levels has been shown experimentally to have a negative inotropic effect and to be cytotoxic to myocytes.

In one study, HIV-infected individuals with dilated cardiomyopathy were much more likely to have myocarditis, and had a broader spectrum of viral infections, than did HIV-negative patients with idiopathic dilated cardiomyopathy.[14] Also, levels of tumor necrosis factor-alpha and induced NO synthase were higher in myocytes from the HIV-infected patients with dilated cardiomyopathy (particularly those with viral co-infections) and levels varied inversely with the CD4 count. Barbaro and associates postulate that immunodeficiency may favor the selection of viral variants of increased pathogenicity or enhance the cardiovirulence of viral strains.[14]

Nutritional Deficiencies.

Nutritional deficiencies are

Figure 68-1 *Top,* Survival curves for 296 HIV-infected patients with structurally normal hearts, dilated cardiomyopathy (DCM), left ventricular dysfunction (LVD), or right ventricular dysfunction (RVD). *Bottom,* Time to death related to AIDS in 81 patients with CD4+ cell counts less than $20\times10^{[6]}$ cells per liter. (From Currie PF, Jacob AJ, Foreman AR, et al: Heart muscle disease related to HIV infection: Prognostic implications. BMJ 309:1605, 1994.)

common in HIV infection, particularly in late-stage disease. Poor absorption and diarrhea both lead to electrolyte imbalances and deficiencies in elemental nutrients. Deficiencies of trace elements have been associated with cardiomyopathy. For example, selenium deficiency increases the virulence of coxsackievirus to cardiac tissue.[15] Selenium replacement reverses cardiomyopathy and restores left ventricular function in nutritionally deplete patients. Levels of vitamin B_{12} , carnitine, and growth and thyroid hormone may also be altered in HIV disease; all have been associated with left ventricular dysfunction.

Pathogenesis in Children.

In children with vertically transmitted HIV infection, two mechanisms of pathogenesis have been described. One is the dilation of the left ventricle with a reduction in thickness-to-end-systolic dimension ratio of the ventricle. The other is concentric hypertrophy of the muscle; with dilation, the thickness-to-end-systolic dimension ratio remains normal or is increased.[6]

COURSE OF DISEASE.

Patients with asymptomatic left ventricular dysfunction (fractional shortening less than 28 percent, with global left ventricular hypokinesis) may have transient disease by echocardiographic criteria. In one serial echocardiographic study, three of six patients with abnormal fractional shortening had normal readings after a mean of 9 months. The three with persistently depressed left ventricular function died within 1 year of baseline.[16]

Prognosis.

Mortality in HIV-infected patients with cardiomyopathy is increased independent of CD4 count, age, sex, and risk group. The median survival to AIDS-related death was 101 days in patients with left ventricular dysfunction and 472 days in patients with a normal heart, at similar infection stage (see Fig. 68-1) . [7] Isolated right ventricular dysfunction or borderline left ventricular dysfunction did not place patients at risk. Compared with idiopathic cardiomyopathy, patients with HIV-related cardiomyopathy had a hazard ratio of 4.0 (95% confidence interval 2.80-5.74) for death over a mean follow-up period of 4.4 years.[16A]

In the P[2] C[2] HIV study of children with vertically transmitted HIV infection (median age, 2.1 years), 5-year cumulative survival was 64 percent.[17] Mortality was higher in children with baseline depressed left ventricular fractional shortening or increased left ventricular dimension, thickness, mass, wall stress, heart rate, or blood pressure (Fig. 68-2). Decreased left ventricular fractional shortening and increased wall thickness were also predictive of survival after adjustment for age, height, CD4 count, HIV RNA copy number, clinical center, and encephalopathy.[6] [17] Fractional shortening was abnormal for up to 3 years before death, whereas wall thickness identified a population at risk only 18 to 24 months before death. Thus, in children, fractional shortening may be a useful long-term predictor and wall thickness a useful short-term predictor of mortality.[18]

Rapid-onset congestive heart failure has a grim prognosis

Figure 68-2 Kaplan-Meier cumulative survival curves for 193 HIV-infected children according to baseline echocardiographic measurements after prospective follow-up. Patients are stratified by Z scores adjusted for age or body surface area for each measurement. *Left,* Fractional shortening. *Right,* Left ventricular mass. (Based on data from Lipshultz SE, Easley KA, Orav EJ, et al: Cardiac dysfunction and mortality in HIV-infected children: The prospective P[2] C[2] HIV multicenter study. Circulation, in press.)

in HIV-infected adults and children, with over half of patients dying of primary cardiac failure within 6 to 12 months of presentation.[6] [12] Chronic-onset heart failure may respond better to medical therapy in this patient population.[12]

Therapy

Therapy for dilated cardiomyopathy associated with HIV infection is generally similar to therapy for nonischemic cardiomyopathy and includes diuretics, digoxin, and angiotensin-converting enzyme inhibitors as tolerated. No studies have investigated the efficacy of specific cardiac therapeutic regimens other than intravenous immunoglobulin.[19] [20]

Opportunistic or other infections should be sought aggressively and treated, with potential to improve or resolve the cardiomyopathy.[21] Right ventricular biopsy may be useful in identifying infectious causes of heart failure to institute targeted therapy.[21] However, right ventricular biopsy is probably underused.

After medical therapy is begun, serial echocardiographic studies should be performed at 4-month intervals.[21] Monitoring recommendations for testing and timing of follow-up are based on studies relating impairment of fractional shortening to a worse prognosis.[21] If function continues to worsen or the clinical course deteriorates, a biopsy should be considered.

Intravenous immunoglobulins have had some success in acute congestive cardiomyopathy and nonspecific myocarditis in HIV-uninfected patients.[20] Immunoglobulin therapy is beneficial in Kawasaki disease, an immunologically mediated illness with cardiac dysfunction resembling that seen with HIV disease.[22] [23] Monthly immunoglobulin infusions in HIV-infected pediatric patients have been associated with minimized left ventricular dysfunction, an increase in left ventricular wall thickness, and a reduction in peak left ventricular wall stress (Fig. 68-3) , suggesting that both impaired myocardial growth and left ventricular dysfunction may be immunologically mediated.[18]

The apparent efficacy of immunoglobulin therapy may be the result of immunoglobulins removing cardiac autoantibodies

Figure 68-3 Mean echocardiographically measured cardiac dimensions in patients taking intravenous immunoglobulin (IVIG) and patients not taking it. All measurements are presented as age- or body surface area-adjusted Z scores. ED=end diastolic; ES=end systolic. (From Lipshultz SE, Orav EJ, Sanders SP, et al: Immunoglobulins and left ventricular structure and function in pediatric HIV infection. Circulation 92:2220, 1995. Copyright 1995, American Heart Association.)

or dampening the secretion or effects of cytokines and cellular growth factors. Immunomodulatory therapy may be helpful in special circumstances or in children with declining left ventricular function. A randomized, multicenter trial is warranted to evaluate the efficacy of this therapy.

Patients should be evaluated for nutritional status, and any with deficiencies should receive supplements. Supplementation with selenium, carnitine, multivitamins, or all three may be helpful, especially in anorexic patients or in those with wasting or diarrheal syndromes.

Animal Models

Chronic pathogenic simian immunodeficiency virus (SIV) infection in rhesus macaques resulted in significant depression of left ventricular ejection fraction and extensive coronary arteriopathy suggestive of a cell-mediated immune response.[24] Notably, two thirds of chronically infected macaques that died of SIV had myocardial pathology with lymphocytic myocarditis in 9 of 15 and coronary arteriopathy in 9 of 15 (6 alone and 3 in combination with myocarditis). Coronary arteriopathy was associated with evidence of vessel occlusion and recanalization, with associated areas of myocardial necrosis in 4 macaques. Two animals had marantic endocarditis, and 1 had a left ventricular mural thrombus on pathological examination. Macaques with cardiac pathology were emaciated to a greater extent than macaques with SIV and similar periods of infection who did not experience cardiac disease.[24]

Left Ventricular Diastolic Dysfunction

Clinical and echocardiographic findings suggest that diastolic dysfunction is relatively common in long-term survivors of HIV infection. Left ventricular diastolic dysfunction may precede systolic dysfunction.[25] One large multicenter echocardiographic study found that asymptomatic HIV-infected patients had 34.6 percent lower E/A ratio (Doppler-derived parameter of diastolic dysfunction: peak early [E] over peak atrial [A] velocity) and 19.7 percent longer isovolumetric relaxation time than healthy adults.[5]

Pericardial Effusion (see Chap. 50)

CLINICAL PRESENTATION.

HIV-infected patients with pericardial effusions generally have a lower CD4 count, marking more advanced disease, than those without effusions.[26] Effusions are generally asymptomatic.

INCIDENCE.

Asymptomatic pericardial effusions are common in HIV-infected patients.[16] [26] [27] The 5-year Prospective Evaluation of Cardiac Involvement in AIDS (PRECIA) study found that 16 of 231 patients (59 subjects with asymptomatic HIV, 62 with AIDS-related complex, and 74 with AIDS) developed pericardial effusions.[26] Three subjects had an effusion on enrollment, and 13 developed effusions during follow-up (12 of them had AIDS). Pericardial effusions were small (maximum pericardial space less than 10 mm at end diastole) in 80 percent and asymptomatic in 87 percent of patients with effusion. The incidence of pericardial effusion among those with AIDS was 11 percent per year.[26] The prevalence of effusion in AIDS patients rises over time, reaching a mean in asymptomatic patients of about 22 percent after 25 months of follow-up.[26]

HIV infection should be suspected whenever young patients have pericardial effusion or tamponade. In a retrospective series of cardiac tamponade cases in a city hospital, 13 of 37 patients (35 percent) had HIV infection.[28]

PATHOGENESIS.

Pericardial effusion may be related to an opportunistic infection or to malignancy (see Table 68-1) , but most often a clear etiology is not found. The effusion is often part of a generalized serous effusive process also involving pleural and peritoneal surfaces. This "capillary leak" syndrome may be related to enhanced cytokine production in the later stages of HIV disease. Other causes may include uremia from HIV-associated nephropathy or drug nephrotoxicity. Fibrinous pericarditis with or without effusion is also well described, comprising 9 percent of cardiac lesions found in AIDS patients in one autopsy series.[26]

COURSE OF DISEASE AND PROGNOSIS.

Effusion markedly increases mortality.[16] [26] [26A] For example, in the PRECIA study, it nearly tripled the risk of death among AIDS patients (Fig. 68-4) .[26] Also 2 of 16 patients with effusions developed pericardial tamponade. Pericardial effusion may, however, resolve spontaneously in up to 42 percent of patients.[16] [26] Mortality was still markedly increased in patients who had developed an effusion.[16] [26]

MONITORING AND THERAPY.

Screening echocardiography is recommended in HIV-infected individuals, regardless of the stage of disease. All HIV-infected patients with evidence of heart failure, Kaposi's sarcoma, tuberculosis, or other pulmonary infections should have baseline echocardiography, Holter monitoring, and ECG testing.[27] Patients should undergo pericardiocentesis if they have pericardial effusion and clinical signs of tamponade (e.g., elevated jugular venous pressure, dyspnea, hypotension, tachycardia, and pulsus paradoxus) or echocardiographic signs of tamponade (e.g., valvular inflow respiratory variation by continuous wave Doppler, septal bounce, right ventricular diastolic collapse) and a large effusion.

Patients with pericardial effusion without tamponade should be evaluated for treatable opportunistic infections such as tuberculosis and for malignancy. Highly active antiretroviral therapy should be considered if this has not already been instituted. Repeat echocardiography is recommended after 1 month, or sooner if clinical symptoms of tamponade develop in the interim.

Infective Endocarditis (See Chap. 47)

Injection drug users are at greater risk than the general population for infective endocarditis, chiefly of right-sided heart valves. Surprisingly, HIV-infected patients may not

Figure 68-4 Survival of patients with and without pericardial effusions at AIDS diagnosis. (From Heidenreich PA, Eisenberg MJ, Kee LL, et al: Pericardial effusion in AIDS: Incidence and survival. Circulation 92:3229, 1995. Copyright 1995, American Heart Association.)

have a higher incidence of endocarditis than people with similar risk behaviors.[29]

Because the autoimmune response to bacterial endocarditis is often largely responsible for valvular destruction associated with endocarditis, variations in the course of the disease in HIV-infected patients may occur. For example, HIV-infected patients have a higher risk of developing *Salmonella* endocarditis than immunocompetent patients because they are more likely to develop *Salmonella* bacteremia during *Salmonella* infection. However, they respond better to antibiotic therapy and may be less likely to sustain valvular damage because of their impaired immune response.[29] [30] [31]

Common organisms associated with endocarditis in HIV-infected patients include *Staphylococcus aureus* and *Salmonella* species.[29] [31] Fungal endocarditis with organisms such as *Aspergillus fumigatus, Candida* species, and *Cryptococcus neoformans* is more common in intravenous drug users with HIV than in those without it and, again, may be responsive to therapy (see Table 68-1) .[29]

Fulminant courses of infective endocarditis with high mortality may occur in patients with late-stage AIDS with poor nutritional status and severely compromised ability to fight infection, but several cases have been successfully treated with antibiotic therapy.[29] Operative indications in HIV-infected patients with endocarditis include hemodynamic instability, failure to sterilize cultures after appropriate intravenous antibiotics, and severe valvular destruction in patients with a reasonable life expectancy after recovery from surgery.

Nonbacterial Thrombotic Endocarditis

Nonbacterial thrombotic endocarditis (or marantic endocarditis) involves large friable sterile vegetations that form on the cardiac valves. These lesions have been

associated with disseminated intravascular coagulation and systemic embolization. Lesions are rarely diagnosed ante mortem; among patients who do receive the diagnosis, clinically relevant emboli occur in an estimated 42 percent of cases.[29] [32] In the early HIV epidemic, several case series suggested a high incidence of this uncommon disorder; however, very few cases have since been reported, and almost none have been found in prospective series. Marantic endocarditis should be suspected in any patient with systemic embolization; yet it should be considered rare in AIDS patients.

Treatment of nonbacterial thrombotic endocarditis should focus on reducing the underlying disease state causing coagulation abnormalities and/or valvular endothelial damage. Anticoagulation risk/benefit assessment must be made on an individual basis.

Cardiovascular Malignancy (See Chap. 49)

Malignancy affects many AIDS patients, generally in the later stages of disease. Cardiac malignancy is usually metastatic disease.

Kaposi's sarcoma (angiosarcoma) is associated with human herpesvirus-8 and affects up to 35 percent of AIDS patients, particularly homosexuals, with an incidence inversely related to the CD4 count. Autopsy found that 28 percent of HIV-infected patients with widespread Kaposi's sarcoma had cardiac involvement, and rarely described it as a primary cardiac tumor.[33] [34] An endothelial cell neoplasm with a predilection in the heart for subpericardial fat around the coronary arteries, Kaposi's sarcoma has not been found invading the coronary arteries.[33]

Kaposi's sarcoma involving the heart is generally an incidental finding at autopsy, rarely causing cardiac symptoms. Specific symptoms may be related to pericardial effusion associated with the epicardial location of the tumor. Pericardial fluid in patients with cardiac Kaposi's sarcoma is typically serosanguineous without malignant cells or infection.[33] Kaposi's sarcoma is difficult to treat. Most patients die of opportunistic infections related to the advanced stage of immunodeficiency, rather than from the malignancy.

Primary cardiac malignancy associated with HIV infection is generally due to cardiac lymphoma. Non-Hodgkin lymphomas are 25 to 60 times more common in HIV-infected individuals. They are the first manifestation of AIDS in up to 4 percent of new cases.[35] [36] Primary cardiac lymphoma may present as dyspnea, right-sided heart failure, biventricular failure, chest pain, or arrhythmias.[36] Cardiac lymphoma is associated with rapid progression to cardiac tamponade, symptoms of congestive heart failure, myocardial infarction, tachyarrhythmias, conduction abnormalities, or superior vena cava syndrome.[33] Pericardial fluid typically reveals malignant cells but may be histologically normal. Systemic multiagent chemotherapy with and without concomitant radiation or surgery has been beneficial in some patients, but overall the prognosis is poor.[33] [36]

Leiomyosarcoma, associated with Epstein-Barr virus, is a rare, malignant tumor of smooth muscle origin with an increased incidence in children with AIDS. Leiomyosarcomas are largely noncardiac and often involve the arterial wall.[33] An intracardiac mass in late-stage HIV infection is associated with a uniformly poor prognosis.

Isolated Right Ventricular Disease and Pulmonary Disease (See Chap. 54)

Isolated right ventricular hypertrophy with or without right ventricular dilation is relatively uncommon in HIV-infected individuals and is generally related to pulmonary disease that increases pulmonary vascular resistance. Possible causes include multiple bronchopulmonary infections, pulmonary arteritis from the immunological effects of HIV disease, or microvascular pulmonary emboli caused by thrombus or contaminants in injected drugs.[37]

Primary pulmonary hypertension has been described in a disproportionate number of HIV-infected individuals, primarily in case reports. Primary pulmonary hypertension is estimated to occur in about 0.5 percent of hospitalized AIDS patients.[38] In one series of 6 AIDS patients with pulmonary hypertension associated with right ventricular hypertrophy and failure, clinical findings included dyspnea on exertion, hypoxemia, restrictive lung disease with decreased diffusing lung capacity for carbon monoxide, and right ventricular hypertrophy on ECG.[38]

Plexogenic pulmonary arteriopathy was demonstrated on lung histology from 5 of 12 patients reported as having primary pulmonary hypertension and HIV infection.[39] All of these patients had clear lung fields on examination and chest radiograph and normal perfusion scans.

Pulmonary hypertension is often explained by lung infections, venous thromboembolism, or left ventricular dysfunction. Pulmonary hypertension found on screening echocardiography or right-sided heart catheterization warrants further examination for treatable pulmonary infections.

Primary pulmonary hypertension has been reported in HIV-infected patients without a history of thromboembolic disease, intravenous drug use, or pulmonary infections associated with HIV.[37] [38] [39] [40] One autopsy and one biopsy specimen revealed precapillary muscular pulmonary artery and arteriole medial hypertrophy, fibroelastosis, and eccentric

intimal fibrosis without direct viral infection of pulmonary artery cells.[40] This suggests mediator release from infected cells elsewhere. Primary pulmonary hypertension has also been found in hemophiliacs receiving lipophilized factor VIII, intravenous drug users, and patients with left ventricular dysfunction, obscuring any relationship with HIV.[37] It may be that HIV causes endothelial damage and mediator-related vasoconstriction of the pulmonary arteries.[16] [38] [40] Therapy includes anticoagulation (based on individual risk/benefit analysis) and vasodilator agents as tolerated.

Vasculitis

Vasculitis is being reported more often in HIV-infected patients.[40A] It should be suspected in patients with fever of unknown origin, unexplained multisystem disease, unexplained arthritis or myositis, glomerulonephritis, peripheral neuropathy (especially mononeuritis multiplex), or unexplained gastrointestinal, cardiac, or central nervous system ischemia. Many types of vasculitis have been described in HIV-infected patients (see Table 68-1) . [41] Successful immunomodulatory therapy, chiefly with systemic corticosteroid therapy, has been described.

Accelerated Atherosclerosis (See Chaps. 30 , 31 , and 32)

Accelerated atherosclerosis has been observed in young HIV-infected individuals without traditional coronary risk factors.[42] [43] [44] Significant coronary lesions were discovered at autopsy in 8 HIV-positive subjects aged 23 to 32 who died unexpectedly.[42] Cytomegalovirus was present in 2, and hepatitis B virus was found in 2. None of the 8 patients had evidence of cocaine use.

Premature cerebrovascular disease is common in AIDS patients. An 8 percent stroke prevalence in AIDS patients was estimated in an autopsy study in the 1980s.[45] Of the patients with stroke, 4 of 13 had evidence of cerebral emboli and 3 of those 4 had a clear cardiac source of embolus.

Protease inhibitor therapy significantly alters lipid metabolism and may be associated with premature atherosclerotic disease. Angiographically proven advanced symptomatic coronary artery disease has been reported in three men younger than age 40 treated with protease inhibitors.[46] Chronic inflammatory states have also been associated with premature atherosclerotic vascular disease.

Autonomic Dysfunction

Early clinical signs of autonomic dysfunction in HIV-infected patients include syncope and presyncope, diminished sweating, diarrhea, bladder dysfunction, and impotence. In one study, heart rate variability, Valsalva ratio, cold pressor testing, and hemodynamic responses to isometric exercise, tilt table testing, and standing showed that autonomic dysfunction occurred in patients with AIDS-related complex and was pronounced in AIDS patients. Patients with HIV-associated nervous system disease had the greatest abnormalities in autonomic function.[47] [47A]

Complications of Therapy for HIV

Potent antiretroviral medications and highly active antiretroviral therapy, which generally combines three or more agents and usually includes a protease inhibitor, have clearly increased the life span and quality of life of HIV-infected patients.[48] [49] [50] [51] However, protease inhibitors, particularly when used in combination therapy or in highly active antiretroviral therapy, are associated with lipodystrophy, fat wasting and redistribution, metabolic abnormalities, hyperlipidemia, insulin resistance, and

increased atherosclerotic risk profiles.[52] [53] [54] HIV-infected patients treated with protease inhibitors have reported substantial decreases in total body fat with peripheral lipodystrophy (fat wasting of the face, limbs, and buttocks) and relative conservation or enhancement of central adiposity (truncal obesity, breast enlargement, and "buffalo hump") compared with patients who have not received protease inhibitors.[54] Lipid alterations associated with protease inhibitors include higher triglyceride, total cholesterol, insulin, lipoprotein(a) and C-peptide levels, and lower high-density lipoprotein levels (all promoting an atherogenic profile).[52] [53] [54] [54A] [54B] Flow-dependent vasodilation measured in the brachial artery by venous occlusion plethysmography was impaired in HIV-infected patients taking protease inhibitors.[54A]

Lipid abnormalities vary with different protease inhibitors.[53] Ritonavir had the largest adverse effects on lipids, with a mean increase in total cholesterol of 2.0 mmol/liter and a mean increase in triglyceride level of 1.83 mmol/liter. More modest increases of total cholesterol without significant triglyceride increases were found in patients taking indinavir and nelfinavir. Combination with saquinavir did not further elevate the total cholesterol. Protease inhibitor therapy increased lipoprotein(a) by 48 percent in patients with pretreatment elevated values (>20 mg/dL).[53] In some cases, switching protease inhibitors can reverse both elevations in triglyceride levels and abnormal fat deposition. At this time, increased coronary artery disease secondary to protease inhibitor related dyslipidemia has not been shown.[54C] [54D]

Zidovudine (azidothymidine) has been implicated in skeletal muscle myopathies.[55] [56] In culture, zidovudine causes a dose-dependent destruction of human myotubes.[56] Human-cultured cardiac muscle cells treated with zidovudine develop mitochondrial abnormalities.[56] However, cardiac myopathies have not been evident in clinical data. In a combined retrospective and prospective analysis, both HIV-infected and HIV-negative children born to HIV-infected women and exposed to zidovudine in utero were not more likely to have abnormal left ventricular structure and function than children who were not exposed to zidovudine.[56B] Rare patients with left ventricular dysfunction, however, have improved with cessation of zidovudine therapy and normal troponin T levels have been measured in some of these patients.[56A]

A transgenic versus wild-type mouse model demonstrated cardiomyopathy by HIV infection alone that is enhanced by zidovudine therapy. Zidovudine-treated mice had mitochondrial ultrastructural damage in cardiac myocytes.[57]

Intravenous pentamidine, used to treat *Pneumocystis carinii* pneumonia in patients intolerant of trimethoprim/sulfamethoxazole, has been associated with cases of torsades de pointes and refractory ventricular tachycardia.[21] [58] [59] Recommendations for the use of intravenous pentamidine are outlined in Figure 68-5 (Figure Not Available) .

Multiple medication reactions and interactions have occurred during the treatment of HIV infection and are a significant cause of cardiac emergencies in HIV-infected patients. Common cardiac drug interactions are outlined in Table 68-2 .

Perinatal Transmission and Vertically Transmitted HIV Infection

Most pediatric patients with HIV are infected in the perinatal period, but HIV transmission can be minimized if mothers

Figure 68-5 (Figure Not Available) Recommendations for HIV-infected patients starting intravenous pentamidine treatment. (From Moorthy LN, Lipshultz SE: Cardiovascular monitoring of HIV-infected patients. *In* Lipshultz SE [ed]: Cardiology in AIDS. New York, Chapman & Hall, 1998, p 345. Data based on Eisenhauer MD, Eliasson AH, Taylor AJ, et al: Incidence of cardiac arrhythmias during intravenous pentamidine therapy in HIV-infected patients. Chest 105:389, 1994.)

are given courses of zidovudine in the second and third trimesters or short courses before parturition.[60] [61] [62] [63] [64] [65] [66] [67]

Rates of congenital cardiovascular malformations in cohorts of HIV-uninfected and HIV-infected children born to HIV-infected mothers ranged from 5.6 to 8.9 percent. These rates were 5 to 10 times higher than reported in population-based epidemiological studies but not higher than in normal populations similarly screened.[68]

In the same cohorts, serial echocardiograms performed at 4- to 6-month intervals found subclinical cardiac abnormalities to be common, persistent, and often progressive.[6] [68A] Some had dilated cardiomyopathy (left ventricular contractility 2 standard deviations or more below the normal mean and left ventricular end-diastolic dimension 2 standard deviations above the mean or more) and inappropriate left ventricular hypertrophy (elevated left ventricular mass in the setting of decreased height and weight). Depressed left ventricular function correlated with immune dysfunction at baseline but not longitudinally, suggesting that the CD4 cell count may not be a useful surrogate marker of HIV-associated left ventricular dysfunction. The development of encephalopathy was highly correlated with a decline in fractional shortening.

In children with vertically transmitted HIV-1 infection, disease may progress rapidly or slowly.[69] Rapid progressors have higher heart rates, higher respiratory rates, and lower fractional shortening on serial examinations than nonrapid progressors and HIV-uninfected children similarly screened. Rapid progressors have higher 5-year cumulative mortality, higher HIV-1 viral loads, and lower CD8+ (cytotoxic) T cell counts than nonrapid progressors.[69] Knowing the patterns of disease allows more aggressive therapy to be initiated earlier in rapid progressors.

Monitoring Recommendations

Routine, systematic cardiac evaluation including a comprehensive history and thorough cardiac examination is essential for the care of HIV-infected adults and children. Asymptomatic cardiac disease may be fatal, and cardiac symptoms are often confounded by secondary effects of HIV-infection; thus, systematic echocardiographic monitoring is warranted.

HIV-infected individuals without cardiac symptoms should undergo annual echocardiography and should have Holter monitoring and ECG every 2 years.[21] Patients with serious noncardiac illness should undergo echocardiography, ECG, and Holter monitoring followed by echocardiography every 8 months and ECG and Holter monitoring every year.[21] Patients with cardiac symptoms should have a formal cardiac assessment including baseline echocardiography, ECG, and Holter monitoring and should begin directed therapy.[21] Recommendations for Holter monitoring are based on studies illustrating the frequency of high-grade arrhythmias and abnormal conduction patterns. Holter monitoring recommendations have not been tested and are a suggestion based on available data.

In patients with left ventricular dysfunction, serum troponin assays are indicated. Serum troponin elevations warrant consideration of cardiac catheterization and endomyocardial biopsy. Myocarditis proven by biopsy warrants considering therapy with intravenous immunoglobulin. Cytomegalovirus inclusions on the biopsy specimen warrant antiviral therapy, and abnormal mitochondria should encourage consideration of a "drug holiday" from zidovudine. Ultrasound examination should be repeated after 2 weeks of therapy to allow a more aggressive approach if left ventricular dysfunction persists or worsens and to encourage continued therapy if improvement has occurred.[21]

Conclusions

The longer HIV-infected patients live and the more advanced their disease, the higher the risk of cardiac complications.[1] [4] [68] An epidemic number of HIV-infected individuals will present with cardiac complications in the next decade as long-term viral infection, co-infections, drug therapy, and immunosuppression take a toll on the heart. The impact that highly active antiretroviral therapy will have on the incidence and prevalence of cardiac complications in HIV-infected patients is unknown. Early screening and therapy of HIV-infected patients, regardless of the stage of disease, will identify the potentially fatal complications of HIV disease and therapy and allow them to be treated.

TABLE 68-2 -- CARDIOVASCULAR ACTIONS/INTERACTIONS OF DRUGS COMMONLY USED IN HIV THERAPY

CLASS	DRUGS	CARDIAC DRUG INTERACTIONS	CARDIAC SIDE EFFECTS
Antiretroviral			

Nucleoside reverse transcriptase inhibitors	Abacavir (Ziagen) Didanosine (ddl, Videx) Lamivudine (3TC, Epivir) Stavudine (d4T, Zerit) Zalcitabine (ddC, Hivid)		Rare--lactic acidosis Hypotension with abacavir
	Zidovudine (AZT, Retrovir)	Dipyridamole	Skeletal muscle myopathy with Zidovudine
Nonnucleoside reverse transcriptase inhibitors	Delavirdine (Rescriptor)	Calcium channel blockers, warfarin	
	Efavirenz (Sustiva)	Warfarin	
	Nevirapine (Viramune)	Beta blockers, nifedipine, quinidine, steroids, theophylline. May decrease effects of warfarin.	
Protease inhibitors	Amprenavir (Agenerase) Indinavir (Crixivan) Nelfinavir (Viracept)	All are metabolized by cytochrome P-450 and interact with sildenafil, amiodarone, lidocaine, quinadine, warfarin, and "statins."	Implicated in premature atherosclerosis, dyslipidemia, insulin resistance, fat wasting and redistribution
	Ritonavir (Norvir) Saquinavir (Invirase, Fortovase)	Calcium channel blockers, prednisone, quinine; increases beta blocker levels 1.5-3 ×; warfarin may increase levels three times	
Antiinfective			
Antibiotics	Erythromycin	Cytochrome P-450 metabolism and drug interactions	Orthostatic hypotension, ventricular tachycardia, bradycardia, torsades (with drug interactions)
	Trimethoprim-sulfamethoxazole (Bactrim)	Increases warfarin effects	Orthostatic hypotension, anaphylaxis
Antifungal agents	Amphotericin B	Digoxin toxicity	Hypertension, arrhythmia, renal failure, hypokalemia, thrombophlebitis, angioedema
	Ketoconazole Itraconazole (Sporanox)	Cytochrome P-450 metabolism and drug interactions; increases levels of sildenafil, warfarin, "statins," nifedipine, and digoxin	
Antiviral agents	Foscarnet		Reversible cardiac failure, electrolyte abnormalities
	Ganciclovir	Zidovudine	Ventricular tachycardia, hypotension
Antiparasitic	Pentamidine (IV)		Hypotension, arrhythmias (torsades), ventricular tachycardia, hyperglycemia, hypoglycemia, sudden death
Chemotherapy agents			
	Vincristine	Decreases digoxin level	Arrhythmia, myocardial infarction, cardiomyopathy
	Interferon alfa		Orthostatic hypotension (only 1/26 non-HIV, common in HIV patients), myocardial infarction, cardiomyopathy, ventricular and supraventricular arrhythmias, atrioventricular block
	Interleukin-2		Hypotension, arrhythmia, sudden death, myocardial infarction, cardiac failure, capillary leak, thyroid alterations
	Doxorubicin (Adriamycin)	Decreases digoxin level	Myocarditis, cardiomyopathy, cardiac failure
Other			
Systemic corticosteroids	Decreases salicylate levels and increases gastric ulceration in combination with salicylates.		Ventricular hypertrophy, cardiomyopathy, hyperglycemia
Pentoxifylline			Decreased triglyceride levels, arrhythmias, chest pain
Growth hormone			Ventricular hypertrophy, activation of the renal angiotension system (hypertension)
Medroxyprogesterone (Megace)			Edema, thrombophlebitis, hyperglycemia

Chapter 69 - Hematological-Oncological Disorders and Cardiovascular Disease

RICHARD M. STONE
KENNETH R. BRIDGES
PETER LIBBY

A dialogue between cardiologists and hematologist-oncologists is often required in the care of patients with a variety of disorders encompassing both fields. Intrinsic cardiac disease in patients with neoplastic or benign hematological disorders affects the natural history of the underlying condition as well as the therapeutic possibilities. How primary hematological disorders can affect the cardiovascular system is illustrated by hypercoagulability due to cancer, bleeding, and/or anemia from bone marrow failure and also by hyperviscosity in polycythemia. Tumors that invade or involve the heart are not uncommon. These two disciplines also frequently intersect because of the generally negative effect of antineoplastic drugs on cardiac function. Such agents may have direct effects on the myocardium or act indirectly owing to chemotherapy-induced myelosuppression with associated sepsis.

IRON AND THE HEART

Iron metabolism and its derangements,[1] especially those associated with deficiency or excess, may have profound effects on the cardiovascular system. Iron-deficiency anemia has been the primary hematological problem faced by humans throughout history. In many parts of the world it continues to be a major scourge. Iron overload (Table 69-1) has become a problem only with advances in medical care that have prolonged life and with advances in medical technology that have made feasible repeated blood transfusions. Hereditary hemochromatosis, the best characterized genetic cause of iron overload, generally manifests after about the third decade of life. As late as 1890, the median life expectancy in Europe was only 40 years, meaning that most people with hereditary hemochromatosis died of other causes before developing complications of the disorder. The longer life spans that we currently enjoy have brought this condition to the forefront.

Transfusions are of equally recent advent. Medical researchers discovered blood antigens only at the beginning of the 20th century. Routine blood transfusion was not feasible until the 1940s. Before the 1960s when repeated transfusion therapy became widespread in the industrialized world, patients with chronic severe anemias, such as thalassemia major, succumbed largely to cardiac complications of the anemia.

Iron overload has relatively uniform manifestations, irrespective of cause. Cardiac dysfunction is a primary cause of death in people with iron overload. The heart does not accumulate iron disproportionately to the other organs. The key to the heart's central role in the pathology of iron overload lies in the need for the complex array of cells and structures in the heart to function coordinately. Half of the liver for instance can be lost to fibrosis or cirrhosis, and a person can still survive. Obviously, this is not true of the heart.

ETIOLOGY OF IRON OVERLOAD.

Hereditary hemochromatosis results from a fractional increase in dietary iron absorption. Tissue iron reaches dangerous levels after 30 or 40 years. The gene responsible for hereditary hemochromatosis, *HFE,* resides on chromosome 6. Discovered in 1996, the gene encodes a protein that is homologous to Class I human leukocyte antigens. The alteration in HFE protein that produces hereditary hemochromatosis in 90 percent of those with the disease involves the mutation of a cysteine to tyrosine at position 282 (C282Y).[2] Individuals who have one copy of the mutant *HFE* gene are carriers who only rarely develop iron overload (usually in association with a second defect). People with two copies of the mutant allele

TABLE 69-1 -- CAUSES OF IRON OVERLOAD

I. Primary Hemochromatosis--genetically transmitted (autosomal recessive)
A. Men affected more than women
B. Alcohol increases iron absorption and worsens disease
II. Secondary Hemochromatosis--transfusion related
A. With intestinal hyperabsorption: thalassemias
B. Without intestinal hyperabsorption: bone marrow failure states
1. Aplastic anemia
2. Pure red cell aplasia
3. Myelodysplastic syndromes
4. Agnogenic myeloid metaplasia/myelofibrosis

Figure 69-1 *A,* The transferrin shuttle pathway. Iron is released from its transferrin-bound state in the circulation intracellularly in endosomes due to proton-pump-mediated acidic pH. The HFE protein, mutated in hemochromatosis, acts as a brake on iron internalization by binding to transferrin receptors. (From Andrews NC: Medical progress: Disorders of iron metabolism. N Engl J Med 341:1985-1986, 1999.) *B,* The transferrin receptor (TFR)-HFE complex. Wild-type HFE protein is associated with $beta_2$ -microglobulin and binds to TFR, decreasing transferrin binding *(left).* The C282 mutant HFE protein does not associate with $beta_2$ -microglobulin, allowing TFR free to bind transferrin *(center).* The H63D mutant HFE does associate with $beta_2$ -microglobin but fails to decrease TFR affinity for transferrin *(right).* (From Andrews NC, Levy JE: Iron is hot: An update on the pathophysiology of hemochromatosis. Blood 92:1845-1851, 1998.)

can develop iron overload, which engenders a vast array of clinical problems.

Only recently have investigators gained insight into the mechanism by which the mutation in *HFE* alters cellular iron metabolism. Iron in the circulation binds to transferrin, the protein that maintains it in a soluble, nontoxic state. The plasma membrane of cells contains transferrin receptors that mediate cellular iron uptake. Transferrin receptors bind iron-transferrin complexes and mediate their internalization through endosomes. Iron is separated from transferrin in the endosome and is

shuttled into the interior of the cell (Fig. 69-1 *A*). The iron-free transferrin (apotransferrin) recycles into the circulation and is free to bind and transport additional iron atoms. The HFE protein associates with transferrin receptors in the plasma membrane, thereby reducing transferrin binding to the receptor and slowing the internalization process.[3]

The cysteine 282 to tyrosine mutation C282Y disrupts the folding of the HFE protein. The mutant HFE protein does not associate with the transferrin receptor and does not act as a brake on iron uptake by cells (see Fig. 69-1 *B*).[4] These insights do not fully explain the increase in gastrointestinal iron absorption, which is the root of hereditary hemochromatosis. They do, however, mechanistically connect HFE and iron metabolism. Improved understanding of the complex process of intestinal iron absorption should provide a better pathophysiological explanation for the clinical manifestations of hereditary hemochromatosis.

Hereditary hemochromatosis is remarkably common. Ten to 12 percent of individuals of European background are heterozygous for the condition.[5] The incidence of homozygosity for the condition approaches 1 in 300,[6] making hereditary hemochromatosis one of the most prevalent genetic conditions in the world.[7] Nonetheless, the clinical incidence of the disorder is less than predicted by the genetic frequency calculations. Variable penetrance, perhaps related to secondary genetic or environmental conditions, must influence clinical manifestations. The C282Y mutation appears to be an uncommon cause of iron overload in people of African[8] or Asian origin.[9]

TRANSFUSIONAL IRON OVERLOAD.

A unit of blood (250 ml) contains about 225 mg of iron. Iron is an integral component of the heme moiety in hemoglobin and cannot be removed from the blood in that state. Reticuloendothelial cells destroy senescent red cells, primarily in the liver and spleen. The iron from the hemoglobin is not excreted but, rather, is used to make new red cells or placed in storage (primarily in hepatocytes).

Those with severe chronic anemias often require regular transfusions to survive. Patients with thalassemia major, a condition in which the genes encoding hemoglobin produce defective protein and consequently defective red cells, require up to 2 units of blood every 3 weeks to avoid the deadly consequences of their severe anemia.[10] Nearly all of

Figure 69-2 Reactive oxygen species derived from intracellular free iron by Fenton chemistry. (Courtesy of N. C. Andrews.)

the iron from the transfused red cells goes into storage and eventually produces severe iron overload. Therefore, the major problem confronting those patients is not anemia but organ damage from iron.[11] Inherited disorders, such as thalassemia major, or acquired conditions, such as myelodysplastic syndrome, can lead to transfusional iron overload. The redistribution of the excess iron to storage sites means that these patients suffer the same consequences as those with hereditary hemochromatosis.

MECHANISMS OF CARDIAC DAMAGE BY IRON OVERLOAD.

Iron deposition in the cardiac myocytes is the initial event in iron-mediated cardiac injury. Transferrin receptors on the cell surface mediate this process through the well-characterized transferrin cycle just described. Iron-saturated transferrin attaches to these receptors and releases iron to the interior of the cell. The excess iron is stored in association with the hemosiderin protein.

Iron that is stored in hemosiderin is innocuous.[12] This iron is in equilibrium, however, with a very small pool of so-called free iron in the cell. This pool of iron is so small that its precise size has eluded determination. Better termed loosely bound iron, this material catalyzes the formation of reactive oxygen species through Fenton chemistry (Fig. 69-2) . These reactive oxygen species can mediate cell injury.

Among the several reactive oxygen species promoted by iron overload, the most damaging is the hydroxyl radical.[13] [14] This molecule is extremely short-lived and yet highly active in its interaction with biological molecules.[15] Lipid peroxides, protein disulfide bridges, and DNA cross-linking are some of the consequences of iron-mediated generation of reactive oxygen species.[16]

Cardiac cells are particularly sensitive to oxidant-mediated injury because they must perform a number of complex functions, which include contraction and transmission of electrical impulses. With iron loading, cardiac cells in culture begin to fail, including loss of their characteristic pattern of beating. Desferrioxamine, a powerful iron chelator that binds iron in culture and prevents generation of reactive oxygen species by the Fenton reaction, can restore normal cellular activity.[17]

CLINICAL MANIFESTATIONS OF CARDIAC IRON OVERLOAD (see alsoChap. 40) .

Restrictive cardiomyopathy (Fig. 69-3) is the most common cardiac defect that occurs with iron overload, but other problems have been described, including pericarditis, restrictive cardiomyopathy, and angina without coronary artery disease. A strong correlation exists between the cumulative number of blood transfusions and functional cardiac derangements in patients with thalassemia.[18] Echocardiographic assessment of patients with beta-thalassemia major who receive concurrent chelation therapy with desferrioxamine shows no difference relative to controls in the fractional shortening.[19] A pronounced pattern of integrated backscatter of the interventricular septum and posterior wall is an important echocardiographic finding indicating iron deposition.

The physical examination reveals surprisingly little even in patients with heavy cardiac iron deposition. Once evidence of cardiac failure appears, however, heart function rapidly deteriorates, often resisting medical intervention. Biventricular failure produces pulmonary congestion, peripheral edema, and hepatic engorgement. This potentially lethal cardiac complication has been reversed on occasion by vigorous iron chelation.

Iron deposition in the bundle of His and the Purkinje system impairs signal conduction from the atrial pacemaker to the ventricles. Patients sometimes die suddenly, presumably due to arrhythmias. At one time, patients treated with the chelator desferrioxamine for transfusional iron overload received supplements of ascorbic acid in the range of 15 to 30 mg/kg/d to promote iron mobilization. Reports of sudden death prompted cessation of this practice. At lower doses (2 to 4 mg/kg), ascorbic acid is a safe adjunct to chelation therapy in patients with transfusional iron overload.

Echocardiography in children and radionuclide ventriculography in adults are the most useful noninvasive diagnostic techniques to detect iron-overload-induced cardiomyopathy. The echocardiographic abnormalities correlate roughly with the number of transfusions. Exercise radionuclide ventriculograms are particularly sensitive in the detection of cardiac dysfunction in patients with iron overload.

Treatment of Cardiac Iron Overload

The degree to which aggressive iron chelation therapy can reverse cardiac dysfunction has given rise to vigorous debate. A number of short-term studies suggested that chelation can restore function in patients with significant cardiac compromise.[20] More recently, investigators examined a cohort of patients with beta-thalassemia major who were

Figure 69-3 Consequences of cardiac hemochromatosis. Apical four-chamber views in diastole *(A)* and in systole *(B),* demonstrating moderate biventricular enlargement with markedly reduced systolic performance (ejection fraction, 18 percent). In addition, marked biatrial enlargement is noted. (From Passen EL, Rodriguez ER, Neumann A, et al: Cardiac hemochromatosis. Circulation 94:2302-2303, 1996. Copyright 1996, American Heart Association.)

transfused while receiving chelation therapy.[21] In this series only persistent plasma ferritin values of greater than 2500 ng/ml were associated with cardiac-related death. Another group of investigators recently reviewed the outcome of aggressive treatment of patients who had transfusional iron overload with associated cardiac dysfunction.[22] This group of 19 patients suffered from severe congestive heart failure and/or cardiac arrhythmias. The patients received intravenously administered

desferrioxamine on a 24-hour per day regimen. For routine iron chelation, most physicians administer the drug over 12- to 16-hour intervals. In addition to the aggressive iron chelation therapy, the investigators administered current conventional cardiac regimens.

The dramatic results revealed an increase in the mean ejection fraction of the patients with congestive heart failure from 30 to 50 percent. Arrhythmias were controlled, and no patient died suddenly. Sudden death occurs commonly in iron-overloaded patients, presumably resulting from malignant arrhythmias. The iron chelation regimens appeared to facilitate management of arrhythmias in this cohort. The plasma ferritin values exceeded 10,000 ng/ml in many of the patients at the onset of treatment. These values declined but never approached normal values (15-400 ng/ml in men).

Bone marrow transplantation now offers a potential cure for some patients with beta-thalassemia major.[23] [24] The correction of the underlying hemolytic anemia creates a clinical situation analogous to hereditary hemochromatosis: patients are iron-overloaded with normal hemoglobin values. Some investigators have taken advantage of this situation to use phlebotomy as a means of removing the iron that has accumulated over years of transfusion therapy, even in patients who continue on an iron-chelation regimen.[25] This strategy removes iron and improves cardiac function in most of these patients.[26]

The lessons from these reports are twofold. First, early iron chelation therapy prevents cardiac dysfunction in patients with transfusional iron overload. Second, congestive cardiomyopathy and arrhythmias in these patients are potentially reversible. Unlike the situation with ischemic cardiomyopathy, the cardiac myocytes have not been destroyed by the pathological events that produced the dysfunction. Iron overload injures myocytes by production of free radicals that interfere with their function. Until irreversible damage leading to cell death occurs, the injury can be halted and reversed by chelators that remove the iron, indirectly blocking production of free radicals. Aggressive intervention with cardiac support and chelation therapy is indicated in patients with iron-mediated cardiac dysfunction.

Iron as a Coronary Risk Factor

An important question concerning iron and the heart is whether body iron stores in the normal range increase susceptibility to myocardial infarction. A number of small anecdotal reports lie on either side of the issue and are uninformative. A study published in 1992 examined the relationship between plasma ferritin levels, a reasonable surrogate measure of body iron stores, and coronary artery disease in a cohort of about 2000 men in Finland.[27] The data indicated that elevated plasma ferritin levels increased the risk of acute myocardial infarction by over twofold. However, a variety of common problems including chronic inflammation and smoking can elevate the serum ferritin level. These investigators attempted to compensate for this factor by using a newer test, the plasma transferrin receptor assay, in a small sample of about 200 men.[28] Results of this smaller study agreed with those that the group reported in 1992.

Investigators from the first National Health and Nutrition Examination Survey Epidemiologic Follow-up Study (NHANES) also addressed the question, using a multivariate Cox proportional-hazards model.[29] Using transferrin saturation as an index of body iron stores, the researchers analyzed data on over 4500 people between the years of 1971 and 1987. They found no statistically significant relationship between transferrin saturation and coronary heart disease. Results of an epidemiological study involving about 2000 men in Iceland agreed with those of the NHANES report.[30] The issue of the role of body iron stores in the "normal" range in coronary artery disease remains open. The variable results in epidemiological studies from different countries suggests that iron plays a small role, if any, in this arena.

ANEMIA AND CARDIAC FUNCTION

The heart and blood comprise a single functional unit with two principal purposes: (1) to deliver oxygen and nutrients to peripheral tissues and (2) to remove metabolic waste products. The Fick principle states that cardiac output is proportional to oxygen consumption and the arteriovenous oxygen difference (Fig. 69-4) (Figure Not Available) . The level of hemoglobin in the blood is the primary determinant of arteriovenous oxygen difference. As the hemoglobin content falls (anemia), cardiac output increases to keep pace with tissue oxygen consumption. Cardiac output depends on the functional capacity of the heart. An important question then, is whether anemia *per se* compromises cardiac function.

One group of investigators examined the question by studying systolic and diastolic left ventricular function in patients with chronic severe anemia (hemoglobin levels of less than 7 gm/dl for more than 3 months). The assessments were done by M-mode, two-dimensional, and Doppler echocardiography.[31] In most instances, the anemia was due to iron deficiency, meaning no primary cardiac insult existed. The cardiac output was elevated as expected, owing to a higher stroke volume and heart rate. Left ventricular contractility was higher than normal, and no evidence existed of diastolic dysfunction. The investigators concluded that, in the absence of primary cardiac disease, anemia does not produce congestive heart failure, at least over the time span studied.

More severe anemia can, however, produce left ventricular dysfunction and circulatory congestion. A group of otherwise healthy children with hemoglobin levels of less than 6 gm/dl due to iron deficiency were also assessed by echocardiography.[32] Left ventricular preload was significantly higher, and left ventricular afterload was significantly lower in the patients relative to controls. Cardiac index was also significantly higher in the severely anemic patients. Iron supplementation eliminated the discrepancy. The interpretation of these results requires consideration that iron deficiency of this severity could impair synthesis of important heme-dependent enzymes, such as the cytochromes.

Figure 69-4 (Figure Not Available) The Fick principle: Cardiac output is proportional to oxygen consumption and the arteriovenous oxygen difference and the hemoglobin concentration. Compensation for hypoxia may be affected by an increase in cardiac output, an increase in erythropoietin production, or shift to the right in the oxygen dissociation curve due to blood pH-mediated increase in red blood cell 2,3-diphosphoglycerate. (From Bunn HF: Pathophysiology of the anemias. *In* Harrison's Principles of Internal Medicine. 13th ed. New York, McGraw-Hill, 1994, p 1720.)

Cardiac myocytes depend tremendously on these enzymes required for oxidative metabolism. Therefore, the cardiac dysfunction in these severely anemic patients could result in part from compromised myocardial metabolism. Nutritional deficiency that often accompanies very severe iron deficiency can also contribute to cardiac dysfunction.[33]

One way to avoid possible confounding due to secondary contributions of anemia, as might occur with severe iron deficiency, is to examine cardiac function in patients with genetically determined anemia. Investigators have carefully examined cardiac function in patients with thalassemia major. The presentation of these studies is complicated, because most people with thalassemia major have some degree of iron overload due to repeated transfusion (see earlier). In contrast to thalassemia, people with sickle cell disease usually do not receive chronic transfusions.

Patients with sickle cell disease typically have hemoglobin values in the range of 7 to 9 gm/dl. Cardiomegaly with ventricular dilation develops early in the course of the condition. Early on, patients with sickle cell disease have hyperdynamic hearts with high ejection fractions and a cardiac index that substantially exceed normal values. The heart's ability to maintain this high state of activity declines over time. By early adulthood, many patients begin to exhibit diastolic dysfunction.[34] Volume overload is required to maintain the cardiac index in the face of the low hemoglobin level. Despite the vasoocclusive nature of the disease, definite episodes of typical transmural myocardial infarction are rare. The slow decline in cardiac reserves means that by the fourth or fifth decades these patients begin to have clinically apparent evidence of cardiac dysfunction. Intolerance to the fluid loading used to treat sickle cell vasoocclusive crises is often the harbinger of cardiac involvement in this disease.

HEMATOLOGICAL DISORDERS AND THE CARDIOVASCULAR SYSTEM

Efficient oxygen delivery to cardiac and peripheral tissues requires adequate blood flow, sufficient oxygen-carrying capacity, and a gradient allowing release of oxygen from hemoglobin, In anemia, compensatory responses include increased blood flow owing to increase in cardiac work and a left shift in the oxygen dissociation curve. In contrast, rheological effects of decreased blood flow due to hyperviscosity can be profound, leading to deleterious consequences, including tissue infarction. Hematological/oncological disorders in which hyperviscosity occurs include plasma cell neoplasms (multiple myeloma and Waldenstrom macroglobulinemia), myeloproliferative disorders (polycythemia vera, essential thrombocytosis, and, in rare cases, chronic myeloid leukemia), lymphoma (if associated with cryoglobulinemia), and acute leukemia (hyperleukocytosis in certain subtypes of acute myeloid leukemia). Patients with a variety of neoplasms, particularly those with mucin-producing adenocarcinomas of the gastrointestinal tract, have an increased risk of thrombotic complications. This so-called hypercoagulable state associated with cancer is not due to increased blood viscosity (see Chap. 62) .

Polycythemia

True or absolute polycythemia refers to a condition in which the red cell mass is above normal. Polycythemia must be distinguished from states in which the hematocrit (red cell volume/plasma volume) is increased due to a decrease in plasma volume. An example of a spurious elevation in the hematocrit is Geisboch syndrome, typically seen in middle-aged, overweight hypertensive men.[35] Reducing the red cell mass by phlebotomy or other means does not alter their predisposition to thrombosis, which is likely related to standard atherogenesis rather than to elevated hematocrit.[36] A red cell mass test[37] using chromium-labeled red blood cells is needed to determine if a further work-up for polycythemia is required.

The polycythemias are subclassified into primary disorders and secondary conditions (Table 69-2) [38] in which the increase in red cell mass results from increased production of erythropoietin, the oxygen-tension regulated protein hormone elaborated by the kidney. Erythropoietin production can be increased in any disorder associated with hypoxemia, such as high-altitude chronic lung disease and cyanotic forms of congenital heart disease[39] ; impaired release of oxygen by certain hemoglobin variants (e.g., hemoglobin Hallamshire), which cause a shift in the oxygen dissociation curve to the left,[40] also leads to an increase in cell mass. The inappropriate production of erythropoietin or erythropoietin-like protein can be the cause of the erythrocytosis associated with certain tumors, such as cerebellar hemangioblastoma,[41] renal cell carcinoma,[42] and hepatocellular carcinomas. [43] An erythropoietin-independent or autonomously driven increase in the red cell mass is the hallmark of polycythemia vera, one of the myeloproliferative disorders.[37]

Whereas there is an increased incidence of symptoms due to thrombosis or impaired blood flow in patients with polycythemia vera,[37] whether the increased red cell mass wholly accounts for these problems is unclear. Supporting the role of erythrocytosis as the major culprit are (1) the known decrease in oxygen transport with increased blood viscosity based on capillary tube experiments (Fig. 69-5) and (Fig. 69-(2) the symptomatic relief achieved by patients when the hematocrit is reduced by phlebotomy.[44] On the other hand, patients with secondary erythrocytosis rarely experience the plethora of nonspecific symptoms (e.g., visual disturbances, dizziness, confusion) typical

TABLE 69-2 -- DIFFERENTIAL DIAGNOSIS OF POLYCYTHEMIA

ERYTHROCYTOSIS ASSOCIATED WITH A NORMAL OR REDUCED RED BLOOD CELL MASS
Acute or chronic hemoconcentration
Spurious polycythemia (stress polycythemia, relative polycythemia, or Gaisbock syndrome)
ERYTHROCYTOSIS ASSOCIATED WITH AN ELEVATED RED BLOOD CELL MASS (ABSOLUTE POLYCYTHEMIA)
Secondary Polycythemia
Increased erythropoietin production (physiologically appropriate)
High altitude
Cardiopulmonary disease
Decreased blood oxygen-carrying capacity due to carboxyhemoglobin
Impaired oxygen delivery, hemoglobin with increased oxygen affinity or congenital decreased red cell 2, 3-diphosphoglycerate
Renal artery stenosis
Familial elevated erythropoietin with appropriate physiological response
Autonomous erythropoietin production
Tumors
Hypernephroma
Cerebellar hemangioblastoma
Hepatoma
Uterine fibroids
Pheochromocytoma
Adrenal cortical adenoma
Ovarian carcinoma
Renal disorders
Cysts
Hydronephrosis
Bartter syndrome
Transplantation
Familial polycythemia due to autonomous erythropoietin production
Polycythemia Vera
From Fruchtman SM, Berk PD: Polycythemia vera. In Handin RI, Lux SE, Stossel TP (eds): Blood: Principles and Practice of Hematology. Philadelphia, JB Lippincott, 1995.
Cyclophosphamide >100-140 mg/m^2 (total dose) Congestive heart failure, hemorrhagic myocarditis/pericarditis/necrosis

Figure 69-5 Capillary tube experiment that documents the relationship between blood viscosity and oxygen transport. Blood that is too viscous due to polycythemia does not carry oxygen efficiently. (From Jandl JH: Blood: Textbook of Hematology. 2nd ed. Boston, Little, Brown, 1996, p 159.)

of the patient suffering from polycythemia vera.[37] Second, those with polycythemia vera often have persistent symptoms requiring antineoplastic therapy, which can lead to an amelioration in symptoms when the hematocrit has already been lowered by phlebotomy, perhaps because the platelets in this condition are intrinsically abnormal (e.g., reduced expression of the thrombopoietin receptor c-mpl).[45]

Polycythemia Vera

Polycythemia vera is a clonal chronic myeloproliferative disorder that is characterized by an increase in the red cell mass.[46] Other cell lineages including leukocytes and platelets may also be elevated. Splenomegaly is common. Studies have suggested that the cause of this disorder is an increased sensitivity of hematopoietic progenitor cells to regulatory factors such as erythropoietin.[47] [48] Patients with polycythemia vera usually have serum erythropoietin levels that are quite low even after phlebotomies have lowered the hemoglobin level. A defect in the cell signaling cascade may cause hypersensitivity to erythropoietin, although some have suggested that red blood cell production in this disease is completely independent of erythropoietin.[49] The *SHP1* gene, which encodes an intracellular phosphatase involved in cell signaling pathways, is potentially dysregulated in polycythemia vera.[50] Mutations in the erythropoietin receptor gene have been reported in a handful of families with familial polycythemia vera.[51]

CLINICAL MANIFESTATIONS.

Patients with polycythemia vera[52] may present with a variety of nonspecific complaints, including headache, weakness, pruritus (especially after showering), dizziness, sweating, abnormal vision, paresthesias, arthralgias, weight loss, or abdominal pain. On physical examination, patients have a ruddy complexion, organomegaly, and hypertension. Both thrombosis and hemorrhage may occur. Thrombosis occurs in up to 30 to 40 percent of patients with the disorder, including deep venous thrombosis of the lower extremities, pulmonary embolism, and coronary, cerebrovascular, or peripheral occlusions.[53] The splanchnic bed is particularly susceptible to thrombosis in patients with polycythemia vera. Cardiac valvular abnormalities also occur in patients with polycythemia vera (usually mitral valve thickening or nonbacterial vegetations). Hepatic or vena caval thrombosis, the Budd-Chiari syndrome, is a serious and not unusual event in patients with polycythemia vera. Of all patients with Budd-Chiari syndrome, up to 10 percent have polycythemia vera.[54] The risk of thrombosis may be related to excessive homocysteine levels.[55] Neurological abnormalities including transient ischemic attacks, cerebral infarction or hemorrhage, fluctuation in mental status, confusional states, and choreic syndromes also have been described. Dizziness, visual disturbances, scalp tenderness, and headache may occur because of increased blood viscosity and reduced cerebral blood flow caused by the erythrocytosis. Basilar artery insufficiency as well as carotid territory strokes may also occur. Peripheral arterial thrombosis,

peripheral vascular disease, and erythromelalgia, characterized by burning pain in the digits and potential ulceration, are further manifestations of the circulatory problems typically seen in those with polycythemia vera. Gastrointestinal and cerebral hemorrhage[56] have been described, particularly after the use of antiplatelet agents.

DIAGNOSIS AND TREATMENT.

The polycythemia study group has developed clinical and laboratory criteria for diagnosis[57] that require the presence of an elevated red cell mass and any three of the following criteria: (1) normal arterial oxygen saturation in the presence of erythrocytosis, (2) splenomegaly, (3) thrombocytosis and leukocytosis, (4) bone marrow hypercellularity associated with mature megakaryocytes without myelofibrosis, (5) low serum erythropoietin levels, and (6) abnormal marrow proliferative capacity as manifested by formation of erythroid colonies in the absence of erythropoietin.

Therapy requires individualization; there is no curative therapy other than perhaps bone marrow transplantation[58] in the rare patient with severe clinical manifestations. For most patients it is appropriate to reduce the blood cell count to normal as rapidly as possible with phlebotomy (1 to 2 units every other day as needed).[59] The hematocrit should be maintained in the 42 to 45 percent range. Pruritus, if present may be treated with cyproheptadine or even interferon alfa.[60] Elective surgery should be delayed until the red cell mass is in the normal range, if possible. Aspirin should be used carefully in a patient with polycythemia vera owing to the risk of hemorrhagic complications.[61] Hydroxyurea, an oral antimetabolite chemotherapy agent, may be helpful in cases where the hematocrit cannot be controlled by phlebotomy alone.[62] The alkylating agent busulfan should be avoided, owing to an increased risk of bone marrow fibrosis and leukemogenesis. Use of phlebotomy alone as a treatment strategy is associated with a higher risk of thrombosis.[59] The risk of leukemogenesis from hydroxyurea is low but real,[63] so this agent must be used carefully as a means of reducing the risk of thrombosis.

THROMBOCYTOSIS

An elevated (>450,000/ml) platelet count can result from physiologically appropriate stimuli, such as those occurring after general surgery, splenectomy, pregnancy, or iron deficiency. Such reactive thrombocytoses are not associated with an increased number of thrombotic events, in contrast to primary or essential thrombocytosis, which is one of the myeloproliferative disorders. In essential thrombocytosis there is a tendency toward increased clotting (as well as to hemorrhage due to intrinsic platelet dysfunction), sometimes with disastrous results, especially in younger patients with this condition.[56] [64] [65] Myocardial infarction is actually less common in those with essential thrombocytosis than with polycythemia vera.[57] [65] The use of hydroxyurea to lower the platelet count (and ameliorate the clonal stem cell defects as well) has been associated with reduction in cardiac risk.[66] The effect of anagrelide, which reproducibly lowers the platelet count, on the natural history of essential thrombocytosis is unclear.[67]

LEUKOCYTOSIS

Leukocytosis in patients with acute leukemia may provoke a host of cardiovascular problems during the course of the disease. Sepsis associated with profoundly myelosuppressive and gut-damaging chemotherapy can be associated with severe, albeit reversible, depression of cardiac function.[68] Two important issues relating leukemia to cardiac physiology are discussed later in this chapter: leukemic cell invasion of the myocardium or pericardium and direct toxic effect of antileukemic drugs, particularly anthracyclines. Occasionally, a very elevated white blood cell count may lead to circulatory compromise. Patients with chronic and acute lymphoid leukemia can tolerate extremely high white blood cell counts (more than several hundred thousand per microliter) without evident problems. However, patients with acute myeloid leukemia, particularly those with the acute monocytic or acute myelomonocytic subtype, may experience so-called leukostatic phenomena.[69] [70] Probably due to adhesion molecules expressed on the leukemia cell surface in those acute myeloid leukemia subtypes, aggregates of such neoplastic cells may cause thrombosis and hemorrhages in microcapillaries of the brain,[71] producing encephalopathy or, in the lung, producing pulmonary infiltrates and hypoxemia.[72] [73] In instances of cerebral or pulmonary leukostasis, rapid lowering of the white blood cell count is required. Usually, such reduction can be accomplished by institution of hydroxyurea or definitive antileukemic chemotherapy[74] ; occasionally, limited radiation to the brain[74] and/or leukophoresis[75] is required to prevent severe complications. Patients with chronic myeloid leukemia in stable phase who may often have high white blood cell counts, composed of mid-range and mature myeloid cells, occasionally experience leukostatic/thrombotic complications[76] such as priapism or stroke.

HYPERVISCOSITY DUE TO QUANTITATIVE OR QUALITATIVE ABNORMALITIES IN PLASMA PROTEINS

Plasma cell neoplasms are characterized by a clonal proliferation of cells capable of elaborating a single immunoglobulin molecule, either light chains or heavy chains or a structurally complete multimeric protein. The so-called M-component may, depending on its biochemical properties and level, interfere with normal process such as nerve conduction[77] or coagulation[78] owing to effects on clotting factors and/or platelet function. The hyperviscosity syndrome, characterized by circulating immune complexes, is more likely at a given level of IgM excess than in the more common IgG myeloma. Patients with an IgM M-spike and an accumulation of plasmacytoid lymphocytes in the marrow and/or lymph nodes have Waldenstrom macroglobulinemia[79] syndrome. When suspected on clinical grounds, the hyperviscosity syndrome can be confirmed by actual measurements of serum viscosity.[80] Hyperviscosity, a medical emergency, requires a prompt reduction in the M-component,[81] usually through a combination of plasmapheresis plus tumor burden reduction with chemotherapy. Elaboration of proteins that can aggregate at low temperature (cryoglobulins)[82] can result from a host of infections, as well as inflammatory or neoplastic conditions such as lymphoma, and can impose peripheral circulating problems, as discussed later.

PLASMA CELL NEOPLASMS

Multiple myeloma and other plasma cell tumors are neoplasms of plasma cells or plasmacytoid lymphocytes. These disorders may result from dysregulation of normal growth suppression genes. Overproduction of interleukin-6, which serves as an autocrine growth factor for myeloma cells, may also contribute to the development of this disease.[83]

Clinical manifestations of multiple myeloma include bone pain, renal insufficiency, anemia, hypercalcemia, infection, bleeding, and neurological symptoms. Hyperviscosity, especially in patients with IgG subclass myeloma,[84] has been described. Hyperviscosity may also be associated with bleeding. The diagnosis can be made by measuring serum viscosity[80] and by eyeground examination, which discloses the slow blood flow in the retinal blood vessels. Plasmapheresis[81] is the appropriate treatment. The overabundantly elaborated monoclonal protein can be deposited in tissues such as the kidney and heart, producing secondary amyloidosis. Cardiac amyloidosis may lead to cardiomyopathy, characterized by a speckled appearance on echocardiography.

The diagnosis of myeloma[85] rests on finding one major and one minor criteria or at least three minor criteria. The major criteria include plasmacytoma on tissue biopsy, marrow plasmacytosis greater than 30 percent, monoclonal protein of significant height (IgG greater than 3.5 gm/dl, IgA greater than 2 gm/dl, or light-chain [Bence Jones] protein in the urine greater than 1 gm/24 hr). The minor criteria include marrow plasmacytosis of 10 to 29 percent, monoclonal protein present but less than the levels defined for major criteria, osteolytic bone lesions, or a decrease in uninvolved immunoglobulins.

Waldenstrom macroglobulinemia [79] is characterized by marrow infiltration with lymphoplasmacytoid cells and high levels of IgM in the blood; lymphadenopathy or splenomegaly, rare in and multiple myeloma, is present in at least 40 percent of those with Waldenstrom macroglobulinemia. Complications caused by the macroglobulin production such as hyperviscosity, cold hemolytic anemia, peripheral neuropathy, renal disease, and bleeding are often the presenting manifestations. Although serum viscosity is elevated in most patients with Waldenstrom disease, only 15 to 20 percent have symptoms related to this problem. Congestive heart failure is not unusual, owing to the anemia and expanded plasma volume as well as the increased viscosity.

Patients with asymptomatic multiple myeloma should not be treated until there is clear evidence of disease progression. The aggressive therapeutic approach to multiple myeloma includes up-front high-dose dexamethasone or a vincristine/doxorubicin/dexamethase (VAD) regimen followed by autologous bone marrow transplantation once a reasonable response has been achieved.[86] Patients who are not candidates for high-dose chemotherapy should be treated for at least 12 months with one of the available regimens, including dexamethasone or VAD. Anemia can be corrected in many patients by administration of erythropoietin.[87] Hypercalcemia should be treated. The use of bisphosphonates such as pamidronate to stabilize bone matrix has resulted in a lower incidence of skeletal complications and improved outcome in patients with myeloma.[88] Patients with Waldenstrom macroglobulinemia are usually managed with combination chemotherapy.[79] Thalidomide, which may work by inhibiting angiogenesis, has efficacy in patients with refractory myeloma.[89]

CRYOGLOBULINS

Cryoglobulins are immunoglobulins that produce high-molecular-weight aggregates at temperatures below 37°C (98.6°F). To detect the presence of these proteins, blood should be drawn through a preheated syringe and stored at body temperature.[82] Hepatitis C virus is a particularly important etiological agent.[90] The chief

symptoms are peripheral vasculitis. Skin and joint manifestations are most common, but central nervous system dysfunction, renal failure, and even severe hypertension leading to cardiovascular and cerebrovascular accidents have been described in severe cases.[91] Interferon alfa to treat hepatitis C-associated disease[92] and cytotoxic drugs to treat the vascular disease[93] are potentially useful therapeutic modalities.

CARDIAC MANIFESTATIONS OF NEOPLASTIC DISEASE

Based on autopsy series, tumors affecting the heart are much more likely to have originated from a neoplasm elsewhere than to have primarily occurred in the heart.[94] Primary cardiac tumors are discussed in Chapter 49 . Metastatic tumors reach the heart most commonly by hematogenous dissemination, which cause multiple nodules, occasionally so diffuse as to lead to restrictive cardiomyopathy.[95] Direct extension, especially from mesotheliomas,[96] sarcomas,[97] [98] and mediastinal lymphomas[99] [100] (Hodgkin and non-Hodgkin) also occur (Fig. 69-6) .

Essentially, any tumor may spread to cardiac structures, including the myocardium, pericardium, and valves. The most common tumors to spread to the heart in descending order of frequency are carcinoma of the lung, breast, malignant melanoma, and leukemia. General autopsy series shows cardiac involvement in 1 to 20 percent of patients with malignant diseases; the frequency ranges as high as 60 percent in those with melanoma.[95]

Clinical manifestations of tumors metastatic to the myocardium are generally nonexistent, in distinction to the effects of tumors invading the pericardium, which may produce life-threatening tamponade. Myocardial invasion can occasionally produce tachyarrhythmias, atrioventricular block, or congestive heart failure.[101] [102] The diagnosis of myocardial metastasis ante mortem may be noted on echocardiographic examination, magnetic resonance imaging, gallium scanning, computed tomography, or positron-emission tomography.[103] [104] [105] Such studies may be particularly helpful in cases in which direct extension plays a role.

Pericardial Involvement

(See also Chap. 50)
Hematogenous spread (e.g., breast cancer, melanoma, sarcoma, leukemia)[106] [107] [108] [109] or direct extension of a thoracic tumor (e.g., mesothelioma, lymphoma, or lung cancer)[96] [110] can lead to pericardial involvement. Pericardial involvement[111]

Figure 69-6 Frequency of metastatic tumors to the heart and pericardium. (From English JC, et al: Metastatic tumors of the heart. *In* Goldhaber SZ [ed]: Cardiopulmonary Diseases and Cardiac Tumors. *In* Braunwald E [series ed]: Atlas of Heart Diseases. Vol 3. Philadelphia, Current Medicine, 1995, pp 116.1-116.6. Adapted from McAllister HA, Fenoglio JJ: Tumors of the cardiovascular system. *In* Atlas of Tumor Pathology. 2nd ed. Washington, DC, Armed Forces Institute of Pathology, 1978, pp 111-119.)

can be classified as either primarily infiltrative, with thickening and adherence to or infiltration of the myocardium, or as effusive, where there is significant reactive expansion of pericardial fluid. Although these two categories are not mutually exclusive, the infiltrative form tends to cause constrictive physiology whereas the effusive form results in pericardial tamponade.

Symptoms of pericardial tamponade include dyspnea and tachycardia due to a failure of cardiac output to meet oxygen demand, especially with exercise; cough and chest pain may also occur, although the key to suspecting the diagnosis is unexplained dyspnea and tachycardia in a cancer patient with normal resting oxygen saturation.

Pulsus paradoxus and paradoxical movement of the jugular venous pulse are important clinical signs of tamponade and should be sought during the physical examination, although their absence does not rule out the syndrome, which may occur only in the setting of relatively advanced pathological findings (see also Chap. 50) . Once the diagnosis of pericardial tamponade is suspected, an echocardiogram should be obtained. Although at cardiac catheterization demonstration of equal diastolic pressure on both sides of the heart is the hemodynamic key to diagnosis, echocardiography also provides critical physiological insight. As intrapericardial pressure rises, the relatively thin right ventricular wall will collapse, particularly in diastole.[112] Such diastolic right ventricular wall collapse is quite sensitive for hemodynamically significant tamponade; sometimes an echocardiogram will also actually delineate the metastasis. Computed tomography or magnetic resonance imaging is more suitable in situations in which pericardial infiltration/constriction is the more prominent physiology.

Not every pericardial effusion in a patient with cancer is due to malignant disease. Prior chest radiation therapy[113] [114] for lung cancer or lymphoma can produce pericardial disease as a late complication. Such radiationinduced effusions do not usually cause tamponade, but extreme care must be taken to exclude this eventuality.

The management of cancer patients with tamponade often requires surgical drainage[115] (e.g., creation of a pericardial window) by thoracotomy, subxiphoid pericardiotomy, or video-assisted thorascopy, [116] which offers a good balance between invasiveness and effectiveness. In patients with lymphoma who present with minimal tamponade early in the course of the disease, chemotherapy can result in rapid amelioration of symptoms.[117]

Figure 69-7 The radiographic appearance of SVC syndrome. Chest venography. (From Roberts JR, et al: Multimodality treatment of malignant superior vena caval syndrome. Chest 116:835-837, 1999.)

Superior Vena Cava Syndrome

Compression of the easily distensible superior vena cava, with or without associated thrombosis, by a thoracic tumor such as carcinoma of the lung or lymphoma can produce significant clinical consequences. The so-called superior vena cava syndrome[118] often presents as facial swelling, headache, and arm edema. A prominent venous pattern can be observed on inspection of the anterior chest wall. The diagnosis can be established by scintigraphy, angiography, or high-resolution contrast medium-enhanced computed tomography (Fig. 69-7) . Although rarely life threatening, the superior vena cava syndrome can lead to considerable morbidity and discomfort. Emergent radiation treatment is the treatment of choice.[119] In patients with responsive tumors such as Hodgkin disease or non-Hodgkin lymphoma, chemotherapy should be initiated as soon as possible. The likelihood of symptomatic relief with antineoplastic therapy depends on the duration of the obstruction and the intrinsic chemosensitivity of the tumor. Local therapies such as stenting, angioplasty, clot removal, or lysis are currently being developed[120] [121] [122] [123] (see also Chap. 42) . The role of anticoagulation is controversial[124] [125] ; some authorities recommend an angiographic evaluation (e.g., magnetic resonance angiogram) to document thrombosis before initiating such therapy.

Arrhythmias

Arrhythmias, typically due to electrolyte imbalance or decreased oxygen-carrying capacity (hypoxia due to pulmonary involvement with tumor or infection; or anemia) are common in patients with cancer. Tumor involvement of cardiac structures may also lead to nonspecific rhythm disturbances, including low voltage, sinus tachycardia, and ST segment and T wave charges. Atrial fibrillation or flutter can occur due to any of the aforementioned issues or to tumor invasion of the atria or of the coronary arteries that supply this chamber. In rare cases, atrioventricular node involvement will occur, leading to complete heart block.[110] Carotid sinus syncope[126] has been associated, in rare cases, with tumorous involvement of cervical lymph nodes.

Ischemic Heart Disease and Malignancy

In addition to the patient with intrinsic arteriosclerotic coronary disease who also happens to have cancer, there is sometimes a relationship between the malignancy and the ischemic heart disease. For example, tumor emboli can occlude[127] or tumor mass can compress the coronary artery.[128] The hypercoagulable state associated with malignancy, especially mucin-secreting adenocarcinoma, can predispose a patient to develop a coronary thrombosis. Radiation therapy promotes arteriosclerosis[129] (see next section).

Myocardial infarction was suspected as the cause of death in 4 percent of 816 patients with solid tumors undergoing autopsy.[95] In most of the nonarteriosclerotic cases (which account for the majority of such infarctions), extrinsic compression of a coronary artery is the cause of the infarction. Typical angina rarely precedes the coronary event in this setting.

Nonbacterial Thrombotic Endocarditis

(See also Chap. 47)
Although the cardiac valves may be directly involved with metastatic tumor, the most common cause of valvular heart disease in the cancer patient is nonbacterial thrombotic endocarditis (NBTE).[130] [131] [132] [133] NBTE generally involves the aortic and mitral valve and occurs in patients with advanced adenocarcinoma of the gastrointestinal tract and lung. Although the precise pathophysiology of NBTE remains uncertain, associated features include tumor-associated immune complexes and the presence of catheters, especially in right-sided valvular lesions. The clinical signs of NBTE may be subtle and resemble those of subacute bacterial endocarditis; more dramatic findings such as stroke[133] or myocardial infarction have been noted. Echocardiography can establish the diagnosis; yet treatment is difficult, in great part owing to the generally advanced stage of cancer in these patients.

INFLAMMATORY MEDIATORS ASSOCIATED WITH CARDIAC DISEASE

The carcinoid syndrome (see also Chaps. 46 and 48) is characterized by the elaboration of serotonin and its metabolites from a neoplastic proliferation of neoendocrine cells derived from ectoderm.[134] Clinical findings may include flushing, hypotension, and/or valvular lesions (Fig. 69-8) .[135] [136] The best treatment is reduction of tumor burden by surgery, although cisplatin-based chemotherapy may offer palliation.[134]

In the hypereosinophilic syndrome (see also Chap. 48) , [137] a myeloproliferative disorder, eosinophils infiltrate the bone marrow and circulate in high numbers in the peripheral blood. Cardiac involvement may result from the elaboration of mediators of inflammation as well as from direct invasion by the eosinophils.[138] Because corticosteroids can cause lysis of eosinophils, these drugs have been used successfully to treat cardiac complications such as cardiomegaly with a thickened right ventricular wall (leading to restrictive physiology[139]), mural thrombosis, and right-sided valvular dysfunction.[140] Mast cell neoplasms, including systemic mastocytosis, can also lead to valvular heart disease by a mechanism[141] similar to that described in association with hypereosinophilic syndrome. Massive release of vasodilatory substances during anesthesia has led to cardiovascular collapse in patients with mastocytosis.[142]

CARDIAC EFFECTS OF ANTINEOPLASTIC THERAPY

As understanding of the pathophysiology of neoplasia grows, it is hoped that molecules that specifically target the genetic lesions accounting for a given neoplasm will allow for a markedly improved therapeutic index (likelihood of benefit compared with toxicity). The successful use of all-*trans* retinoic acid in acute promyelocytic leukemia, characterized by a translocation of the retinoic acid receptor alpha gene to the promyelocytic leukemia gene, is one such example of relatively specific therapy, albeit in a rare disease.[143] However, for the most part, chemotherapy or irradiation entails significant side effects that always must be weighed against the goals of treatment, be they palliative or curative. Although many antineoplastic approaches are particularly toxic to tissues with a high cell turnover rate, such as the bone marrow, hair, and gastrointestinal tract, the heart is frequently adversely affected. In particular, as patients live longer after the diagnosis and therapy of cancer, late cardiac toxicity can lessen the quality of life.

Radiation Therapy

Therapeutic ionizing radiation to the chest is used to prevent local recurrence of breast cancer, to improve disease control in lung cancer and esophageal cancer, as well as to improve the cure rate with Hodgkin and non-Hodgkin lymphoma of the mediastinum. Essentially, all cardiac structures, including the pericardium, myocardium, and coronary arteries may be affected by such efforts.

MECHANISMS OF RADIATION-INDUCED CARDIAC INJURY.

Damage to both normal and neoplastic tissues occurs due to the free electrons, liberated due to the impact of high-energy proton beams, which directly damage DNA or do so indirectly, resulting in the creation of hydroxyl radicals from water.[144] Although the degree of DNA damage induced by radiation is most closely linked with cytotoxicity and therefore generally involves proliferating cells, more long-lived cells can also be affected. Radiation also induces early response genes such as c-*jun, fos,* and *EGR1,* cytokines such as tumor necrosis factor, and fibroblast growth factor, which may also contribute to the toxic effect. Moreover, radiation-induced apoptosis, or programmed cell death, may be a key component of tumor radiosensitivity, as well as cardiac toxicity, owing to endothelial cell damage mediated in this fashion.[145]

The subacute radiation injury to the heart noted clinically may result from a combination of microvascular destruction and apoptosis. The microvascular destruction can lead to coronary artery disease, ischemia, progressive cellular loss, and fibrosis. Late tissue injury to the myocardium, valves, and pericardium[146] [147] [148] [149] may occur. Cardiotoxicity is common at doses over 45 Gy, indicating increased radiosensitivity compared with the brain, esophagus, or bladder.[144]

Radiation-Induced Pericardial Disease

(See also Chap. 50)
Radiation therapy can produce acute or delayed effects on the pericardium. Especially with radiation techniques employed before the 1990s, almost all patients who received over 40 Gy to the anterior mediastinum would develop pericardial effusion or thickening within 9 months of treatment,[150] but symptoms of pericardial disease can be delayed for up to 10 years.[151] [152] Such symptoms occur in a minority of irradiated patients in whom up to 70 percent may have pathological evidence of radiation-related pericardial disease.[153] Late pericardial fibrosis with development of constrictive pericarditis occurred in 3 of 102 Hodgkin patients treated with mediastinal reduction in the 1970s.[154] In the case of pericardial effusions that produce tamponade physiology, a pericardectomy with creation of a window can be a critical therapeutic and diagnostic maneuver, because it is also important to rule out recurrence of the neoplasm. Removal of the entire pericardium may be alternatively necessary and may be required in patients with constrictive disease. The actual rate of pericardectomy was reported to be 4 percent at 17 years in one study that followed children and adolescents with Hodgkin disease.[154] However, postpericardiectomy mortality is high,[155] presumably because of the problems associated with diffuse damage to the entire heart, such as coronary artery disease, conduction system disturbances (e.g., sinus node disease),[156] and atrioventricular block,[157] and valvular pathology.[153] [158]

Radiation-Induced Myocardial and Ischemic Disease

Although radiation-induced myocardial fibrosis is common,[153] it is more difficult to show that left ventricular dysfunction derives solely from radiation therapy, as opposed to combined modality therapy with anthracycline chemotherapy. Children are certainly at risk for late effects due to chest radiotherapy. The incidence of late electrocardiographic abnormalities in children who received spinal or mediastinal irradiation in childhood is as high as 31 percent; cardiac-limited exercise dysfunction occurs in over 70 percent of children undergoing spinal irradiation, compared with 32 percent who had received flank/mediastinal radiation.[159] However, the most common and arguably the most important late effect is myocardial ischemia/infarction. The distribution of proximal coronary artery narrowing at autopsy[160] may result from the design of radiation ports that tend to primarily encompass the origin of these vessels.

One of the best retrospective series documenting the risk of significant coronary heart disease due to radiation is the Stanford study,[161] which examined the records of 635 individuals younger than the age of 21 treated for Hodgkin disease. Seven of 12 patients who experienced fatal cardiac events had a myocardial infarction (6-22 years post therapy), each of whom received 42 to 45 Gy to the mediastinum between ages 9 and 20 (relative risk was 41.5 percent [95 percent confidence interval was 18.1-82.1 percent]). Chemotherapy did not add risk for myocardial infarction. The actuarial risk of a fatal or nonfatal myocardial infarction was 8 percent at 22 years after therapy. Adults may be at somewhat lower risk, given the case-cohort study of 4665 patients[162] demonstrating an age-adjusted relative risk of death due to myocardial infarction of 2.56 percent after mediastinal irradiation. It has been strongly suggested that patients receiving mediastinal radiation be longitudinally screened

for the presence of preclinical cardiac disease.[163]

Given the frequent use of radiation therapy in women with breast cancer after conservative surgery, concerns have been raised about the potentially increased risk of coronary disease in this setting. In 244 patients with stage I or II breast cancer who received breast tangential irradiation (45 Gy with a 16-Gy boost) either before or after doxorubicin-containing chemotherapy regimens, there was no increase in cardiac events in those with either left- or right-sided breast cancer.[164] The trend toward the use of either chemotherapy only or low-dose radiation after chemotherapy for Hodgkin disease will likely result in a markedly decreased incidence of cardiac disease compared with the era when curative intent radiation was primarily employed.[165] [166] Amifostine is a thiol that can salvage the oxygen-derived free radicals that mediate irradiation (and chemotherapy)-induced cytotoxicity and may be selectively taken up by normal, compared with neoplastic, tissues.[167] There are, however, no data at this point supporting the administration of this agent to protect the heart from the damaging effects of radiation.[168]

There is little prospectively collected data concerning the risk of radiation-induced heart disease. Based largely on retrospective series, the following points are clear: (1) accelerated coronary artery narrowing results from chest irradiation and may lead to serious clinical consequences[160] [162] [169] [170] ; (2) irradiation during childhood or adolescence carries greater impact than similar therapy given later in life[161] [171] [172] ; (3) effects of radiation impairing

function of noncardiac site such as the thyroid, gonads, skeleton, and lungs can have important indirect cardiac effects[163] ; and (4) improvements in radiation techniques such as more focused high-energy beams, careful field design, modified fractionation, and better shielding are lessening the incidence of this problem.[163]

Chemotherapy-Induced Cardiac Disease

Combination chemotherapy leads to cures in patients with germ cell neoplasms, acute leukemias, and lymphomas and performs a critical adjunctive role, along with local tumor control in many other neoplasms, including breast cancer, lung cancer, and colorectal cancer. Toxicities of such regimens that contain cell-cycle or S-phase specific antineoplastic agents generally most markedly impact tissues such as the gastrointestinal tract and bone marrow, characterized by rapid cell tumor. However, chemotherapy-induced myocardial damage is a considerable problem, particularly in patients who are either cured or experience major palliation. Because long-surviving patients may be at risk for a delayed-onset cardiomyopathy, understanding risk factors for and minimizing the likelihood of development of this problem represents a major direction of research in the fields of both oncology and cardiology. The anthracyclines (doxorubicin, daunorubicin, idarubicin, and epirubicin) and the related anthracenedione mitoxantrone are the chemotherapeutic agents most widely recognized for causing cardiotoxicity; however, many other agents, including those in the biological response modifier class, are associated with cardiovascular pathology (Table 69-3) .

PATHOGENESIS OF ANTHRACYCLINE-INDUCED CARDIAC INJURY

Anthracyclines are part of curative therapy for acute leukemias, Hodgkin and non-Hodgkin lymphoma, breast cancer, and sarcomas of the bone. They are employed as palliative therapy in a variety of other neoplasms. These drugs contain an aromatic ring structure that intercalates in-between DNA base pairs; however, the mechanism of cytotoxicity appears to be inhibition of the function of topoisomerase II, an enzyme critical in allowing DNA to undergo efficient repair. Second, these drugs generate free radicals, which can damage cell membranes, in part by lipid peroxidation. The latter effect correlated most closely with cardiac toxicity; members of this class such as amsacrine and mitoxantrone, which produce lower quantities of free radicals, are less likely to cause cardiomyopathy.[173]

Enzymes such as P450 reductase, xanthine oxidase, and mitochondrial NADH oxidase are plentiful in the energy-dependent and mitochondrial-rich cardiac tissue and are responsible for reducing the anthracyclines to their corresponding semiquinone free radicals. However, the heart may have relatively low ability to detoxify the free radicals because of the presence of only small amounts of catalase, which converts hydrogen peroxide to water.[174] Lack of general free radical scavenging may be less important than the chelation of iron by the anthracyclines. The anthracycline-iron complexes generate tissue-damaging hydroxyl radicals in the immediate vicinity of the target.[173] Consequently, dexrazoxane (Zinacard), a drug that undergoes hydrolysis to a carboxylamine capable of accepting the iron from the anthracycline-iron complex, is the only clinically effective cardioprotectant.[168] [175] General free radical scavengers such as *N*-acetylcysteine are ineffective.[176]

Downstream effects of the free-radical-mediated damage induced by the anthracyclines include defective calcium binding by the sarcoplasmic reticulum; decreased actin, troponin, and myosin light chain 2 gene expression; and release of vasoactive amines and proinflammatory cytokines, such as tumor necrosis factor and interleukin-2.[177] Moreover, the presence of free radicals may activate certain intracellular signaling pathways,[178] [179] which turn on the apoptotic or programmed cell death machinery.[180] The disturbance in sarcoplasmic structures corresponds to ultrastructural damage to these elements and may cause calcium overload leading to deleterious transient activation of contractile proteins.[181] The findings of myofibrillar loss, mitochondrial swelling cisternal disruption, (Fig. 69-9) , and nuclear degeneration are the histopathological consequences of the biochemical changes noted earlier. Second, myocyte loss on the basis of apoptotic cell death has been documented. The degree of pathological changes has been used to establish a grading system to classify the severity of injury.[182] Serial endomyocardial biopsies are seldom used now because of the invasiveness and lack of predictive value of this technique relative to other monitoring strategies.

Clinical Aspects of Anthracycline-Induced Cardiotoxicity

In rare cases, a single dose of anthracycline produces acute or subacute cardiac toxicity. The most common acute toxicities include electrophysiological abnormalities, among them nonspecific ST and T wave abnormalities, decreased QRS voltage, and prolongation of the QT interval.[177] Rhythm disturbances including sinus tachycardia, ventricular and supraventricular arrhythmias, as well as conduction system alterations including atrioventricular block and bundle branch block can occur.[183] [184] Very rare cases of an acute myocarditis-pericarditis syndrome causing sudden death or rapidly progressive heart failure within 2 weeks of administration of the drug have been described.[184]

The common, clinically relevant type and potentially severe anthracycline-induced cardiac toxicity is the chronic cardiomyopathy that results from cumulative exposure to these agents. Although many risk factors, including older age and antecedent heart disease, for the development of anthracycline-induced cardiomyopathy have been described, the most important is cumulative dose of the drug. There is a nonlinear increase in the incidence of cardiomyopathy from 0.15 percent or lower at 400 mg/m^2 or less cumulative doses, compared with a 7 percent incidence at 550 mg/m^2 (Fig. 69-10) . Although endomyocardial biopsies demonstrate a progressive loss in cardiac myocytes with increasing doses beginning at a low level of total drug administered,

TABLE 69-3 -- CARDIOTOXICITY ANTINEOPLASTIC AGENTS

DRUG	TOXIC DOSE RANGE*	COMMENTS
Doxorubicin	>550 mg/m^2 (total dose) >550 mg/m^2 (total dose)	Congestive heart failure (cumulative toxic effect), arrhythmias Cardiac toxicity with additional risk factors
Daunorubicin	>550 mg/m^2 (total dose)	Same toxicity as doxorubicin
Mitoxantrone	>100-140 mg/m^2 (total dose)	Congestive heart failure, decreases in left ventricular ejection fraction
Cyclophosphamide	>100-120 mg/kg over 2 days	Congestive heart failure, hemorrhagic myocarditis/pericarditis/necrosis
5-Fluorouracil	Conventional dose	Angina/myocardial infarction
Vincristine	Conventional dose	Myocardial infarction
Vinblastine	Conventional dose	Myocardial infarction
Busulfan	Conventional oral daily dose	Endocardial fibrosis
Mitomycin C	Conventional dose	Myocardial damage similar to radiation-induced injury
Cisplatin	Conventional dose	Acute myocardial ischemia
Amsacrine	Conventional dose	Ventricular arrhythmias
Taxol	Conventional dose	Bradycardia
Interferons	Conventional dose	Exacerbates underlying cardiac disease
Interleukin-2	Conventional dose	Acute myocardial injury, ventricular arrhythmias, hypotension

From Holland JF: Cancer Medicine. 4th ed. Baltimore, Williams & Wilkins, 1997, p 897.

*Route of administration is intravenous unless otherwise indicated. Conventional dose is the commonly accepted therapeutic range.

Figure 69-9 Ultrastructural features of an anthracycline-induced cardiac toxicity. *A,* Normal. *B,* Vacuolation. *C,* Myofibrillar dropout. *B* and *C* are after doxorubicin therapy. (From Ali MD, Ewer MS: Cancer and the Cardiopulmonary System. New York, Raven Press, 1984, pp 62-63.)

the clinical expression of the dilated congestive cardiomyopathy generally does not occur until a threshold cumulative dose (which differs for each anthracycline) is reached. Although mortality for anthracycline-induced cardiomyopathy was formerly believed to be as high as 40 percent, recent reports in the current era of afterload reduction suggest a better prognosis. Nonetheless, once heart failure due to long-term exposure to these agents becomes clinically apparent, the disease should be taken very seriously. In a recently published study in which the outcomes of 1230 patients with cardiomyopathies were assessed with a median follow-up of 4.4 years, patients with doxorubicin-associated cardiomyopathy had an inferior survival (hazard ratio 3.46, 95 percent confidence interval 1.67-7.18) compared with patients with idiopathic cardiomyopathy[185] (Fig. 69-11). The timing of the onset of clinical symptoms of congestive heart failure relative to anthracycline exposure can vary substantially. In one small series, heart failure developed at a mean time of 4 weeks (range, 1-17 weeks) from the last dose of chemotherapy. The course was more severe in those patients who had a higher (>300 mg/m^2) dose of doxorubicin.[186]

Standard therapy including inotropic agents, diuresis, and afterload reduction represent the typical medical management of patients with anthracycline-induced cardiomyopathy; some studies have suggested that beta-receptor antagonists might also have a role.[187] [188] [189] Selected patients with severe cardiomyopathy who also have a lower likelihood of responding to medical therapy have undergone successful heart transplantation.[190] [191]

Chronic cardiomyopathy resulting in overt congestive heart failure that might require such a drastic intervention as cardiac transplantation is probably less common than the so-called late-onset anthracycline cardiotoxicity, which can cause a more subtle degree of ventricular dysfunction and/or arrhythmias[177] many years after the anthracyclines have been given.[192] Such delayed-onset effects are a particularly important issue in children who have received moderate to large doses of anthracyclines during therapy for acute lymphoblastic leukemia.[193] [194] [195] Because several studies that have observed patients longitudinally after exposure to anthracyclines during childhood have shown that echocardiographic abnormalities progress over time, there is concern about the potentially widened scope of eventual clinical cardiac dysfunction in such patients. For example, a reduction in intraventricular septum and posterior wall diastolic dimensions is more pronounced 7 years after exposure to anthracyclines than in control subjects.[196] The long-term clinical relevance of such findings is unclear. Moreover, whether the low level of elevation in serum cardiac troponin-T levels, indicating some degree of acute injury, which occurs during acute therapy with doxorubicin, has any clinical impact is unclear, although elevations correlated with abnormal echocardiograms 9 months after chemotherapy.[197] Some clinical deterioration of cardiac function can be detected more readily with the specialized technique of automatic border detection compared with conventional echocardiography[198] or with indium-111/antimyosin scintigraphy.[199] Echocardiographic abnormalities are more common in girls and those patients exposed at a young age to a high cumulative dose of doxorubicin.[200] Although the eventual clinical impact of the type of systolic and diastolic dysfunction documented as a late effect in children and adults treated with anthracyclines remains unclear, the onset of laboratory evidence of cardiac abnormality has correlated with congestive symptoms in patients with cardiomyopathies due to other causes.[201]

MONITORING OF PATIENTS RECEIVING ANTHRACYCLINES.

The ideal monitoring system for the occurrence of anthracycline-induced cardiotoxicity would be noninvasive, a reliable predictor of eventual clinical dysfunction, and detect disease early enough so that an effective therapeutic strategy could be used. Endomyocardial biopsy, radionuclide angiocardiography, resting echocardiography, and exercise echocardiography have each been used in an effort to predict the development of the so-called early or classic cardiomyopathy. Although endomyocardial biopsy grade can predict the rate of potential clinical progression, sampling errors due to patchy myocardial involvement, invasiveness, and expense have limited the routine use of this technique.[177] [202]

Patients receiving anthracyclines over time are often followed with radionuclide ventriculography, based on an earlier study that suggested that a 15 percent decline in left ventricular ejection fraction (LVEF), or a LVEF of less than 40 percent, occurred in those at high risk for clinical cardiac decompensation.[203] However, concerns have been raised regarding the problem that by the time the LVEF falls a significant amount of myocardium has already been irretrievably lost. Echocardiographic features, such as measurement

Figure 69-10 Anthracycline cardiotoxicity: relationship of dose to the incidence of congestive heart failure. (From Shan K, et al: Anthracycline-induced cardiotoxicity. Ann Intern Med 125:47-58, 1996.)

of the rate of relaxation and fractional shortening of diastolic filling, can also serve as a potentially sensitive means of detecting the early onset anthracycline-induced chronic cardiomyopathy.[204]

The value of very sensitive tests of ventricular function to detect so-called late-onset cardiomyopathy has been discussed earlier with regard to findings on echocardiography or radionuclide angiography in children many years after receiving anthracyclines. Dobutamine/exercise echocardiography and exercise radionuclide angiography have each been somewhat predictive of this late-onset cardiac dysfunction in patients with normal resting cardiac function.[177] However, the importance of these relatively subtle abnormalities, generally of diastolic dysfunction, is even more unclear in the case of late-onset cardiomyopathy, compared with that of early detection of the chronic dilated cardiomyopathy, which occurs much earlier relative to the chemotherapy treatment.[205]

PREVENTION OF ANTHRACYCLINE-INDUCED CARDIOTOXICITY.

Strategies for minimizing cardiotoxic effects of anthracyclines include altering the dose and schedule, use of new formulation of anthracyclines (e.g., liposome-encapsulated), calcium channel or beta-adrenergic blocker pharmacological approaches, and "true" cardioprotection using iron-chelating agents and/or free radical scavengers. Each of these strategies has shown some ability to limit cardiotoxicity. However, ensuring antineoplastic efficacy remains a major issue with regard to most of the putative cardioprotective agents. It has been recognized for more than 20 years that administration of a given dose of doxorubicin in smaller fractions or by continuous infusion schedules would produce less cardiac toxicity without any apparent compromise of antineoplastic activity.[206] [207] [208] [209] Examples of changes in dose schedule to produce less cardiotoxicity include weekly dosing of doxorubicin (rather than every 3 weeks) in breast cancer patients, continuous infusion of doxorubicin in patients with multiple myeloma or non-Hodgkin lymphoma (which might also have better activity in drug-resistant cells), or giving the drug over 6 hours.[210]

Liposome-encapsulated anthracyclines may allow administration of a higher total with less cardiotoxicity. Endomyocardial biopsies indicate less marked histopathological changes at a given dose of anthracycline when given by the liposomal route.[211] [212] [213] [214] However, it remains of critical importance to ensure that the use of liposome-encapsulated anthracyclines does not reduce antitumor efficacy. A recent provocative study compared docetaxel, a taxane, versus doxorubicin, in patients with metastatic breast cancer who had received previous

Figure 69-11 Mortality from various causes of cardiomyopathy. (From Felker GM, et al: Underlying causes and long-term survival in patients with initially unexplained cardiomyopathy. N Engl J Med 342:1077-1084, 2000.)

alkylating-agent chemotherapy.[215] Not only was the median time to progression longer in the docetaxel group but there was no cardiotoxicity in this group, compared with four deaths in the patients who received doxorubicin. Therefore, substitution of alternative efficacious agents for the anthracyclines is yet another strategy for reducing cardiotoxicity.

Several compounds have been tested for their ability to protect against anthracycline-induced cardiomyopathy, including dexrazoxane, amifostine, glutathione, vitamin E, mesna, and ORG 2766.[168] [175] [216] [217] These drugs block toxicity by either reducing free radical generation or increasing free radical scavenging. Dexrazoxane, which has received the most attention, readily penetrates cell membranes and appears to complex with metal cofactors, including iron. Chelation of intracellular iron may decrease doxorubicin-induced free radical formation.[175] The drug should be given within 30 minutes of anthracycline administration. Three randomized, placebo-controlled clinical trials of dexrazoxane in patients with advanced breast cancer have been conducted in which a total of 626 patients were enrolled.[175] [218] [219] [220] The mean decrease in left ventricular injection fraction by radionuclide scanning was lower in women treated with dexrazoxane. However, dexrazoxane was not shown to increase overall or disease-free survival. At higher doses, there was an increase in the incidence of myelosuppression, and concern remains that tumor response rates may be decreased.[168] Moreover, it is not known whether the drug can protect against delayed-onset cardiotoxicity. The vagueness of the American Cancer Society Clinical Practice Guidelines reflects the many unanswered questions regarding the use of the agent. In fact, the only setting in which the agent is recommended even for consideration is in patients who have received 300/mg/m^2 or more of doxorubicin yet who might benefit from further anthracycline.[168]

Other agents with antioxidant effect, such as probucol, coenzyme Q10, and melatonin, may provide cardioprotection without affecting tumor response rates, at least based on animal data.[221] [222] [223] [224] These promising early results await additional confirmatory studies. Pilot data with calcium antagonists[225] and beta-adrenergic blockers,[189] [226] such as metoprolol, have also been developed. Finally, a transgenic mouse overexpressing the human complementary DNA for multiple drug resistance, driven by an alpha-cardiac myosin gene, has been developed.[227] The animals are resistant to doxorubicin-mediated myocyte dropout.

Cardiotoxicity of Other Antineoplastic Agents

5-FLUOROURACIL (5-FU).

This is a fluorinated pyrimidine that undergoes under intracellular metabolism to deoxy-5-fluorouracil monophosphate, an inhibitor of the enzyme thymidylate synthase (as well as interfering with DNA and RNA metabolism). 5-FU is used to treat several important solid tumors, including colorectal cancer, squamous cell carcinoma of the head and neck, and breast cancer. Although it is not a common cause of cardiotoxicity, patients with prior coronary disease and/or those receiving concurrent radiation therapy are at risk for 5-FU-induced heart disease. Vasoocclusive complications, particularly acute myocardial infarction, may be somewhat more likely in patients receiving 5-FU-based chemotherapy. Clinical manifestations of 5-FU cardiotoxicity, which occurs in less than 2 percent of patients receiving this drug, include typical ischemic electrocardiographic changes, chest pain, nausea, and diaphoresis.[228] 5-FU may cause endothelial cell contraction and lysis, perhaps on a vasospastic basis.[229] Vasospastic-type ischemia, arrhythmias, contractile dysfunction, and frank infarction have also been documented in connection with 5-FU.[230] [231] [232] Fortunately, the cardiac effects, including mild depression of contractile function, are usually reversible when the drug is withdrawn.[233] [234] [235] [236] [237]

CYCLOPHOSPHAMIDE AND IFOSFAMIDE.

The bifunctional alkylating agents cyclophosphamide and ifosfamide are converted in the liver to an active form. In the case of cyclophosphamide, hepatic microsomal mixed function oxidases metabolize the drug to the active moiety, 4-hydroxycyclophosphamide. A severe myocardiopathy may occur in patients receiving high doses of these drugs. Most of the available data comes from patients who have received cyclophosphamide at high doses during preparation for stem cell transplantation who have developed serious heart failure.[238] [239] Cyclophosphamide-induced cardiac failure is manifested by reduction in the electrocardiographic voltage on systolic function and increase in myocardial mass due to edema, with pathology indicating acute myocyte necrosis, hemorrhagic myopericarditis, and endothelial injury. Preexisting heart disease is a predisposing factor,[240] and mortality approaches 33 percent. Six of 19 women undergoing autologous bone marrow transplantation for breast cancer developed transient clinical and chest radiographic evidence of moderate congestive heart failure during the course of recovery from transplantation, with a median time of onset on day 13 after chemotherapy. The median area under the curve of cyclophosphamide concentration was lower in those patients who developed cardiotoxicity, presumably owing to a high rate of conversion of parent compound to the active metabolite.[239] Ifosfamide can cause a similar syndrome of heart failure.[241]

OTHER AGENTS.

Preparative regimens for bone marrow transplantation involving high doses of cyclophosphamide, frequently along with total-body radiation, are not infrequently associated with subacute cardiotoxicity.[242] Life-threatening cardiotoxicity is rare (less than 2 percent) in the posttransplant setting; however, cardiac events seem to be more common in those with a reduced ejection fraction at baseline. Consequently, most transplant protocols eliminate from eligibility patients who have impaired cardiac function at the time of transplant. It is possible that with the advent of so-called miniallogeneic transplant protocols[243] in which the dose of conditioning regimens is decreased in favor of the graft-versus-cancer effect, that such cardiotoxicity will be less common in the future.

Although cisplatin,[244] bleomycin,[245] and *Vinca* alkaloids[246] do not generally cause direct cardiac muscle damage, each of these agents does have potential endothelial and vasospastic[247] effects. As such, it is perhaps not surprising that myocardial infarction has been described. Moreover, because cisplatin causes renal tubular potassium and magnesium wasting, electrocardiographic abnormalities are not uncommon.

The taxanes, relatively new to the clinic, are useful in patients with a host of neoplasms, including breast, lung, and ovarian cancer. Paclitaxel and docetaxel have been associated with the development of brachycardia; it is now recognized that such events are rare (<10 percent), may have been due to the formerly used carrier, and are generally not clinically significant.[248] These agents do not appear to have any long-term cardiac side effects. Minimal added toxicity from the addition of paclitaxel to doxorubicin for the treatment of breast cancer has been noted.[249] [250] Interferon alfa, which is used in hairy cell leukemia, chronic myelogenous leukemia, and Kaposi sarcoma, can occasionally cause a severe congestive cardiomyopathy with myocardial dysfunction, which is generally reversible with discontinuation of the drug.[251] [252]

High-dose interleukin-2, which may have a role in the treatment of selected patients with renal cancer and melanoma, can cause high fevers and myalgias, as well as, in some cases, life-threatening capillary leak syndromes, including tissue edema, hypotension, noncardiogenic pulmonary edema, renal failure, and an occasional myocardial infarction.[252] [253] [254]

Trastuzamab (Herceptin) is a humanized monoclonal antibody that targets the human epidermal growth factor receptor (HER-2), which is overexpressed in 30 percent of breast carcinomas. This novel agent is associated with clinical responses in HER-2, overexpressing breast cancer when given alone[255] or with other agents such as taxanes or anthracyclines.[256] However, a cardiomyopathy similar to that observed after doxorubicin therapy has been noted. In the context of the known expression of HER-2 or HER-3 receptors in myocardial tissue, this is of concern. The precise mechanism and incidence, if any, of Herceptin-mediated heart problems requires evaluation.[257]

HEMATOLOGICAL EFFECTS OF CARDIAC MEDICATIONS (See also Chap. 62)

Reports exist linking virtually every drug with hematological abnormalities. The focus in this section is primarily on the more common and clinically important hematological effects produced by medications currently employed in the clinical practice of cardiovascular medicine. For a broader discussion of hematological effects of cardiac medications currently less used, the reader can consult previous editions of this text. This discussion considers, in turn, thrombocytopenia, granulocytopenia/aplastic anemia, and anemia.

Thrombocytopenia

HEPARIN-INDUCED THROMBOCYTOPENIA (HIT)

(see also Chap. 62) . Heparin, a commonly used anticoagulant in cardiovascular diseases, frequently causes thrombocytopenia. Two forms of HIT can occur. In type I HIT, thrombocytopenia occurs within days of initiating therapy. Type I HIT causes modest thrombocytopenia with levels seldom below 75,000 cells/muL. This form of HIT probably results from increased aggregation of platelets that have been cross-linked by the highly negatively charged heparin molecule. Type I HIT is common, occurring in several percent of patients receiving heparin therapy. Type I HIT generally improves with time, even with continuation of heparin treatment.

In contrast, type II HIT produces more severe thrombocytopenia with levels often below 50,000 cells/cm[3] . Type II HIT occurs later after initiation of therapy, typically between 4 days and 2 weeks of treatment. In type II HIT, thrombosis as well as bleeding can occur. The mechanism of type II HIT involves binding of exogenously administered heparin to a platelet surface protein known as platelet factor 4 (PF4). When an IgG antibody that recognizes this PF4/heparin complex binds, the ternary complex associates with platelet receptors for the Fc portion of the immunoglobulin molecule. Ligation of the Fc receptors causes platelet activation and thrombosis.

The second form of HIT requires immediate cessation of heparin therapy. Even heparin flushes of peripheral intravenous catheters should be avoided. Low-molecular-weight heparin is associated with a much lower incidence of HIT.[258] Thrombin inhibitors such as hirudin and argatroban may be very useful as replacement for heparin in type HIT, when even low-molecular-weight heparin must be used with caution.[259]

GLYCOPROTEIN (GP) IIb/IIIa ANTAGONISTS (see also Chap. 62) .

The introduction of IIb/IIIa antagonists represents one of the major advances in cardiology in the past decade. Numerous studies have shown improved outcomes after coronary intervention and the acute coronary syndromes due to administration of these agents.[260] GP IIb/IIIa antagonists currently available for intravenous use include a chimeric antibody (abciximab), small organic molecules (e.g., tirofiban), and a cyclic oligopeptide (eptifibatide). A number of orally active agents exist as well. Each of these drugs can cause thrombocytopenia[261] (Fig. 69-12). Defining clinically significant thrombocytopenia as less than 50,000/muL, the incidence with small molecules is 0.6 to 0.8 percent, with abciximab up to 2 percent.

Administration of these agents requires careful monitoring for thrombocytopenia. A baseline platelet count should be obtained; a basal level of less than 100,000/muL is a relative contraindication to GP IIb/IIIa antagonist use. A platelet count should be obtained 1 to 4 hours after administration of a GP IIb/IIIa antagonist. If the platelet count falls below 50 percent of baseline or less than 100,000/muL,

Figure 69-12 A meta-analysis of rates of thrombocytopenia associated with use of intravenous GP IIb/IIIa antagonists. Data shown compile results from 28 clinical trials. The odds ratio (OR) and 95% confidence intervals (CI) for each agent are depicted on the whisker plots. (After Giugliano RP; from Madan M, Berkowitz SD: Understanding thrombocytopenia and antigenicity with glycoprotein IIb-IIIa inhibitors. Am Heart J 138:317-326, 1999.)

the agent should be discontinued. Because the clinical indications for GP IIb/IIIa and heparin therapy are similar, coadministration of these agents occurs commonly. Hence, the differential diagnosis of thrombocytopenia due to GP IIb/IIIa antagonists versus heparin-induced thrombocytopenia is a common clinical dilemma. Clues to the differential diagnosis include the time course of onset of the thrombocytopenia. The decline in platelet count with GP IIb/IIIa antagonists typically occurs during the first day, whereas there is a delay of 3 to 4 days in type I HIT. Laboratory evaluation of heparin/PF4/IgG complexes can also aid the differential diagnosis.

Several mechanisms may account for the thrombocytopenia associated with GP IIb/IIIa antagonist administration.[262] One mechanism is analogous to the "innocent bystander" mechanism often responsible for drug-induced hemolytic anemia. In this situation, an antibody binds to the drug, as well as to the platelets. Complement-induced lysis, or enhanced clearance by the spleen due to opsonization, can reduce platelet number. Another potential mechanism involves an antibody response directed against a conformational epitope on the IIb/IIIa complex itself. When a ligand binds to GP IIb/IIIa, it can induce a shape change that uncovers a new antigenic determinant, or epitope, a ligand-induced binding site. The immune response targets a normally concealed part of the GP IIb/IIIa molecule revealed upon binding of the antagonist.

Another potential mechanism is applicable specifically to the chimeric antibody abciximab.[263] In this situation, a portion of the chimeric antibody that retains mouse sequences in the hinge region of the immunoglobulin molecule can engender an antibody response. This mechanism has been called a human anti-chimeric antibody reaction. Because this mechanism requires generation of a antibody response to the foreign epitope (mouse sequences in the chimeric antibody), its onset would be later than most GP IIb/IIIa antagonist-induced thrombocytopenic episodes. Complement-induced lysis of platelet binding the antibody presumably causes the thrombocytopenia. Readministration of abcximab within 2 weeks can lead to profound thrombocytopenia in approximately 12 percent of patients.[264]

The treatment of thrombocytopenia associated with administration of GP IIb/IIIa antagonists involves stopping the drug. Platelet transfusion may prove necessary if the platelet count drops below 20,000/muL3. Although the mechanisms may differ, all three structurally distinct classes of GP IIb/IIIa antagonists can cause thrombocytopenia. Curiously, a number of recent trials with oral GP IIb/IIIa antagonists have shown not only no benefit in terms of event reduction but also a tendency to increase events.[265] The reason for the unexpected lack of efficacy of the oral GP IIb/IIIa antagonists remains uncertain.

THIENOPYRIDINES AND THROMBOTIC THROMBOCYTOPENIC PURPURA.

The introduction of thienopyridine antiplatelet agents has proven a boon in interventional cardiology and for aspirin-allergic patients with atherosclerotic

disease. These drugs (ticlopidine and clopidogrel) bind to an adenosine diphosphate receptor on the surface of platelets that mediates platelet activation and propagation of platelet aggregation. Before the use of thienopyridine agents, abrupt thrombosis represented a major limitation to the use of coronary stents. Lengthy hospital stays to achieve therapeutic anticoagulation with warfarin were inconvenient for patients, expensive, fraught with the risk of bleeding with intensive warfarin therapy, and eventually proved less effective than administration of aspirin and thienopyridine after coronary stenting.[266]

Patients with atherosclerosis with indications for aspirin who are unable to take this agent due to allergy have also benefited from thienopyridine therapy.[267] Considerable data establish the utility of agents of this class in reducing unstable coronary events and stroke in patients at risk. However, the possibility of developing thrombotic thrombocytopenic purpura (TTP) requires careful thought when considering use of thienopyridines. First recognized with ticlopidine, and subsequently with clopidogrel, TTP due to thienopyridines presents as the classic findings of thrombocytopenia, microangiopathic hemolytic anemia, central nervous system abnormalities, and renal dysfunction. Because prevention of recurrent strokes is a common indication for this class of drugs, mental status changes due to TTP can present a diagnostic challenge. TTP due to ticlopidine occurs in approximately 1 in 1600 treated patients.[268] The incidence of clopidogrel-induced TTP requires more extensive study but is probably substantially lower.[269]

TTP is life threatening. Death occurs in about a third of patients with ticlopidine-associated TTP. Plasmapheresis should be instituted as soon as the diagnosis is made and appears to strikingly reduce mortality (from 60 percent from patients not undergoing plasmapheresis to 22 percent of those plasmapheresed).[268] The physician should remain vigilant in all patients receiving thienopyridines for early clinical signs of TTP, including rashes or confusion. The finding of schistocytes on a peripheral blood smear supports the diagnosis of TTP. Fortunately, most episodes of TTP due to thienopyridines occur during the first 3 months of therapy, after which point patients require less surveillance.

The precise mechanism of thienopyridine-induced TTP remains elusive. However, it may involve generation of an antibody that inhibits a metalloproteinase important for processing large multimers of von Willebrand factor.[270] [271] Antibody-induced inhibition of this metalloproteinase favors the accumulation of the large von Willebrand factor multimers, which more effectively promote platelet aggregation and cross-linking than lower molecular weight forms.

TTP, although rare, is a serious and frequently lethal complication of thienopyridine therapy. In patients requiring coronary stent placement, the risk/benefit ratio of thienopyridine use, limited to a few weeks, supports the use of these agents to prevent the otherwise common and often disastrous complication of abrupt thrombosis. In candidates for antiplatelet therapy with aspirin allergy, selection of a thienopyridine also likely has a net benefit for the patient. In patients able to tolerate aspirin, individual decisions regarding the use of thienopyridines based on the particular clinical scenario seem warranted.

QUINIDINE.

Quinidine, once a mainstay of antiarrhythmic therapy, has lost popularity in recent years. Hematological side effects, including thrombocytopenia, in addition to a potential proarrhythmic effect, has contributed to the decline in quinidine's use in the clinic. The mechanism of quinidine-induced thrombocytopenia probably involves a humoral immune response.[272] Cessation of the drug generally leads to a gradual increase in platelet number over a period of days. Alkalization of the urine can help promote the elimination of quinidine, a weak base. Intravenous immunoglobulin may also mitigate quinidine-induced thrombocytopenia. [273]

OTHER CARDIOVASCULAR MEDICATIONS ASSOCIATED WITH THROMBOCYTOPENIA.

Several other cardiac medications cause thrombocytopenia less frequently. However, several of these agents are in very common clinical use, resulting in the number of patients at risk is considerable (Table 69-4) . These agents include the thiazide diuretics, furosemide, digoxin, procainamide, and the phosphodiesterase inhibitor inotropic agents, such as amrinone or milrinone.[274] A comprehensive listing of drugs that induce thrombocytopenia can be found on the Internet at http://moon.ouhsc.edu/jgeorge.

Leukopenia/Aplastic Anemia

Granulocytopenia can occur during treatment with a wide variety of cardiovascular drugs.[275] The sulfhydryl group containing angiotensin-converting enzyme inhibitors (the "prils") represents one class of cardiac medications that with increasing use occasionally causes leukopenia. Procainamide (particularly sustained-release procainamide) can cause severe leukopenia.[276] [277] The granulocytopenia improves after cessation of procainamide treatment. Interestingly, the leukopenia can occur independently of the well-known procainamide-induced lupus syndrome.[278] Granulocyte colony-stimulating factor is one therapeutic option for drug-induced thrombocytopenia.[279] Other cardiovascular drugs that can cause agranulocytosis or aplastic

TABLE 69-4 -- CURRENTLY USED CARDIAC DRUGS IMPLICATED IN DRUG-INDUCED THROMBOCYTOPENIA-

AGENT	FREQUENCY OF USE	INCIDENCE	BLEEDING	THROMBOSIS	CLINICAL IMPORTANCE

Amrinone, milrinone	+	++	++	-	+
Procainamide	+	+	++	-	+

-Plus (+) and minus (-) signs indicate subjective impressions of the frequency and importance of selected aspects of drug-induced thrombocytopenia, ranging from very low (-) to very high (++++).*Adapted from Giugliano RP: Drug-induced thrombocytopenia: Is it a serious concern for glycoprotein IIb/IIIa receptor inhibitors? J Thromb Thrombolysis 5:191-202, 1998.*

anemia include beta blockers, such as propranolol, dipyridamole, digoxin, and nifedipine.[275] The thienopyridine ticlopidine causes granulocytopenia in about 2.5 percent of recipients. A leukocyte count should be obtained before and at 2-week intervals during the first 3 months. If the drug is omitted during the first 3 months of therapy, a follow-up white blood cell count should be monitored for an additional 2 weeks, because patients are at risk for leukopenia even after stopping ticlopidine. Among the immunosuppressants used in cardiac transplantation recipients, azathioprine can cause a dose-related decrease in white blood cell count. This represents a mechanism-based toxicity related to the drug's primary mode of action as an immunosuppressant.

Anemia

Cardiac medications seem to cause anemia less commonly than thrombocytopenia or leukopenia. Hemolytic anemia due to methyldopa is seen less frequently, because use of this antihypertensive agent has declined. One currently used medication associated with hemolytic anemia is quinidine. Phenytoin, now uncommonly used as an antiarrhythmic agent, and triamterene, a common component of combination diuretic drugs, can cause megaloblastic anemia.

Chapter 70 - Psychiatric and Behavioral Aspects of Cardiovascular Disease

ARTHUR J. BARSKY

Daily life offers ample empirical evidence of an intimate relationship between the psyche and the heart. Intense emotions such as anxiety, anger, elation, and sexual arousal are accompanied by predictable increases in heart rate and blood pressure. Our everyday speech is filled with cardiac metaphors; the heart "races" with excitement, "pounds" in eager anticipation, "stands still" in dread, "aches" with grief. Many cultures have regarded the heart as the seat of emotion, the origin of love, the source of courage, or the abode of the soul. Generous people have "big hearts," and stingy people are "heartless." When you first met your first love, your heart "skipped a beat," and you were "broken hearted" when you parted ways soon thereafter. We attend funerals with a "heavy heart" and offer our "heartfelt" condolences. The interaction of heart and psyche is bidirectional. Emotions and stressful experiences affect the heart directly through the autonomic nervous system and indirectly through neuroendocrine pathways. Conversely, cardiac activity and function can reach conscious awareness and may be experienced as symptoms.

PSYCHIATRIC AND BEHAVIORAL ASPECTS OF CORONARY HEART DISEASE

Type A Behavior Pattern and Hostility

Clinicians dating back to Sir William Osler have observed that a surprising number of coronary heart disease (CHD) patients seem to be compulsive, driven overachievers who are unable to relax and quick to feel angry and frustrated when things do not proceed as planned. Such observations were reified in the 1960s by Friedman and Rosenman, who advanced the concept of Type A behavior, which was actually a cluster of psychological traits and behavioral patterns. Type A individuals struggled to obtain numerous objectives, as rapidly as possible, from an environment that continually seemed to oppose their efforts. Type A behavior is suffused with ambition, time urgency, and anger and hostility. Type A persons are excessively competitive and aggressive, with an extreme desire for achievement and recognition--impatient people leading fast-paced lives in continual and strenuous pursuit of a goal. This was contrasted to Type B individuals who are relaxed, unhurried, and less aggressive and who do not get as upset when thwarted. Large-scale, prospective studies in the 1970s and 1980s (including the Western Collaborative Group Study) conducted on initially healthy individuals showed that those with Type A behavior pattern, versus Type B individuals, had a significantly elevated rate of developing CHD (two times higher) and myocardial infarction (five times higher) at 5- to 8½-year follow-up and had more extensive CHD at the time of angiography.[1] Some additional longitudinal studies replicated these findings, but a substantial number, including the Multiple Risk Factor Intervention Trial (MRFIT), failed to support this association. In particular, several studies did not find that Type A behavior pattern predicted the subsequent incidence of cardiac events among patients with already established CHD. This suggested that perhaps the association between Type A and the development of CHD might be stronger than the association between Type A and the progression of disease.

These contradictory findings led to a search for more specific features or components of Type A behavior that might be more closely associated with CHD. A body of work emerged suggesting that anger and/or suppressed anger are the pathogenic components of Type A personality,[2] and laboratory studies provided evidence of pathophysiological changes that were associated with anger and hostility. Hostility is thought of as an underlying, enduring personality trait that encompasses a cynical, suspicious, and denigrating attitude toward others. This attitude then results in more frequent, intense, or longer-lasting episodes of anger when the individual is provoked, challenged, or otherwise stressed. Anger, hostility, antagonistic interactions, cynicism, and mistrust have been associated in long-term, prospective studies with the incidence of CHD, coronary events, and total mortality; and this literature suggests that such anger and hostility are independent risk factors for the development of CHD.[2] [3] In a 7-year, follow-up study of 1305 men, for instance, the relative risk for men with the greatest levels of anger was 2.66 for cardiac events (cardiac death, nonfatal myocardial infarction, and angina) as compared

with men with the lowest levels of anger.[4] In the Western Electric study, the baseline hostility scores of 1877 middle-aged men were predictive of CHD events over a 10-year period.[5] Most recently, in a sample of 2890 middle-aged men observed for more than 8 years, suppressed anger was a significant predictor of a major cardiac event (relative odds=1.70; 95 percent confidence interval [CI]=1.26 to 2.29), and this relationship persisted after controlling for physiological, psychosocial, and behavioral risk factors.[6] Several cross-sectional angiographic studies also report an association between the degree of hostility and the extent of CHD.

Other studies, however, have not found an association between anger and CHD, and the evidence linking irritability, anger, and hostility to CHD prognosis and mortality is less conclusive than its association with the incidence of CHD. It has been reported in a 3-year, follow-up study that anger was significantly associated with CHD mortality in men with already established heart disease and with the incidence of restenosis after angioplasty,[7] but in general it appears that hostility and anger may predispose more to the initial cardiac event than they adversely influence the course of already established coronary artery disease. It is unclear to what degree hostility's effect may be mediated through its influence on other risk factors, such as lack of social supports, smoking, diet, and alcohol use. Possible associations between anger and race, socioeconomic status, and gender also represent potential confounds. In sum, although more research is necessary to establish the specifics of the relationship, it appears that anger and hostility do play a role in the development of CHD.

Depression and Anxiety

DEPRESSION.

Recent work has begun to focus on the influence of depression and, to a lesser degree, anxiety on the onset, course, and outcome of CHD. A substantial body of prospective research indicates that major depression and subthreshold depressive symptoms, in both healthy individuals and in patients with CHD, confer an increased risk for subsequent cardiac events. Depression is prevalent in patients with CHD. Clinically significant depressive symptoms are found in 40 to 65 percent of patients after a myocardial infarction, and the prevalence of major depressive disorder is 20 to 25 percent in such patients.[8] [9] In one study, 31.5 percent of post-myocardial infarction patients experienced major depression in the hospital or within 1 year after discharge.[10] The prevalence of depression is also elevated in patients with stable CHD who have not had a recent myocardial infarction or other cardiac event (as high as 20 percent in some studies) and in patients who have undergone coronary artery bypass surgery.[11] Although most subjects in these studies have been male, there is evidence that the risk of depression in women with CHD is twice as high as that of men. Studies also reveal that depression is consistently underdiagnosed by cardiologists and primary care physicians in these patients.

Depression is of course important in and of itself because of the very considerable suffering it imposes. But in addition, depression exacerbates, prolongs, and amplifies cardiac symptoms. CHD patients with depression have more severe cardiac symptoms than nondepressed CHD patients, even after controlling for the severity of cardiac disease. Thus, depressed patients have greater levels of angina during exercise treadmill testing, terminate the treadmill test sooner, and have more persistent angina after myocardial infarction. In addition, depression engenders disability and role impairment, adversely affects compliance with medical therapy, and

is detrimental to cardiac rehabilitation. In a 1-year, prospective study of patients who had undergone catheterization for documented CHD, physical functioning and interference with activities were better predicted by baseline depression and anxiety than by the number of stenosed vessels, even after controlling for medical comorbidity and treatment.[12] Although major depression is most powerful in this regard, less severe forms of depression that do not meet diagnostic criteria for major depressive disorder also produce significant functional impairment, after controlling for individual differences in cardiac and medical comorbidity.

Depression also exerts a negative prognostic influence on the course and outcome of CHD. In patients with documented CHD, depression predicts future cardiac events and is associated with significantly elevated rates of cardiac mortality.[8] [13] [14] Major depressive disorder at the time of cardiac catheterization is a significant predictor of subsequent myocardial infarction, angioplasty, coronary artery bypass grafting, and death in patients with evidence of CHD, and this effect is independent of CHD severity, left ventricular ejection fraction, and smoking.[13] After myocardial infarction, depression increases the risk of future coronary events, including reinfarction, cardiac arrest, and death, after taking the severity of CHD into account.[8] [14] [15] In an important longitudinal study of 222 patients, baseline depression was a significant predictor of cardiac mortality 6 and 18 months after myocardial infarction, and this association persisted after taking into account the effects of baseline left ventricular dysfunction, Killip class, previous myocardial infarction, and frequency of premature ventricular contractions.[8] [14] For longer periods, from 6 to 27 years, the relative risk of myocardial infarction or cardiac mortality associated with depression has been reported to be between 1.5 and 6, after controlling for severity of cardiac disease.[14] [16] [17]

The degree of risk associated with depression is as great as that associated with traditional risk factors (e.g., cholesterol, smoking, hypertension) and is largely independent of them. This risk is elevated for women as well as men and not limited to diagnosable, major depressive disorder but also includes depressive symptoms. That is, there is a continuous, linear relationship between the number of depressive symptoms and the risk of subsequent cardiac events. An interaction effect may exist, in which the co-occurrence of both depression and ventricular arrhythmias exerts a particularly poor prognostic influence.[14] Interestingly, optimism seems to have a positive influence on prognosis; optimism at the time of coronary artery bypass surgery is associated with a lower rate of rehospitalization for cardiac events over the subsequent 6 months, after controlling for sociodemographic differences and disease severity.[18]

Depression also appears to be a risk factor for the development of CHD, although the evidence here is less extensive and somewhat less conclusive, especially since depression tends to co-occur with other risk factors for CHD. Some prospective studies report a modest association between depression and the incidence of CHD, but others fail to find a correlation. In longitudinal studies of initially healthy, community residents without a history of CHD, depression has been associated with a relative risk between 1.5 and 2 for the subsequent development of CHD, myocardial infarction, and cardiac death over periods from 6 to 40 years, and this risk is largely independent of the more traditional risk factors.[16] [17] [19] [20] [21] For example, in a prospective study of 2832 healthy adults, depressed mood was a significant predictor of subsequent fatal and nonfatal CHD.[16] Similar prospective findings have been reported in men and women over a 27-year period and in men over 40 years. Other work, however, has failed to confirm these findings: depression was not associated with an increased risk of CHD over a 15-year period in a study of 2573 adults,[22] nor was it associated with an increased risk of myocardial infarction in a 5-year follow-up of elderly individuals with hypertension.[23]

In sum, the evidence at this point indicates that depression confers an increased cardiovascular risk on healthy individuals and on individuals with already established CHD. Both major depressive disorder and elevated levels of depressive symptoms are significant in this regard. The degree of risk associated with major depression is comparable to that associated with other, established risk factors and is largely independent of them.

This relationship between depression and CHD may be mediated by several different behavioral and physiological mechanisms. Depression may operate through its influence on behavior: Depressed individuals may take poorer care of themselves, pay less attention to diet, drink more alcohol, smoke more, have less motivation and energy to exercise regularly, and be less likely to seek medical care and adhere to the medical regimen. There is, however, only limited empirical evidence bearing on this hypothesis. In addition, depression hinders recovery and causes poorer psychosocial adjustment to, and coping with, disease. Depressed post-myocardial infarction patients are more likely to experience social readjustment problems in the year after myocardial infarction than nondepressed post-myocardial infarction patients, are slower to return to work, and report more associated stress. Depression has an additional adverse consequence: It is associated with poorer adherence to the medical regimen[24] and to cardiac risk factor modification and rehabilitation programs, and depressed patients are more likely to drop out of exercise programs.

At least three separate pathophysiological mechanisms may link depression to CHD.[25] [26] First, depression results in autonomic arousal with hypothalamic-adrenocortical and sympathoadrenal hyperactivity. Depressed patients show hyperactivity of the hypothalamic-pituitary-adrenocortical axis and hypercortisolemia, and corticosteroids have atherogenic effects, including the induction of high blood pressure and increases in cholesterol and free fatty acids. In addition, there is hypersecretion of norepinephrine in depression, and such sympathoadrenal activation can contribute to cardiovascular disease through the direct effects of catecholamines on cardiac function, blood vessels, and platelets. Second, depressed patients exhibit diminished heart rate variability, and this has been found specifically in depressed cardiac patients as well.[27] This is believed to result from a relative increase in sympathetic tone and/or a relative decrease in parasympathetic tone, and it places depressed cardiac patients at greater risk for fatal arrhythmias. Third, depression may be accompanied by changes in platelet aggregability. Serotonin, which plays a role in depression, influences thrombogenesis and enhances platelet activation and responsiveness to other thrombogenic agents.

ANXIETY.

In addition to depression, chronic anxiety and anxiety disorders such as panic disorder and phobias appear to exert a negative influence on the heart, and several studies suggest a relationship between anxiety disorder and increased cardiac morbidity and mortality. Anxiety has been found to predict CHD mortality and sudden cardiac death in a large, population-based, prospective study, after adjusting for a range of potential confounding variables.[28] In another study, anxiety was an independent predictor of cardiac events after myocardial infarction, after the influence of depression was taken into account.[29] There is also suggestive evidence for anxiety as a risk factor predisposing one to the development of CHD. Thus, initially healthy men who reported phobic anxiety were found to have a strikingly increased likelihood of subsequent death due to CHD, even after taking other CHD risk factors into account.[30] Possible mechanisms explaining this association include a decrease in vagal activity and consequently in heart rate variability in intensely anxious patients, microvascular angina, or idiopathic cardiomyopathy.

Psychosocial Factors

A number of psychosocial, cultural, and environmental factors increase the risk of CHD, either independently or in combination. These include social isolation and lack of social support, life stresses such as job strain, and sociodemographic characteristics. It is important to remember that these psychosocial risk factors tend to be associated with each other and therefore to co-occur within the same individuals. For example, job strain and socioeconomic position may be inversely correlated, and depression may be positively associated with social isolation. These psychosocial factors also tend to be associated with life-style behaviors that are unhealthy. For example, life stress may be correlated with smoking and increased alcohol consumption and body weight, and people with fewer social supports are less likely to stop smoking or to adhere to the medical regimen. This co-occurrence or clustering of psychosocial factors within the same individual is important because they may have a synergistic and not merely an additive effect in elevating risk. This interaction effect also makes studying the role of these variables more difficult.

SOCIAL ISOLATION, LACK OF SOCIAL SUPPORT, AND SOCIAL DISRUPTION.

The literature on social support and cardiac disease emerged from population-based, cross-sectional surveys revealing that measures of social integration (such as being married, having regular contact with friends, and belonging to organizations) were associated with lower levels of CHD. Subsequent work substantiated this, revealing that social isolation and low social support (living alone, having few friends or family members, and not belonging to organizations, clubs, or churches) are associated with an increased incidence of CHD and a poorer outcome after the first diagnosis of CHD. Thus, those who live alone, are unmarried, or are without a confidante have a higher rate of recurrent myocardial infarction, fatal myocardial infarction, and all-cause cardiac mortality than those who are more socially integrated. Among patients with documented CHD, being unmarried and without a confidante confers a significantly worse 5-year prognosis, even after medical risk factors have been taken into account.[31] Berkman and associates found that elderly men and women who reported less emotional support from others before they sustained a myocardial infarction were almost three times more likely to die in the 6 months after it, after controlling for severity of infarction, comorbidity, coronary artery disease, and socioeconomic status.[32] This effect may be particularly robust in men.

However, many studies of social support and survival after myocardial infarction are retrospective or do not adequately assess and control for comorbid disease. There is suggestive evidence of an interaction effect between low social support and Type A behavior pattern such that low social support is a negative cardiac influence in Type A individuals but not in Type B individuals. Interestingly, animal studies also suggest social support has a protective role against atherogenesis. Thus the fondling by research personnel of laboratory rabbits placed on an atherogenic diet retards the development of coronary artery disease.[33] Crowding and social disruption of animal colonies on the one hand and isolation of individual laboratory animals on the other[34] both result in significantly increased rates of atherogenesis, and this effect is not due to increases in serum lipids.

Acculturation also influences the development of CHD. A classic epidemiological survey compared Japanese men living in Japan, Hawaii, and California. Traditional

Japanese culture and lifestyle declined across the three groups, and this was accompanied by an increased incidence of CHD.[35] Similar findings emerged when comparing Japanese-Americans living in California who retained the traditional Japanese culture to varying degrees.[36] Animal work is also

provocative in this regard. Dominant male monkeys fed an atherogenic diet develop coronary atherosclerosis at an accelerated rate when repeatedly moved from one social group to another rather than when left in a single, stable group.

Several mechanisms of action have been proposed to explain the relationship between social integration and CHD. First, concerned and supportive others may encourage healthy behaviors and adherence to the medical regimen and provide a motivation for altering unhealthy, behavioral risk factors. Conversely, loneliness may foster unhealthy behaviors such as smoking and drinking. Second, social support may attenuate and buffer the individual's emotional and/or physiological response to environmental stress. This may occur by virtue of the emotional benefits of comfort, encouragement, and consolation, as well as through practical assistance that mitigates the impact of stressful life events, for example, lending money, assisting with errands, and providing transportation.

LIFE STRESS AND JOB STRAIN.

There has long been interest in the relationship between life stress and the development and progression of CHD. In animal studies ranging from mice to primates, stressful experimental paradigms that increase aggression and fear, and that decrease social affiliation and disturb stable social hierarchies, are associated with atherosclerosis. Thus, monkeys moved repeatedly from one stable monkey society to another developed more CHD than control monkeys.[37] In humans, two different forms of stress have received particular attention: major life events that tax one's abilities to adapt (such as getting divorced, moving, encountering financial difficulties, or being involved in a lawsuit) and more minor, recurrent irritants and daily frustrations. Some studies of individuals undergoing major, stressful life events have found an association with the incidence of myocardial infarction, the development of CHD, or cardiac mortality, whereas other prospective studies have not found a statistically significant association. At this point, the evidence remains inconclusive.

When turning to daily life stress, job strain and other forms of work-related stress have received considerable attention. Job strain is defined as the combination of high job demands with little autonomy or control over one's working conditions, routine, or schedule. Job strain has been associated with an increased risk of CHD in previously healthy people,[38] but its impact on the prognosis of already developed CHD is less clear. Cross-sectional studies in both the United States and Europe disclose that both male and female workers high in job strain have a higher prevalence of CHD and a higher incidence of myocardial infarction than do those with low job strain.[39] Longitudinal studies also provide some support for this hypothesis. In a large, 1-year prospective study, both men and women in higher-strain jobs had significantly higher rates of myocardial infarction.[40] Johnson and associates[41] conducted a longitudinal study of 12,517 Swedish men over a 14-year period and found that low levels of control over one's work conditions were an independent risk factor for cardiovascular disease mortality. After adjusting the data for the influences of age, smoking, exercise, and social class, workers with low levels of control over their jobs had a relative risk of 1.83 (95 percent CI=1.19 to 2.82) for cardiovascular mortality. Workers with both low control over their work and low levels of social support had a relative risk of 2.62 (95 percent CI=1.27 to 5.61) for cardiovascular mortality.

SOCIODEMOGRAPHIC CHARACTERISTICS.

Health status in general is correlated with socioeconomic position, and persons of lower position have higher rates of CHD and a poorer prognosis after myocardial infarction. Lower socioeconomic status (whether assessed by education, occupation, or income) prospectively predisposes healthy people to an increased risk of CHD and CHD patients to a poorer prognosis. The decline in cardiovascular disease mortality over the past 30 years in the United States has been more pronounced among those of higher socioeconomic status, and the reasons for this are not clear. Because beneficial health habits (including not smoking and weight control) tend to be associated with socioeconomic status, they may play a role. Poorer nutrition and difficulty obtaining medical care may contribute. In addition, exposure to stressful life events, greater job strain, lack of social support, and diminished sense of self-control may also contribute to the relationship between socioeconomic status and CHD. Finally, hostility and depression may be inversely correlated with social position. There are also complex racial and ethnic differences in cardiovascular disease that remain poorly understood. Because race and ethnicity tend to be confounded with differences in socioeconomic position, it has been difficult to isolate their effects on the incidence, prevalence, course, and outcome of CHD.

Acute Mental Stress

Sudden, acute mental stress has negative cardiovascular consequences. Cardiovascular mortality rises in the month immediately after the death of a loved one,[42] and the incidence of cardiac events also rises immediately after natural disasters and among civilians subjected to military attack. The direct cardiovascular effects of sudden, acute mental stress have been observed during daily life with continuous, ambulatory monitoring and with laboratory paradigms that induce stress experimentally. These laboratory paradigms involve performing tasks that are aversive, challenging, or demanding, such as public speaking or accomplishing difficult intellectual tasks under time pressure or in frustrating circumstances. Such stressors reliably increase heart rate, blood pressure, and myocardial oxygen demands. The effect of acute mental stress on the heart already damaged by preexisting CHD has been studied extensively. Recent work has employed relatively sensitive measures of myocardial ischemia, including regional myocardial perfusion (measured with positron emission tomography) and wall motion abnormalities (assessed with radionuclide ventriculography and echocardiography). Such stress can precipitate myocardial ischemia in 30 to 60 percent of CHD patients.[43]

Mental stress-induced ischemia occurs at lower heart rates and at a lower level of myocardial work than does exercise-induced ischemia, suggesting that decreases in myocardial perfusion may play a role in mental stress-induced ischemia. In a representative study, 59 percent of CHD patients (and 8 percent of controls) exhibited myocardial ischemia during periods of experimentally induced stress using radionuclide ventriculography to detect wall motion abnormalities indicative of ischemia.[44] One third of the CHD patients had a decrease of at least 5 percent in ejection fraction. Clinical characteristics, such as extent of CHD, did not differentiate between those who did and did not develop ischemia when stressed.[44] Such mental stress-induced ischemia is more likely to be "silent" or asymptomatic than is the ischemia induced by exercise. In the study just referred to, 83 percent of mental stress-induced ischemic episodes were asymptomatic.[44]

When patients with preexisting CHD are monitored during daily life, mental challenges, in the absence of strenuous physical exertion, are frequently accompanied by transient myocardial ischemia. Such ischemia has been observed, for example, while driving and during public speaking. Whereas most ischemic episodes during daily life do not appear to be precipitated by psychological or mental stress, a sizable minority (perhaps as many as one fourth) are.[45] [46] Methodological difficulties however, make it difficult

to establish the relative frequency of such psychological stressor-induced episodes.

CHD patients who exhibit mental stress-induced ischemia during daily life or in the laboratory setting appear to be at increased risk of subsequent fatal and nonfatal cardiac events.[47] [48] This relationship persists after other risk factors (including age, left ventricular function, and prior myocardial infarction) have been taken into account.[47] Acute stress may promote ischemic heart disease in a number of ways. First, stress increases myocardial oxygen demands as a result of its hemodynamic effects. There may also be a decrease in coronary blood flow secondary to vasospasm, especially in more severely diseased vessels.[49] Stress also activates the sympathoadrenal medullary and pituitary-adrenocortical systems, with increases in circulating cortisol and catecholamines, which activate platelets and promote platelet aggregation and which increase cholesterol and decrease high-density lipoproteins. The net result of all these effects is to increase cardiac demand while at the same time decreasing coronary blood supply and to promote plaque rupture and increase thrombus formation.

Sudden Emotion

The work on anger, depression, and anxiety discussed earlier deals with the long-term consequences and sequelae of enduring, persistent emotions. There is also a body of work on the immediate and acute effects of sudden, intense, negative emotion on the cardiovascular system. Because much of this work focuses on its role in triggering arrhythmias and sudden cardiac death, it will be reviewed in the next section. It is important to note here, however, that mental activities leading to intense anger and, to a lesser degree, to anxiety are also potent triggers of myocardial ischemia.[50] [51] Thus, there is a twofold increase in the risk of myocardial infarction in the 2 hours after an episode of intense anger.[52] Because these intense, negative emotional states involve sympathetic arousal, they may act by triggering coronary vasospasm, rupture of atherosclerotic plaques, and increased platelet aggregation. Anger and hostility in particular have been associated with increased platelet adhesion.[53] Hostility is also associated with decreased parasympathetic arousal during ambulatory monitoring.[54] When anger is experimentally induced, patients scoring higher on hostility scales exhibit greater sympathetic nervous system-mediated cardiovascular responses than those who are less hostile.[55]

ARRHYTHMIAS AND SUDDEN CARDIAC DEATH

Increasing evidence links mentally stressful and emotionally powerful events with lethal arrhythmias and sudden cardiac death (SCD). Intense emotions such as anxiety and anger, and the events that arouse them, have been associated with both benign and lethal arrhythmias, including ventricular premature contractions, ventricular tachycardia, and ventricular fibrillation. This effect is most evident in hearts that are already diseased, ischemic, or electrically unstable. There are at least three lines of investigation into the arrhythmogenic potential of stress, emotion, and psychiatric distress: epidemiologic surveys examining the role of life stress or psychiatric distress in predisposing to the subsequent development of lethal arrhythmias or SCD; psychophysiological experiments and anecdotal case reports of sudden, intense emotion or acute stress as immediate precipitants of arrhythmias or SCD; and investigations of the central nervous system's influence over cardiac rate and rhythm.

It has long been suspected that acutely stressful events and sudden, intense emotion can on occasion precipitate fatal arrhythmias and SCD. In 1971, Engel, using reliable, historical anecdotes, compiled a series of cases in which individuals were observed to die suddenly at the peak of intensely stressful and overwhelmingly emotional or traumatic experiences.[56] Reich and colleagues[57] subsequently conducted a careful, retrospective, psychiatric interview of patients hospitalized after a documented episode of ventricular tachycardia or ventricular fibrillation. They found that 21 percent had a major emotional disturbance or psychological trigger in the preceding 24 hours.[57] These included interpersonal conflicts, bereavement, public humiliation, marital separation, and business losses. Other studies produced comparable findings: one fourth to one half of SCD victims were thought to have died within minutes to hours after major psychological stress and acute emotional arousal.[58] [59] Although studies like these tend to suffer from problems of retrospective bias and selective recall, inadequate or absent control groups, and sampling bias, when taken together they nonetheless suggest that acute stress (perhaps in conjunction with other factors such as preexisting ischemic heart disease) can precipitate lethal arrhythmias and contribute to sudden cardiac death in a sizable fraction of cases.

Another line of research has examined the link between emotionally provocative daily stresses and arrhythmias. In healthy subjects, increases in ventricular ectopy occur during driving, public speaking, and stressful interviews. Among cardiac patients undergoing ambulatory monitoring, daily life stresses (but not major life change events) are statistically associated with ectopy. Lown[60] [61] and others have shown that experimentally induced psychological stress lowers the ventricular vulnerable period and the threshold for ventricular fibrillation and increases the frequency of ventricular ectopic beats in patients with preexisting ventricular arrhythmias. The acute, arrhythmogenic effect of stress-induced, sympathetic arousal has been demonstrated in patients with the long QT syndrome. Thus it is clear that stressful experiences and events can produce rhythm changes in both normal subjects and CHD patients. The clinical importance of this remains to be established, but the combination of severe, acute mental distress and a myocardium made vulnerable by virtue of preexisting disease can result in lethal arrhythmias and SCD.

Stressful events and the emotional distress that they evoke also have a less immediate and more prolonged effect in predisposing the individual to lethal arrhythmias and SCD over the long term. Thus, a number of studies report increases in life stress in the months preceding SCD. One prospective study of post-myocardial infarction patients found that a measure of life stress predicted sudden cardiac death in the following 3 years. However, for the most part this research is based on retrospective recall by a spouse or other informant and is subject to systematic reporting bias. In addition, many of these studies lack suitable control groups and/or employ problematic measures of life stress.[62]

EPIDEMIOLOGICAL SURVEYS.

These suggest that some psychiatric disorders may also predispose to SCD. Anxiety disorders in particular appear to confer an increased risk of cardiac events, cardiac mortality, and SCD.[26] [63] [64] However, these studies are limited in number and generalizability. In one study, psychiatric distress during hospitalization for myocardial infarction predicted ventricular arrhythmias during ambulatory monitoring in the year after the infarct,[61] although a subsequent study by the same investigators failed to confirm these findings.[65] In retrospective work, female SCD victims with no prior history of cardiovascular disease were more likely to have had a psychiatric history than demographically matched, healthy controls.[66] Depression was the most common psychiatric diagnosis in these

studies, and hopelessness may be the most toxic element of depression in this regard.[26] However a number of possible confounds make this work difficult to interpret, and on balance the evidence at this time must be considered equivocal.

Sociocultural and sociodemographic factors may also play a role in SCD. The inverse relationship found between socioeconomic status and cardiac mortality in general is especially robust for SCD, although this may be confounded by an association between socioeconomic status and access to emergency medical care. Other work has disclosed that cardiac mortality is significantly higher immediately after, as compared with immediately before, an important religious holiday. There are also well-recognized, culture-specific syndromes in which sudden death follows ritualized events that have a powerful, culture-specific significance (such as "voodoo death").

The link between stress and arrhythmias has been explored in experimental animal work. When dogs are subject to aversive restraint and electric shock, there is a 49 to 66 percent decrease in the repetitive extrasystole threshold.[67] If a coronary artery occlusion is first produced experimentally, then the same stressful paradigm induces spontaneous ventricular fibrillation.[68] Similarly, when pigs with a coronary artery occlusion are placed in a stressful environment, there is a high incidence of spontaneous ventricular fibrillation.[69] Conditioning and adaptation to the stress reduce its arrhythmogenic effect.

NEURAL CONTROL OF RHYTHM.

A number of pathways mediate neural control of heart rate and rhythm. First, activation of the hypothalamic-adrenomedullary axis, with a resulting increase in circulating catecholamines, increases myocardial irritability and decreases the threshold for inducing ventricular fibrillation. Second, direct sympathetic innervation of the heart exerts a proarrhythmic effect, increasing ventricular ectopy and lowering the threshold for inducing ventricular arrhythmias, especially in the heart with preexisting ischemic damage or electrical instability. This effect is moderated by an antiarrhythmic, protective effect exerted by the parasympathetic system through the vagus nerve. Animal work has revealed evidence of cortical and brain stem control of cardiac rhythm. Pathways run from the frontal cortex and hypothalamus to the brain stem nuclei controlling cardiovascular function. Stimulation of the lateral and posterior hypothalamus lowers the ventricular fibrillation threshold, and blockade of these corticofrontal pathways can raise the threshold. In humans, electrocardiographic (ECG) changes in rhythm and/or repolarization are seen in many patients suffering cerebrovascular accidents involving the cortex.[70]

Finally, extreme stress and acute psychological trauma can result in myocardial necrosis. In animal models, large quantities of catecholamines, either exogenously administered or stress induced, can result in myofibrillar degeneration and myocardial necrosis. Pathological examination reveals widespread calcification, the result of peroxidation of myocardial lipid membranes and blockage of the calcium channel pump. This same lesion has also been reported in humans who died suddenly at the peak of extreme psychic stress and trauma.[71]

PSYCHIATRIC AND BEHAVIORAL ASPECTS OF HYPERTENSION AND CONGESTIVE HEART FAILURE

Hypertension (see also Chap. 28)

Stress, conditioned learning, and autonomic arousal can all elevate blood pressure. Stimulation of brain sites with connections to the sympathetic nervous system elevates blood pressure, and many of these sites are in turn connected with higher centers involved in the perception of the environment. But the transient elevations of blood pressure that humans manifest in stressful and provocative situations may be unrelated to the persistent, sustained elevation that constitutes the disease of hypertension.

STRESS AND BLOOD PRESSURE.

Stressful environments and situations that are challenging or aversive transiently increase the blood pressure of both normotensive and hypertensive individuals. This has been demonstrated in field studies using ambulatory monitoring of blood pressure during daily life and in laboratory studies assessing blood pressure reactivity to a discrete stimulus or specific experimental stressor. Some individuals exhibit greater reactivity than others, consistently responding to psychological stressors with greater increases in blood pressure and heart rate, more vasoconstriction and catecholamine secretion, and a more prolonged recovery phase. These individual differences in cardiovascular reactivity emerge early in life and appear to be stable and enduring over time. Such physiological hyperreactivity has long been thought to predispose to the eventual development of hypertension and atherosclerosis, but the hypothesis remains unproven and the evidence is still inconclusive. Patients with clinically diagnosed hypertension have been reported to show greater blood pressure responses to behavioral challenge than normotensive individuals,[72] and some prospective studies suggest that greater cardiovascular reactivity to stress is associated with subsequent, higher systolic and diastolic blood pressure.[73] [74] But the use

of laboratory challenges is problematic, and it is not clear that transient blood pressure increases in response to such stressors are precursors of pathological, sustained hypertension.[75] A number of studies have examined whether normotensive individuals with a family history of hypertension show greater cardiovascular reactivity to experimental mental stressors than normotensive individuals without such a family history. The results of this work remain inconclusive and equivocal.[76]

In surveys examining the relationship between naturally occurring stress and blood pressure, major life stress has been associated with the onset or worsening of essential hypertension. Job strain in particular has been associated with an elevated prevalence and incidence of hypertension in men (although this is less clear in women), and the blood pressures of people in more stressful occupations tend to be higher than those in less stressful jobs. However, it appears that such chronic stress requires the simultaneous presence of other etiological factors (e.g., genetic endowment, dietary factors, or renal disease) to cause sustained hypertension. This situation may be analogous to that emerging from animal work. In animals predisposed to hypertension by genetic endowment or salt ingestion, repeated exposure to stress can lead to sustained hypertension.[77] But sustained hypertension does not appear to result in healthy animals without such predisposing factors.

PSYCHOLOGICAL INFLUENCES.

Anger and anxiety are accompanied by increases in peripheral vascular resistance and blood pressure. Anger has been thought to predispose to the development of essential hypertension, but this is controversial, particularly because much of the relevant research is either retrospective or cross-sectional.[78] Hostile individuals respond to provocation, conflict, and disagreement with larger increases in blood pressure than do people who are less hostile.[79] There have been reports of higher levels of anger and suppressed anger among hypertensive patients, but the direction, significance, and certainty of this association remains unclear. In a prospective study, increases in trait anger in women did predict increases in blood pressure over a 3-year period, after controlling for biological and genetic variables.[80] However, it does not appear that the prevalence of essential hypertension

is elevated in hostile, Type A individuals. Studies of minority populations tend to disclose a closer link between anger and hypertension than do studies of nonminorities.

Recent work has focused on the more-difficult-to-measure construct of repressed or*suppressed* emotion (particularly anger), and there are reports of an association between emotional inhibition and essential hypertension. A meta-analysis concluded that there does appear to be an association between*suppressed* anger and resting blood pressure.[81] In one prospective study, men who suppressed their feelings when faced with an interpersonal conflict were more likely to be hypertensive at follow-up.[82] But, in general, this literature is still inconclusive, in part because of the difficulty in distinguishing transient angry states from anger as a stable, enduring personality trait.

Other studies have examined the role of anxiety. There is some evidence that chronically anxious persons develop greater increases in systolic blood pressure over the ensuing years[80] [83] and may also be at increased risk of developing essential hypertension.[80] [84] It has been suggested that psychological stressors tend to produce more anger in males and more anxiety in females.[79] Both of these affective states are accompanied by arousal of the sympathetic nervous system, and this suggests that chronically increased sympathetic tone is a final common pathway to elevated blood pressure.[80] Finally, the possible etiological role of depression has also been investigated. The prevalence of hypertension is reported to be higher in depressed community residents, depressed medical patients, and depressed psychiatric patients than in nondepressed comparison groups.

Based on this work, therapies such as relaxation training and meditative techniques, blood pressure and heart rate biofeedback, and psychotherapy incorporating relaxation training have all been employed to treat hypertension. Relaxation techniques and meditation apparently decrease blood pressure by lowering total peripheral resistance and vasoconstrictive tone.[85] One potential weakness of such therapies is that the treatment effect may decay upon discontinuation of active treatment. Some studies, however, have found that the beneficial effects of relaxation training (combined with pharmacotherapy) were still evident at long-term follow-up after the behavioral treatment ended.[86] In one study, relaxation training lowered blood pressure while the exercises were being practiced, but ambulatory blood pressure readings during daily life did not decline.[87] In sum, although these behavioral techniques are not very effective when used alone, they may provide some incremental benefit when added to the conventional antihypertensive regimen.[78] They may lead to modest reductions in blood pressure or enable the physician to employ lower doses of antihypertensive medication.[78] The latter outcome is of more than trivial significance because nonadherence to the antihypertensive medication regimen is very common and constitutes a major impediment to effective treatment.

SOCIOCULTURAL FACTORS.

Epidemiological and animal studies suggest a relationship between high blood pressure and sociocultural conditions. Essential hypertension tends to be less prevalent in societies with stronger cultural traditions and more widely held value systems and in those that are safer and more stable, than in societies with more disintegration, higher crime rates, and less stable social orders. In societies undergoing transition, conflict, or disintegration, blood pressures tend to rise over time, but many factors (e.g., changes in diet) may be contributing.[88] Individuals in more crowded and stressful living and working environments tend to show increased levels of catecholamines, increased cardiovascular reactivity, and higher average blood pressures. Animal studies seem to corroborate these findings: Mice subjected to crowding and exposed to threat from cats develop sustained high blood pressure.[89]

Congestive Heart Failure (see also Chap. 17)

The psychiatric and behavioral aspects of congestive heart failure (CHF) have only recently been subjected to scrutiny. It appears that the sorts of psychosocial factors that influence the course and outcome of CHD may also influence CHF. Stress and emotional distress have been linked to the onset or exacerbation of CHF, perhaps by increasing heart rate and blood pressure and/or by provoking myocardial ischemia in patients with preexisting, severe CHD. Emotional factors have been reported to precede admission in 49 percent of hospitalizations for CHF.[90] It has been suggested that left ventricular function is impaired during psychological stress,[91] and stress-induced heart failure has been described. In a study of patients with idiopathic cardiomyopathy, experimental psychological stress (mental arithmetic) was shown to induce changes in left ventricular diastolic function.[92]

Depression has received particular attention in CHF populations because it is chronic and debilitating, and because of its increased prevalence in the elderly. Freedland and coworkers[93] found that 17 percent of elderly patients hospitalized with CHF had current, major depression, and Havranek and colleagues[94] found a significantly higher prevalence of depressive symptoms in outpatients with CHF than in outpatients with hypertension. Others, however, have not found an elevated rate of depression in CHF. This research is complicated by difficulty in differentiating CHF from depressive disorders. The anorexia, fatigue, weakness, and insomnia (resulting from orthopnea and paroxysmal nocturnal dyspnea) accompanying CHF can be confused with the symptoms of depression, and the cardiac cachexia of end-stage CHF may also suggest severe depression. When CHF is severe enough to cause cerebral ischemia, then cognitive dysfunction, confusion, and delirium with psychotic symptoms may result. This may at times be difficult to distinguish from anxiety disorder and panic.

Social support appears to be an important moderator of the clinical course of CHF. Elderly women hospitalized with CHF who have no sources of emotional support have a more than threefold increase in the risk of cardiovascular events in the ensuing year than comparable patients with emotional support.[95] Elderly men without emotional support were not at increased risk. This work also underscored the importance of social ties, because patients without social ties had a more than twofold increase in cardiovascular events, even after taking emotional support into account.[95]

CARDIAC SYMPTOMS: CHEST PAIN AND PALPITATIONS (see also Chap. 3)

Chest Pain

Chest pain, the classic symptom of CHD, is a nonspecific, insensitive, and unreliable indicator of ischemia. Pain does not bear a fixed, one-to-one relationship to demonstrable pathology; many patients with chest pain have no heart disease, and ischemia and infarction are often asymptomatic. Approximately one fourth of myocardial infarctions are "silent," and 70 to 80 percent of out-of-hospital, ischemic episodes in CHD patients are asymptomatic. Conversely, no cardiac cause is found for the vast majority of complaints of chest pain. Even in patients with documented CHD, two thirds of chest pain episodes occur in the absence of ST segment depression indicative of ischemia.[51]

In one study of primary care patients presenting with chest pain that led to a diagnostic work-up, a definite medical cause could be established in only 5 of 80 patients, at a cost of $4354 per diagnosis.[96] Even among patients undergoing coronary angiography for chest pain, 10 to 30 percent have minimal or no angiographic evidence

of CHD.

The absence of demonstrable heart disease, however, does not mean that the patient's chest pain is either inconsequential or self-limited. Follow-up studies of chest pain patients with negative angiography and/or negative exercise stress testing reveal persistent distress and disability. Although rates of myocardial infarction and of cardiac morbidity and mortality remain low in these populations, these patients continue to exhibit elevated levels of symptoms, disability, and medical care utilization. At least half of these patients continue to report recurrent chest pain, the persistent belief that they have serious heart disease, and impaired functioning (at work, socially, and in daily activities) comparable to that of patients with myocardial infarction and angina.[97] [98]

Psychological, psychiatric, and behavioral factors mediate the relationship between CHD on the one hand and the resulting symptoms and disability on the other. Emotional distress is correlated with reports of chest pain in both CHD patients and in those free of cardiac disease.[12] Generalized psychological distress and body awareness is higher in patients with chest pain and normal coronary arteries than in those with CHD.[99] Mood and daily activities may account for as much of the variability in ambulatory patients' reports of chest pain as does ST depression indicative of ischemia.[51] The level of disability in patients with medically unexplained chest pain is strongly associated with the presence of psychiatric morbidity.[98]

Several psychological factors tend to differentiate chest pain patients with and without demonstrable cardiac disease. When those with normal angiography or normal stress tests are compared with those with positive tests, the former group is younger, more likely to be female, and has more psychological distress and a higher prevalence of diagnosable psychiatric disorder.[100] [101] Patients with medically unexplained chest pain have a higher than expected prevalence of depressive and anxiety disorder.[100] When compared with chest pain patients with positive findings on angiography, they have elevated rates of panic disorder (35 to 50 percent vs. 5 percent) and of major depressive disorder (approximately 35 to 40 percent vs. 5 to 8 percent). Of course, cardiac and psychiatric disorders are not mutually exclusive and not infrequently co-occur. Thus, 5 to 23 percent of patients with angiographic evidence of CHD also have panic disorder. These cases of psychiatric and cardiac comorbidity pose especially difficult diagnostic dilemmas, and it is in them that panic disorder is most likely to be overlooked. The chest pain seen in panic disorder is more likely to be atypical in clinical character and to be accompanied by palpitations, dizziness, paresthesias, and multiple other somatic symptoms.

Palpitations

Palpitations are among the most common symptoms encountered in medical practice, reported by 16 percent of patients in a large survey of a primary care clinic.[102] Yet this subjective sensation corresponds very poorly to demonstrable abnormalities of cardiac rate or rhythm: Most palpitations are not accompanied by arrhythmias, and most arrhythmias are not perceived and reported as palpitations. When patients complaining of palpitations undergo 24-hour, ambulatory ECG monitoring, 39 to 85 percent manifest a rhythm disturbance (the vast majority being benign and clinically insignificant). Approximately three fourths of these patients with arrhythmias report at least one palpitation during 24 hours of monitoring, but in less than 15 percent of them do their symptoms coincide in time with the arrhythmia. Thus, accurate symptom reports occur in less than 10 percent of all patients being monitored.

Because palpitations are rarely accompanied by a clinically significant arrhythmia, it is not surprising that a high proportion of such patients either have a psychiatric cause for their symptom or no etiology can be established. In a careful survey of 190 patients presenting with palpitations, 31 percent were judged to have a psychiatric basis for their presenting symptom and no etiology could be established in an additional 16 percent.[103] The most common psychiatric cause of palpitations is panic disorder, which is found in more than a fourth of ambulatory medical patients complaining of palpitations. In one study, 31 percent of 229 such patients had panic disorder or panic attacks, and in another study, 28 percent of patients referred for 24-hour ambulatory ECG monitoring for palpitations met criteria for lifetime panic disorder and 19 percent met criteria for current panic disorder.[104] In the latter study, a high prevalence of depressive disorder was also reported.

Palpitations that have no demonstrable cardiac basis are nonetheless a persistent and disturbing problem for many patients. In a naturalistic, 1-year follow-up study, 75 percent of palpitation patients were found to have experienced recurrent symptoms, 19 percent reported impairment of their work performance, and 37 percent reported impairment in their role functioning at home.[103] In another study, 84 percent of palpitation patients remained symptomatic 6 months after initially presenting, and they had an elevated rate of medical utilization during the follow-up interval.[105]

Panic attacks and arrhythmias may be difficult to distinguish clinically. Both may present with palpitations, shortness of breath, and lightheadedness, and both not infrequently occur in the young and in those who are otherwise healthy. Frank syncope, however, is unusual in panic disorder and if there have been multiple episodes, panic attacks are more stereotyped and more consistent from episode to episode. Recurrent panic attacks tend to lead to agoraphobia, in which the patient first becomes apprehensive about, and then avoids, situations such as being left alone, trapped in large crowds, and journeying far from home. Conversely, to make matters more difficult, the sympathetic arousal that may accompany an arrhythmia (and other acute cardiac events such as pulmonary emboli, acute valvular dysfunction, and myocardial ischemia as well) may be experienced and reported by the patient as acute anxiety or panic rather than as a cardiac event.

Delay and Denial of Cardiac Symptoms

Myocardial infarction patients commonly ignore, rationalize, or explicitly deny their symptoms, so that the average interval between the onset of symptoms and arrival in an emergency department is between 3 and 9 hours, depending on the study.[106] Delay before seeking medical attention for acute myocardial infarction is a serious problem, in part because a high proportion of myocardial infarction deaths occur soon after the event and in part because the newer therapies to preserve myocardial tissue (e.g., intravenous thrombolysis) require early intervention (see Chap. 36) . Delay is greater in women and in the elderly[107] [108] and (paradoxically) in those with a history of previous myocardial infarction.[107] From a practical standpoint, a crucial determinant of the length of delay is the interval before the myocardial infarction sufferer informs someone else of his or her symptoms; once the patient informs another person of his or her distress, help is usually rapidly obtained.

PSYCHIATRIC CARE OF THE CARDIAC PATIENT

Acute Care of the Hospitalized Patient

The onset or sudden progression of cardiac disease is a frightening and powerful emotional experience. Pain and physical discomfort, the specter of sudden death or invalidism, and the knowledge that one has a chronic and potentially lethal disease are all profoundly distressing. The initial reaction is almost always one of anxiety. Fears of premature, sudden death loom, and worries about physical, sexual, social, and occupational incapacity materialize and plague patients. They may become terrified of any physical activity or strong emotion, fearing that these can immediately trigger sudden death. As time passes and chronicity sets in, anxiety may be replaced with despondency and a heightened sense of physical vulnerability and of one's mortality. The individual may come to feel damaged or diminished. Patients may feel that their job performance and future livelihood have been irrevocably compromised, that they are old and decrepit, and that they face a restricted and empty future. They may feel guilty and blame themselves for falling ill, ascribing their plight to their failure to exercise enough, diet sufficiently, or maintain other "healthy" habits. All of this may lead to a clinically significant, depressive episode.

Several psychiatric and behavioral problems commonly arise in patients hospitalized for an acute cardiac event. In addition to the illness itself, the experience of hospitalization (and in particular admission to the coronary care or intensive care unit) can be frightening and stressful. Patients suddenly find themselves in an unfamiliar, alien, and terrifying world, surrounded by fearsome machines with blinking lights and beeping alarms, subjected to painful procedures and tests about which they know little and understand less, while their lives seemingly hang in the balance from moment to moment. The daily routine and the food are alien, and patients feel cut off from family, friends, neighbors, and all that is familiar. Sustained sleep is next to impossible, and many are afraid to fall asleep, believing that the heart is in greater jeopardy during sleep. Their worst fears may seem to come true when they witness a cardiac arrest, or even the death, of another patient.

Hospitalized patients should be kept well informed about what is transpiring, what is being done medically for them, and why. They should be told what to expect before procedures are carried out; the functions of equipment should be explained; and the effects and (especially) side effects of medications should be described in advance. The patient should be reassured that anxiety is a normal and entirely appropriate reaction. Anxiolytics are often prescribed because anxiety is not only uncomfortable but its concomitant sympathetic arousal can be medically dangerous. Benzodiazepines are most commonly used for this purpose and should be prescribed on a regular, round-the-clock (rather than as needed) basis. In the elderly and in those with compromised liver function, the shorter-acting benzodiazepines (e.g., oxazepam or lorazepam) are preferred, because they are cleared primarily by the kidneys. The pharmacology of anxiolytics is discussed in the following section.

DELIRIUM.

This condition is not infrequent in hospitalized cardiac patients, especially after cardiac surgery. Delirium is characterized by an altered level of consciousness and a fluctuating state of confusion. The delirious patient is disoriented to time and place, has impaired memory and attention, develops delusional ideas, and experiences perceptual disturbances such as illusions or hallucinations. The sleep-wake cycle is disrupted, and the level of consciousness and arousal is disturbed, so that the patient may be either stuporous or obtunded, or hyperalert, restless, and agitated. The onset of delirium may be insidious (e.g., insomnia, mild nocturnal confusion, and

restlessness) and go unnoticed by the staff, or it may be dramatic and abrupt. The patient begins to misinterpret sensory information (for instance mistaking a shadow for someone lurking in a corner of his or her room) and becomes suspicious and increasingly frightened. As confusion, fear, and excitement mount, frank paranoia sets in and the patient may become agitated, disruptive, belligerent, and out of control. This is a psychiatric emergency, because in their confusion and frenzy, delirious patients may harm themselves accidentally, fall, or pull out therapeutic life lines, catheters, and implanted devices. The incidence of delirium after cardiac surgery is as high as 30 percent in some studies,[109] typically following a lucid interval of 3 to 5 days after surgery. The risk factors for postcardiotomy delirium are advanced age (older than age 70 years); more extensive aortic atherosclerosis (large atheromas may be liberated by surgical manipulation of the aorta); a prior history of neurological disease, particularly preexisting cerebrovascular disease; a history of pulmonary disease, with the concomitant risks of poorer cerebral oxygenation and more hypoxia; and surgery that is more extensive and of longer duration.[110]

Treatment of Delirium.

This rests on rapid identification and correction of the underlying cause of the delirium, medication for behavioral control if necessary, and supportive measures to provide comfort and safety. The etiological search is paramount. This means checking for cerebral hypoperfusion or hypoxia, acid-base disturbance, inadequate hydration, fluid and electrolyte imbalance, renal or hepatic failure, endocrine dysfunction, infection, and nutritional deficiency. Medications must be carefully reviewed because anticholinergics, narcotics, sedative-hypnotics, and H_2 blockers are common causes of delirium. Common offenders include cimetidine, digoxin, aminophylline, anticonvulsants, and all sedatives and hypnotics. Alcohol or drug withdrawal is a frequent cause, and the history must be searched carefully with this possibility in mind.

If the patient is agitated, combative, or confused enough to require behavioral control, high-potency antipsychotic drugs can be administered. Haloperidol has been widely used for this purpose and is safe and effective in critically ill patients, whether given orally or parenterally (including intravenously in emergency situations).[111] [112] Mild, delirious agitation is treated with 0.5 to 2 mg of haloperidol and moderate delirium with 5 to 10 mg; and the severely delirious patient can be given 10 or more mg of haloperidol. If the agitation persists unabated after 20 to 30 minutes, twice the original dose may be readministered. It has a minimal effect on heart rate, blood pressure, and respiration, and extrapyramidal effects are rare when it is administered intravenously. Parenteral droperidol is sometimes used. If excitement, hyperarousal, and motor agitation are especially prominent, the antipsychotic may be supplemented with a short-acting benzodiazepine such as lorazepam. Antipsychotic agents are discussed in the following section.

Supportive measures should be undertaken to calm, orient, and comfort the delirious patient. He or she should be reoriented frequently by the staff, and a clock and calendar should be prominently displayed to aid in this process. It is helpful to preserve as much of a day-night cycle as is feasible considering the hospital routine and to limit awakenings by staff during the night as much as possible. Family visitation should be encouraged because it is helpful in reassuring and calming the patient and in reducing paranoia. Familiar objects, such as family photographs, should be prominently displayed and plainly visible. Staff need to continually reintroduce themselves, educate the patient about what they are doing, and repeatedly explain the situation.

Physical restraint should be employed whenever necessary to prevent self-harm or harm to the staff.

Convalescence and Recovery

In the weeks after hospital discharge, depression is common, although it varies widely in severity. It is often self-limited, gradually diminishing as the patient resumes his or her old activities and as the specter of the acute episode and the hospitalization recede into the past. Frank discussion of the patient's concerns and educational information about common myths and fears are helpful. Lingering anxiety may have led patients to avoid activities or situations that they fear will provoke symptoms, cardiac events, or even sudden death. Early, progressive mobilization is the best antidote to anxiety and depression. The patient may be shocked and dismayed at the degree of exhaustion produced by even mild exertion, and although this easy fatigability is actually the result of deconditioning, it is mistakenly interpreted as evidence of permanent cardiac damage. As a result, exercise may be assiduously avoided, which only exacerbates the problem.

Patients are often apprehensive about returning to work because of the stress is engenders. Many believe that strong emotions can be lethal and try to protect themselves by assiduously avoiding all situations or activities that arouse strong feelings, such as sexual activity or watching sports on television. Sexual activity in particular is diminished, and sexual dysfunction is common in both women and men with cardiac disease.[113] Such concerns should be elicited by the physician and then discussed frankly and openly. Recommendations should be as specific as possible about which activities are prescribed and proscribed; simply saying "use your judgment" or "do it in moderation" is not helpful.[114] Group meetings of cardiac patients (such as post-myocardial infarction groups) to share common concerns, provide support, obtain educational information, and guide the progressive resumption of activities can be helpful in recuperation.

If depression lasts more than several weeks and is profound enough to meet diagnostic criteria for major depressive disorder, as happens in one third of patients in the year after myocardial infarction,[10] aggressive therapy is indicated. If left untreated, depression imposes a serious psychosocial burden, medical rehabilitation and recovery are impeded, and the depression itself is likely to become chronic. More than three fourths of post-myocardial infarction patients with major depressive disorder remain depressed 6 to 12 months later.[115] [116] It is thought that successful treatment (psychopharmacological and/or psychosocial) of depression in post-myocardial infarction patients will reduce subsequent cardiac morbidity and mortality, and large-scale, multiinstitutional intervention trials (e.g., Sertraline Antidepressant Heart Attack Randomized Trial [SADHART], Enhancing Recovery in Coronary Heart Disease [ENRICHD]) are now underway to test this hypothesis. The pharmacotherapy of depression is discussed in the following section.

Over the long term, some cardiac patients adopt a persistent coping style that is maladaptive and dysfunctional.[114] They may ignore the episode and deny their illness entirely, maintaining that nothing serious has happened at all. They may refuse to acknowledge any limitations or adhere to a therapeutic regimen, and generally overdo things. Alternatively, they may capitulate completely to their illness and retreat into unwarranted invalidism, becoming "cardiac cripples" who are preoccupied with their health, terrified by every benign twinge or cramp, and living a life of psychological invalidism and disability. Each of these profoundly maladaptive coping patterns deserves psychiatric attention.

Primary Prevention and Rehabilitation

Primary prevention programs attempt to modify behavioral risk factors in individuals who have not yet manifested significant disease, with the aim of preventing cardiac events from occurring or of delaying their onset. Secondary prevention programs focus on similar factors in patients who already have clinical evidence of disease, with the aim of retarding its progression. These psychosocial, educational, and behavioral programs may include many different components. Most programs assist patients to modify lifestyle behavioral risk factors, including smoking cessation, curtailing alcohol abuse, lowering saturated fat intake, and controlling weight. Almost all emphasize a formal program of graduated, progressive, aerobic exercise. Many programs include educational counseling about CHD, its risk factors and its treatment. Many also attempt to modify hostility or Type A behavior with cognitive/behavioral therapy.

Rehabilitation programs for patients who have sustained a cardiac event often aim to promote psychosocial adjustment and may include psychotherapy (see Chap. 39) . Most programs include stress management and relaxation training, in which patients are taught to identify social and environmental stressors, improve their use of social supports, and develop new skills for managing stressful situations and the disturbing effects that they evoke. Relaxation training generally combines elements of progressive muscle relaxation, diaphragmatic breathing, and focused attention. Patients are taught these techniques and are then encouraged to practice them regularly.

It is difficult to summarize the effectiveness of these heterogeneous psychotherapeutic, psychosocial, and behavioral programs because they vary so widely in quality, content, design, and intensity. Many intervention trials are flawed by small sample size, high dropout rates, insufficient long-term follow-up, and inadequate comparison or control groups. In addition, as standard cardiac care improves so substantially, it becomes more difficult to demonstrate the incremental benefit of these programs in terms of hard cardiac endpoints.[117] Trials reporting positive benefits have generally not been replicated. Nonetheless, it generally appears that when added to standard medical care, many of these programs are more effective than usual care alone in reducing psychiatric distress and morbidity, and in improving quality of life, disability status, and role functioning, and probably in reducing cardiac morbidity and mortality as well.[118] [119] [120] [121] [122]

A careful meta-analysis of 23 randomized, controlled intervention trials involving over 2000 patients, disclosed that when added to standard cardiac care, psychosocial interventions resulted in significant reductions in systolic blood pressure, heart rate, and serum cholesterol, and significantly lower rates of cardiac mortality and cardiac morbidity. These benefits were most evident in the 2 years after the intervention and became less evident thereafter.[118] Two meta-analyses of psychoeducational therapies found favorable effects on cardiac mortality, systolic blood pressure, and on exercise and diet.[123] [124] Finally a recent, thorough meta-analysis of 37 programs with varying components of psychoeducation and stress management found that they resulted in a 34 percent reduction in cardiac mortality and a 29 percent reduction in recurrent myocardial infarction, as well as significant effects on blood pressure and weight.[125]

PSYCHOSOCIAL INTERVENTIONS.

There is a growing interest in supportive, psychosocial interventions designed particularly to improve social support and lessen social isolation, often in combination with counseling or other treatment for depression and anxiety. In one study of 435 post-myocardial infarction patients randomized to a nursing-based psychosocial intervention or to medical care as usual, 1-year cardiac mortality was half as high in the intervention group[126] and the incidence of recurrent myocardial infarction was significantly lower at 7-year follow-up.[127] On the other hand, three large, randomized trials of multimodal, case management interventions conducted by nurses or health visitors[128] [129] [130] failed to demonstrate a clear reduction in depression or psychological dysphoria. Two of these studies found no effect on cardiac disease outcomes,[128] [129] and one study showed a marginally significant,*negative* impact of the intervention on cardiac outcomes in women.[130]

RELAXATION TRAINING.

Stress management techniques and relaxation therapy have been found to improve cardiac outcomes in some studies. Various combinations of these techniques have been shown to decrease the incidence and frequency of anginal episodes,[131] fatal and nonfatal cardiac events,[126] and disability and role impairment[132] and to improve quality of life. Relaxation training alone has been found to decrease fatal and nonfatal myocardial infarction[133] and to

improve cardiac function.[134] In one large-scale study, a 4-month program of stress management was compared with exercise training and usual care in patients with documented CHD. At follow-up an average of 3 years later, the former group had a lower incidence of cardiac events and fewer ischemic episodes.[135] On the contrary, other studies disclose either a very limited and transient benefit (i.e., seen only in the first month after the intervention) or no benefit at all in terms of anginal frequency, cardiac events, or reduction in blood pressure.[129] [136] Jones and West, for example, randomized over 2000 patients with a recent myocardial infarction to a psychosocial treatment or to care as usual and found no significant differences between the groups in cardiac mortality after 1 year. [128] In summarizing this outcome literature, it appears that these psychosocial and stress reduction programs, when they are focused, well designed, and added to standard cardiac care, do decrease psychiatric distress and improve health-related quality of life and role functioning. They probably also decrease cardiac morbidity and/or mortality, but this has not yet been definitively established.

PSYCHOLOGICAL TREATMENT OF HOSTILITY AND TYPE A BEHAVIOR.

Several intervention trials have specifically assessed psychological treatments to modify hostility and Type A behavior. These treatment programs are manualized and protocol driven. They aim to enhance the awareness and effective management of anger and other negative feelings and thoughts and to improve problem solving and communications skills. A meta-analysis of 18 such controlled trials concluded that treatment had a moderately large effect size in modifying anger, hostility, impatience, and time urgency.[137] The authors also found a marginally significant effect on cardiac events and mortality in the year after treatment. In a recent, controlled, randomized trial of an eight-session workshop to reduce hostility, the intervention was found to significantly decrease hostility at 2-month follow-up.[140] In the Recurrent Coronary Prevention Project (RCPP), the addition of Type A behavior counseling to a standard psychosocial rehabilitation program of 862 post-myocardial infarction patients produced a significant reduction in Type A behavior and a 44 percent reduction in nonfatal myocardial infarction and cardiac death at 3-year follow-up.[138] The effect on nonfatal myocardial infarction persisted 4½years after the intervention.[139]

Graduated, aerobic exercise training is another keystone of many cardiac rehabilitation programs. Such training improves exercise capacity and lowers blood pressure and body weight, as well as improving subjective, health-related quality of life. It is less clear, however whether these risk factor reductions in turn lead to significant differences in cardiac outcomes.[120] This may be because a sizable fraction of patients do not continue to adhere to the exercise regimen over long periods of time after the program ends.

PSYCHOPHARMACOLOGY IN THE CARDIAC PATIENT

Cardiovascular Aspects of Psychotropic Agents

Antidepressants (Table 70-1)

SEROTONIN REUPTAKE INHIBITORS (SRIs).

The SRIs have superseded the tricyclic antidepressants (TCAs) as the first-line agents for treating the cardiac patient with major depressive disorder. Their efficacy is comparable to that of

TABLE 70-1 -- ANTIDEPRESSANTS

AGENT	STARTING DOSE	MAXIMUM DOSE	SIDE EFFECTS	CARDIOVASCULAR EFFECTS	
Serotonin Reuptake Inhibitors					
Sertraline	12.5-25 mg/d	200 mg/d	Sexual dysfunctionNausea, diarrheaHeadache		Benign bradycardia
Fluoxetine	5-10 mg/d	80 mg/d	Anxiety, agitation, insomniaSomnolence, sedation		
Paroxetine	10 mg/d	50 mg/d	Tremor		
Tricyclics					
Amitriptyline	10-25 mg h.s.	300 mg/d	Sedation, somnolence	Dry mouthBlurry vision	Increase QT, PR, QRS intervals Decrease T wave amplitude
Imipramine	10-25 mg h.s.	300 mg/d		Constipation Urinary retention	Tachycardia Arrhythmias
Nortriptyline	10 mg/d	150 mg/d	Anxiety, insomnia	Postural hypotensionWeight gain	Postural hypotension
Desipramine	25 mg/d	300 mg/d			
Psychostimulants					
Methylphenidate	2.5 mg b.i.d.	20 mg b.i.d.	Anxiety, agitationInsomniaAnorexiaParanoia		Tachycardia (mild)Hypertension (mild)
Other Agents					
Bupropion	75 mg/d	150 mg t.i.d.	Anorexia, nauseaAnxiety, agitationInsomniaSeizures		
Venlafaxine	12.5 mg b.i.d.	125 mg t.i.d.	NauseaHeadacheSexual dysfunctionAnxiety, insomniaSomnolenceDizziness		Hypertension (dose related)
Trazadone	25 mg/d	600 mg/d	SedationNauseaHeadachePriapism (rare)		Postural hypotensionArrhythmias (rare)
Mirtazapine	15 mg q.h.s.	45 mg q.h.s.	Sedation, somnolenceWeight gainDry mouth, anticholinergic effectsDizzinessAgranulocytosis (rare)		

the older TCAs, they are better tolerated and safer in overdose, and they have less pharmacological action on the heart. The serotonergic antidepressants have little anticholinergic, antihistaminic, or noradrenergic activity. However, because they have become available only relatively recently, there has been less systematic study of their efficacy and safety in CHD populations and in the elderly, and few randomized, controlled trials in these populations have been completed. Although more extensive investigation is still necessary, the data thus far suggest that the SRIs have minimal cardiovascular effects and a large margin of safety in treating patients with even very severe heart disease.[141]

In healthy patients, the SRIs have no adverse effects on cardiac contractility or conduction and there is no evidence of cardiotoxicity in overdose. In cardiac populations, they do not appear to cause significant electrocardiographic or blood pressure changes, although they can slow heart rate. Only very rarely do they produce a clinically significant degree of sinus bradycardia. The SRIs have the potential to interact with a number of medications used to treat cardiac disease. They inhibit hepatic cytochrome P450 isoenzymes,[142] a series of isoenzymes involved in the oxidative metabolism of many drugs. These include lipophilic beta blockers (e.g., metoprolol and propranolol), calcium channel blockers, type IC antiarrhythmics, angiotensin-converting enzyme inhibitors, anticonvulsants, antihistamines, benzodiazepines, TCAs, codeine, and warfarin. The SRIs therefore can raise the blood levels of these other agents when co-administered. However, although these interactions can be demonstrated in vitro, their significance in clinical practice is still unclear. Caution should be exercised when giving SRIs to patients on these medications, and in particular the prothrombin time of patients receiving both warfarin and an SRI should be monitored closely. Because the SRIs are highly protein bound, they may displace other protein-bound drugs when co-administered, thereby increasing their bioavailability. This interaction can occur with warfarin and digitoxin, but it does not appear to be clinically significant in magnitude.

TRICYCLIC ANTIDEPRESSANTS (TCAs).

TCAs were previously the mainstay of antidepressant pharmacotherapy and remain effective agents that are still widely employed. However, their multiple cardiovascular side effects and their potential lethality in overdose are disadvantages in patients with cardiac disease. TCAs act on adrenergic neurons in the central nervous system, and in the periphery have anticholinergic properties, have quinidine-like effects, and produce alpha-adrenergic receptor blockade. They affect heart rate, rhythm, conduction, contractility, and blood pressure. Accordingly, these agents are not generally used in the presence of rhythm or conduction disturbances, severe congestive heart failure, or within 4 to 6 weeks of a myocardial infarction. A guiding principle when using them in the elderly and those with cardiac disease is to initiate treatment with low doses and to titrate the dosage upward slowly and carefully. Among the TCAs, the tertiary amines (e.g., imipramine and amitriptyline) are associated with more side effects, and the secondary amines (e.g., nortriptyline) have a preferable side-effect profile in cardiac patients.[143]

The TCAs are type IA antiarrhythmic agents (see Chap. 23) and accordingly depress cardiac conduction, decrease ventricular irritability, and suppress ectopic activity. They slow atrial and ventricular depolarization; increase the QT, PR, and QRS intervals; and decrease T wave amplitude. In the absence of preexisting conduction abnormalities, this action is unlikely to be clinically significant at therapeutic doses. However, second-degree heart block, sick sinus syndrome, bundle branch block, a prolonged QT interval, and the concurrent administration of antiarrhythmic agents are all considered contraindications to their use. In contrast to this antiarrhythmic effect, the TCAs can on occasion be arrhythmogenic. This is probably due to their prolongation of the QT interval and/or an increase in myocardial norepinephrine resulting from their peripheral inhibition of norepinephrine reuptake. Although the most common arrhythmias are atrial or ventricular premature beats, these may give way to more malignant ventricular arrhythmias. These toxic, proarrhythmic effects are seen primarily in overdose, and at therapeutic levels they are rare and more likely in those with preexisting CHD, a prolonged QT interval, electrical instability, or a recent myocardial infarction.[144] At toxic levels, in overdose, any type of arrhythmia may be seen. These may last for 3 to 4 days after the ingestion. The TCAs also elevate heart rate 5 to 20 beats per minute, as a result of their anticholinergic blockade. Although this does not pose a problem in relatively healthy patients, it may be a consideration in those with heart disease.

TCAs produce postural hypotension in up to 20 percent of patients. In the elderly, in whom orthostatic hypotension can produce cerebral hypoperfusion and lead to falls and fractures, this side effect can be crucial. In these patients, blood pressure should be checked immediately after standing up when treatment is initiated and after increments in dosage. Elderly patients should be advised to stand up slowly after lying or sitting for prolonged periods. The magnitude of this effect is related to the magnitude of pretreatment orthostatic hypotension,[145] and it is more likely to be clinically significant in patients with CHF, impaired left ventricular function, volume depletion, or in patients who are taking antihypertensive medications.[146] Orthostatic hypotension is less likely to be a problem with nortriptyline than with amitriptyline or imipramine. Caution is indicated when treating patients with poor ejection fractions because in animal studies, TCAs exert a depressant effect on myocardial contractility. However, in humans this effect is evident only at toxic doses and only rarely aggravates CHF.[147]

TCAs are generally not prescribed within 4 to 6 weeks after an uncomplicated, acute myocardial infarction. However, the decision of whether or when to initiate treatment with these agents after a myocardial infarction must be made on an individual basis, weighing the particular indications and contraindications (CHF, arrhythmias, and conduction abnormalities) on a case-by-case basis.

OTHER ANTIDEPRESSANTS.

Psychostimulants such as*methylphenidate* and*dextroamphetamine* are used to treat depression in medically compromised and elderly patients.[148] These agents tend to be used when depression is life threatening and immediate treatment response is crucial (because they have a rapid onset of action) and in depressions with very prominent anergia and apathy. Although there is considerable clinical support for their use, there are few rigorously controlled trials demonstrating their sustained efficacy over time. Serious cardiovascular side effects such as tachycardia, hypertension, and arrhythmias are relatively rare, but caution must be exercised when administering these medications to patients with significant hypertension, tachycardia, or ventricular ectopy, and blood pressure and heart rate should be monitored.

Bupropion, a nontricyclic antidepressant that acts on both the dopamine and norepinephrine systems, causes less hypotension than the TCAs; does not affect cardiac rate, conduction, or contractility; and is safely used in patients with cardiac disease.[149] It does not exacerbate ventricular arrhythmias or conduction block in patients with these conditions.[149] An increased incidence of seizures is seen at higher doses, and bupropion may occasionally elevate blood pressure.

Venlafaxine affects the reuptake of both serotonin and norepinephrine. It appears to have very few cardiovascular actions and no effect on the electrocardiogram.[150] At higher doses, however, venlafaxine has been associated with elevation in blood pressure.[151] Unlike the SRIs, it does not inhibit

P450 cytochrome isoenzymes and may therefore be useful in patients on cardiac medications.

Trazodone, a triazolopyridine antidepressant, is often used in low doses as a hypnotic. Cardiovascular complications from trazodone are very rare. It has few, if any, antiarrhythmic properties, although it has very rarely been associated with heart block and ventricular arrhythmias.[152] Because of its weak alpha-adrenergic blockade, it may also produce orthostatic hypotension.

Mirtazapine is a tetracyclic antidepressant with a complex mechanism of action. It has not been studied in patients with cardiovascular disease, but in noncardiac populations it does not affect blood pressure significantly and does not affect cardiac conduction.[153] It has no anticholinergic activity, but it may increase heart rate slightly.[153]

Neuroleptics (Table 70-2)

Neuroleptic or antipsychotic drugs are used in the treatment of schizophrenia, organic psychoses, and mood disorders with psychotic features. They are also widely used in geriatric patients for agitation, confusion, excitement, and behavioral dyscontrol. In general, neuroleptic drugs affect cardiac conduction and rhythm and produce hypotension. They have alpha-adrenergic blocking and quinidine-like properties, along with anticholinergic activity. They can produce prolongation of the PR and QT intervals, ST segment depression, T wave changes, ventricular arrhythmias, and heart block. Although the quinidine-like effects of the neuroleptics are usually negligible, they can become significant in patients already taking type I antiarrhythmics or in those with hypokalemia or with clinically significant conduction delays.[154] When administering a low-potency neuroleptic along with an antiarrhythmic, the ECG should be monitored for conduction delays. The lower-potency neuroleptics produce more orthostatic hypotension (by means of alpha-adrenergic blockade) and tachycardia (by means of anticholinergic action), and this is of particular concern in the elderly and in the acute myocardial infarction patient.[155] Orthostasis is more likely to be a problem when these agents are combined with antihypertensives.

The higher-potency neuroleptic agents, such as haloperidol and the piperazine phenothiazines, produce less of these effects and are therefore preferred in the presence of significant cardiac disease (especially conduction problems) and after cardiac surgery.[111] Haloperidol in particular has been frequently used with safety and efficacy in severely ill cardiac patients. Oral haloperidol does not significantly affect the ECG, and intravenous haloperidol is used in acute emergencies such as agitated deliria. Intravenous administration can on rare occasions cause torsades de pointes, and the QT interval should therefore be monitored during aggressive, intravenous haloperidol therapy.[156]

Experience with the newer, "atypical" antipsychotics in cardiac patients is much more limited but suggests a generally similar profile. Clozapine can cause tachycardia and orthostatic hypotension and has significant anticholinergic activity (along with a risk of myelosuppression and agranulocytosis). There are recent reports of an infrequent association of clozapine with ECG changes, arrhythmias, myocarditis, and congestive heart failure.[157] [157A] Olanzapine produces mild orthostatic hypotension but has little effect on the electrocardiogram. Sertindole prolongs the QT interval and may therefore pose a problem in cardiac patients. Risperidone

produces hypotension and has a quinidine-like effect, prolonging the QT interval, although this may occur only in overdose.

Mood Stabilizers (Table 70-3)

LITHIUM.

Lithium exerts minimal cardiotoxicity at therapeutic doses in most patients and can be used safely in cardiac disease if initiated at a low dose, increased gradually, and monitored carefully. Benign, reversible T wave changes (including inversion and flattening) are common with lithium administration and are not clinically significant. Clinically significant cardiovascular side effects of lithium are very rare; they may include sinus node dysfunction and increases in ventricular irritability. The major toxic effects of lithium are neural (confusion, sedation), and the primary concern in cardiac patients is lithium toxicity resulting from decreased renal clearance or hypovolemia. This is of concern in patients with congestive heart failure, and it is exacerbated by their restricted sodium intake and the use of diuretics. Sodium depletion decreases renal clearance of lithium. In the kidney, lithium is filtered out at

the glomerulus and then reabsorbed in the proximal tubules. Sodium depletion, such as with diuretics, causes an increased proximal reabsorption of sodium, and lithium is reabsorbed more efficiently at the same time. A given lithium dose thus results in a higher blood lithium level. Lithium may still be administered to the patient on diuretics, but lithium levels must be monitored and lithium dosage may need to be reduced as much as 25 to 50 percent. The elderly also require lower lithium doses because of a decline in the glomerular filtration rate. On rare occasion, lithium may worsen arrhythmias in patients with sinus node dysfunction.[158]

ANTICONVULSANTS.

These drugs are increasingly prescribed to stabilize the mood of patients with bipolar disorder (manic-depressive illness). Their use in cardiac patients has not yet been systematically studied. It is known that carbamazepine has quinidine-like effects and can aggravate heart block,[159] and it may also exacerbate CHF.[160] Carbamazepine can also produce hyponatremia, and this effect is potentiated by other factors that cause hyponatremia, such as diuretics and CHF.[161] Valproate, although not yet studied widely in cardiac populations, does not appear to have adverse cardiac effects. It can, however, lower the platelet count, decrease fibrinogen levels, and increase the prothrombin time.

Benzodiazepines (Table 70-4)

Benzodiazepines have anxiolytic, sedative, anticonvulsant, and muscle relaxant properties. Anxiety disorders, especially panic disorder and generalized anxiety disorder, are prevalent in patients with cardiac disease. Panic disorder is treated either with a benzodiazepine with antipanic efficacy (such as clonazepam, lorazepam, or alprazolam) or an antidepressant. Generalized anxiety disorder can also be treated with benzodiazepines, buspirone, or SRIs. Hospitalized cardiac patients are acutely anxious; and because anxiety itself can threaten cardiac status, benzodiazepines are widely and almost routinely used in coronary care units. They can decrease respiratory drive in patients with chronic obstructive pulmonary disease and chronic hypercapnia but are free of cardiac side effects and can safely be used in seriously ill cardiac patients, even in the period immediately after myocardial infarction.

Benzodiazepines with longer half-lives (e.g., diazepam, flurazepam, chlordiazepoxide) accumulate in the body with repeated administration. A steady state is reached very slowly, and clearance of the drug after discontinuation is prolonged. Intramuscular absorption of these agents, other than lorazepam and midazolam, is erratic and unpredictable. The most prominent side effects are sedation, fatigue, memory complaints, and psychomotor impairment. In hospitalized patients and in the elderly, these effects can result in oversedation or delirium. Patients with preexisting cognitive impairment or organic brain syndromes often react to benzodiazepines with further confusion, increased memory loss, behavioral disinhibition, and belligerence. Ambulatory patients should be cautioned about driving and participating in activities requiring a high degree of alertness.

TABLE 70-4 -- BENZODIAZEPINES

AGENT	STARTING DOSE	MAXIMUM DOSE	SIDE EFFECTS	CARDIOVASCULAR EFFECTS
Short-Acting Benzodiazepines				
Oxazepam	10 mg b.i.d.	120 mg/d		
			Sedation, drowsiness

Clonazepam	0.25 mg/d	6 mg/d	Amnesia
Alprazolam	0.25 mg b.i.d.	8 mg/d	

Psychiatric Side Effects of Cardiovascular Drugs

ANTIHYPERTENSIVES.

Many antihypertensive agents have central nervous system side effects.[162] Depression is not uncommon with methyldopa, clonidine, reserpine, and guanethidine. Therefore, calcium channel blockers and angiotensin-converting enzyme inhibitors may be preferable in the hypertensive patient with a history of depression. Abrupt discontinuation of antihypertensive agents can cause anxiety, agitation, and vivid dreams.[163] Clonidine and methyldopa are relatively common causes of insomnia.

BETA-ADRENERGIC RECEPTOR ANTAGONISTS.

There is a long-standing clinical impression that beta blockers can cause depression. Although there are reports that patients maintained on these agents have an elevated rate of concurrent antidepressant pharmacotherapy,[164] other studies have failed to find an association between beta blocker use and depression.[165] Some of the confusion may stem from the fact that these agents cause sedation, lethargy, fatigue, and impotence, side effects that overlap with, and may be confused with, depression. Depression may be more likely in those with a past history or family history of depression, with the more lipophilic agents (e.g., propranolol, metoprolol),[162] and when using higher doses. Beta blockers are also occasionally the cause of vivid dreams and nightmares, hallucinations, and other psychotic symptoms. These tend to occur more often in the elderly.

CALCIUM CHANNEL BLOCKERS.

In general, calcium channel blockers do not have prominent psychiatric side effects. There are isolated case reports of depression associated with their administration, but this has not yet been demonstrated conclusively.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS.

These agents appear to have relatively few central nervous system side effects, although they may, on rare occasion, induce depression.

ANTIARRHYTHMICS.

Lidocaine is a relatively common cause of anxiety, confusion, disorientation, hallucinations, and central nervous system excitement. Confusion, hallucinations, and delirium have also been reported with high doses of quinidine. Procainamide may cause depression, hallucinations, and other psychotic symptoms.

DIGITALIS.

Anxiety, depression, visual illusions (e.g., yellow halos), and confusion may be the first signs of digitalis toxicity, but psychiatric symptoms may emerge at therapeutic serum levels as well.[166]

DIURETICS.

Diuretics can induce cognitive mental status changes as a result of their producing electrolyte imbalances (e.g., hyponatremia) or hypovolemia, and a secondary mood disorder may also occur, often characterized by anorexia, lethargy, and weakness.

Interactions of Psychotropic and Cardiac Drugs (Table 70-5)

Because many cardiac and psychotropic agents lower blood pressure, additive hypotensive effects are not uncommon, as for example between the TCAs and antihypertensives. Many psychotropic agents slow conduction and prolong the PR, QRS, and QT intervals, and synergistic effects can occur when they are used in conjunction with antiarrhythmic medications, resulting in heart block or the long QT syndrome. There are several interactions between the TCAs and cardiac medications. The TCAs interfere with neuronal reuptake of clonidine and guanethidine and thus antagonize their antihypertensive action. They may potentiate the antihypertensive action of prazosin. And the dry mouth induced by TCAs may hinder the absorption of sublingual nitrates.

Serotonin reuptake inhibitors (e.g., fluoxetine, sertraline,

TABLE 70-5 -- INTERACTIONS OF PSYCHOTROPIC AND CARDIAC DRUGS

MEDICATION	EFFECT ON CARDIAC AGENT
Interactions Involving Tricyclic Antidepressants	
Type IA antiarrhythmics	Potentiate delay in cardiac conduction; heart block
Antihypertensives: guanethidine, clonidine, reserpine	Antagonize antihypertensive effect; potentiate orthostatic hypotension
Sublingual nitrates	Oral absorption hindered by dry mouth
Alpha-adrenergic blocking agents	Potentiate antihypertensive effect
Interactions Involving Serotonergic Antidepressants	
Lipophilic beta blockersCalcium channel blockersType IC antiarrhythmicsAngiotensin-converting enzyme inhibitorsWarfarin	Increase blood levels due to decreased hepatic degradation
DigitoxinWarfarin	Increase bioavailability due to displacement from protein-binding sites

MEDICATION	EFFECT ON PSYCHOTROPIC AGENT
Interactions Involving Lithium	
Diuretics that cause sodium loss	Increase blood lithium levels
Calcium channel blockers	Enhance lithium toxicity; bradycardia
Angiotensin-converting enzyme inhibitors	Enhance lithium toxicity
Methyldopa	Enhance lithium toxicity

MEDICATION	EFFECT ON PSYCHOTROPIC OR CARDIAC AGENT
Interactions Involving Carbamazepine	
Calcium channel blockers	Enhance carbamazepine toxicity
Antiarrhythmics	Potentiate delay in cardiac conduction

paroxetine, and fluvoxamine) are bound to plasma proteins and can displace other protein-bound drugs, thereby increasing the level of active drug and resulting in possible toxicity. This is particularly salient with warfarin and digitoxin, although the clinical significance of these interactions is not yet clear.[160] As noted earlier, diuretics may raise lithium levels into the toxic range. This can generally be dealt with by reducing the lithium dose, although during acute diuresis the proper adjustment of lithium is difficult because of the massive shifts in sodium and fluid balance.[160]

There are reports of idiosyncratic toxic reactions and of bradycardia when lithium is co-administered with the calcium channel blockers verapamil and diltiazem, and of lithium toxicity precipitated by the use of angiotensin-converting enzyme inhibitors. Methyldopa seems to have a number of interactions with psychotropic agents, including possible toxicity when combined with lithium. The metabolic degradation of carbamazepine may be inhibited by calcium channel blockers, thereby increasing the risk of carbamazepine toxicity.[167] Carbamazepine and antiarrhythmics may have additive effects in slowing cardiac conduction.

Chapter 71 - Neurological Disorders and Cardiovascular Disease

WILLIAM J. GROH
DOUGLAS P. ZIPES

Cardiovascular disease that occurs secondary to an underlying neurological disorder is related either to direct involvement of the heart or due to induced neurohormonal abnormalities that act on the heart. In several neurological disorders, the cardiovascular manifestations can be responsible for a greater risk of morbidity and mortality than the neurological manifestations. This chapter reviews those neurological disorders associated with important cardiovascular sequelae.

THE MUSCULAR DYSTROPHIES

The muscular dystrophies are a diffuse group of heritable disorders in which direct involvement of cardiac muscle is present to a variable degree. The muscular dystrophies can be classified into:

1. Duchenne and Becker muscular dystrophies
2. Myotonic muscular dystrophy
3. Emery-Dreifuss muscular dystrophy
4. Limb girdle muscular dystrophy
5. Facioscapulohumeral muscular dystrophy

Duchenne and Becker Muscular Dystrophies

GENETICS

Both Duchenne and Becker muscular dystrophies are X-linked recessive disorders in which the genetic locus has been identified as an abnormality in the dystrophin gene.[1] [2] This gene is the largest identified in humans to date.[3] [4] Dystrophin messenger RNA is expressed predominantly in skeletal, cardiac, and smooth muscle with lower levels in brain. The dystrophin protein complexes with muscle cytoskeleton, possibly functioning to link contractile proteins to the cell membrane.[5] Its absence can lead to membrane fragility, resulting in myofibril necrosis and eventual loss of muscle fibers with fibrotic replacement. In Duchenne muscular dystrophy, dystrophin is nearly absent; whereas in Becker muscular dystrophy, dystrophin is present but reduced in size or amount.[6] [7] This leads to the characteristic rapidly progressive skeletal muscle disease in Duchenne muscular dystrophy and the more benign course in Becker muscular dystrophy. The heart as a muscle is also involved. Indeed, studies have recognized a distinct clinical syndrome of X-linked dilated cardiomyopathy producing a progressive and severe cardiomyopathy with minimal skeletal muscle weakness that involves a dystrophin mutation.[8] [9] Involvement of the heart with sparing of skeletal muscle occurs secondary to selective abnormalities in certain dystrophin isotype transcripts, allowing functional dystrophin expression in all tissue but cardiac muscle.[10]

CLINICAL PRESENTATION.

Duchenne muscular dystrophy is the most common inherited neuromuscular disorder, with an incidence of 30 per 100,000 live male births. Patients with disease become symptomatic before age 5, presenting with skeletal muscle weakness that progresses such that the boy becomes wheelchair-bound before the age of 13 years (Fig. 71-1). Death occurs commonly by age 20 to 25 years primarily from respiratory failure or cardiac arrest. Becker muscular dystrophy is less common (3 per 100,000 live male births), has a more variable presentation of skeletal muscle weakness (Fig. 71-2) , and has a better prognosis, with most patients surviving to age 40 to 50 years.

CARDIOVASCULAR MANIFESTATIONS.

Virtually all patients with Duchenne muscular dystrophy develop a cardiomyopathy, but clinical recognition may be masked by severe skeletal muscle weakness. Preclinical cardiac involvement is present in one fourth by age 6, with the onset of clinically apparent cardiomyopathy after age 10 being common.[11] Predilection for involvement in the posterobasal and posterolateral left ventricle has been observed (Fig. 71-3) . This has been hypothesized to be related to the increased axial stress that cardiac myocytes encounter in the posterior wall and thus a more important role for dystrophin in limiting sarcolemma damage.[12] As with the skeletal muscle weakness, cardiac involvement in Becker muscular dystrophy is more variable, ranging from none or subclinical to severe cardiomyopathy requiring transplant.[13] [14] Cardiac involvement in Becker muscular dystrophy is independent of the severity of skeletal muscle involvement, with some investigators observing increased likelihood of cardiovascular disease in older individuals.[14] [15] More than one half of patients with subclinical or benign skeletal muscle disease were noted to have cardiac involvement when carefully evaluated.[16] In follow-up studies, progression in the severity of cardiac involvement is common.[15] Cardiomyopathy can initially only involve the right ventricle.[16]

The cardiovascular examination in Duchenne muscular dystrophy may be altered by thoracic deformities and a high diaphragm. A reduction in the anteroposterior chest dimension is commonly responsible for a systolic impulse displaced to the left sternal border, a grade 1-3/6 short midsystolic murmur in the second left interspace, and a loud pulmonary component of the second heart sound. In both Duchenne and Becker muscular dystrophy, mitral regurgitation is commonly observed. This is believed related to posterior papillary muscle dysfunction in Duchenne muscular dystrophy and to mitral annular dilatation in Becker muscular dystrophy.[17]

Electrocardiography.

In patients with Duchenne muscular

Figure 71-1 *A,* Classic X-linked muscular dystrophy. *Left,* Exaggerated lumbar lordosis. *Right,* Calf pseudohypertrophy and shortening of the Achilles tendons. *B,* Seventeen-year-old boy with Duchenne muscular dystrophy. also striking enlargement of both calves (not shown). (*A* and *B* courtesy of Joseph K. Perloff, M.D.)

dystrophy the electrocardiogram (ECG) is abnormal in 90 percent, demonstrating a distinctive pattern of tall R waves and an increased R/S amplitude in V_1 and deep narrow Q waves in the left precordial leads related to the characteristic posterolateral left ventricular involvement (Fig. 71-4) . In patients with Becker muscular dystrophy ECG abnormalities are present in up to 75 percent.[14] [15] The ECG abnormalities observed include tall R waves and an increased R/S amplitude in V_1 , similar to that seen in Duchenne muscular dystrophy, but may also show frequent incomplete right bundle branch block. This may be related to early involvement of the right ventricle. In patients with congestive heart failure, left bundle branch block is common (Fig. 71-5) . [15]

In both Duchenne and Becker muscular dystrophies, elevated serum creatinine kinase activity is observed, over 10-fold and 5-fold normal values, respectively.[18]

Arrhythmias.

In Duchenne muscular dystrophy, arrhythmias secondary to disturbances in both rhythm and conduction are observed. Persistent or labile sinus tachycardia is the most recognized abnormality.[19] The pathogenesis of this tachycardia is unknown but does not appear related to abnormal autonomic function.[20] Atrial arrhythmias including atrial fibrillation and atrial flutter occur commonly as a preterminal rhythm.[21] Abnormalities in atrioventricular (AV) conduction have been observed. Up to 10 percent of individuals have PR intervals of less than 120 milliseconds, with an additional 10 percent having prolonged PR intervals.[22] Ventricular arrhythmias occur on monitoring in 30 percent (primarily ventricular premature complexes). More complex ventricular arrhythmias have been reported as well. These are more commonly present in individuals with severe muscle disease.[19] [23] Sudden death occurs in Duchenne muscular dystrophy, primarily in patients with severe skeletal muscle weakness. Whether this is an arrhythmic death is not clear.

Arrhythmic manifestations in Becker muscular dystrophy tend to correspond to the degree of the associated dilated cardiomyopathy but are not well characterized.[24] Distal conduction system disease with complete heart block and bundle branch reentry ventricular tachycardia have been observed.[25] [26]

Female carriers of Duchenne muscular dystrophy are at increased risk of dilated cardiomyopathy.[27] [28] [28A]

TREATMENT AND PROGNOSIS.

Duchenne muscular dystrophy is a progressive disorder with respiratory or cardiac death common by age 20 to 25. A primary cardiac etiology for death occurs in about one fourth of patients with an equal distribution of death from progressive heart failure and sudden death.[19] [21] Intravenous verapamil used for preterminal atrial arrhythmias can lead to acute respiratory failure.[29] A report of the use of an implantable cardioverter-defibrillator for recurrent drug refractory ventricular tachycardia resulted in a periprocedural respiratory death.[30]

In Becker muscular dystrophy or female carriers of Duchenne muscular dystrophy, it is not known whether therapy to decrease myocardial wall stress is beneficial in preventing or delaying progression to cardiac failure. Once heart failure is established, conventional therapy is indicated. Orthotopic cardiac transplantation has been reported.[31]

Myotonic Muscular Dystrophy

GENETICS

Adult myotonic muscular dystrophy (dystrophica myotonia, Steinert disease) is a heredofamilial disease (autosomal dominant) characterized by reflex and percussion myotonia, weakness, and atrophy of distal skeletal muscles as well as systemic manifestations of early balding, gonadal atrophy, cataracts, mental retardation, and cardiac involvement (Fig. 71-6) .[32] The genetic abnormality responsible for this diffuse systemic disease is an amplified and unstable trinucleotide (cytosine-thymine-guanine [CTG]) repeat found on the long arm of chromosome 19. This repeat sequence is located in the 3 untranslated

Figure 71-2 Late onset, slowly progressive Becker muscular dystrophy in a 22-year-old man. *A,* There is dystrophy of the shoulder girdle, arms, and pelvic girdle (last not shown). *B,* Asymmetric calf pseudohypertrophy is greater on the left than on the right. Dystrophy of proximal leg muscles is not shown. (*A* and *B* courtesy of Joseph K. Perloff, M.D.)

region of a gene encoding a protein homologous to serine/threonine protein kinases, identified as myotonic protein kinase (Mt-PK or DMPK).[33] [34] [35] In individuals without myotonic dystrophy, between 5 and 37 copies of this CTG repeat are present. In individuals with myotonic dystrophy, 50 to several thousand CTG repeats are observed. A direct correlation exists between an increasing number of CTG repeats and earlier age at onset and increasing severity of neuromuscular involvement.[36] [37] [38] Whether increasing CTG expansion correlates with increasing cardiac involvement is debated.[39] [40] [41] [42]

MECHANISM.

The mechanism by which the amplified CTG repeat flanking Mt-PK leads to the characteristic involvement in myotonic dystrophy is not clear but likely involves alterations in tissue phosphorylation related to reduction in Mt-PK activity and possibly a resultant change in ion channel structure or function.[43] [44] Studies using transgenic mice deficient in Mt-PK have shown divergent results regarding the replication of the skeletal muscle disease.[45] [46] Cardiac conduction disease was observed in the transgenic mouse model, similar to what is seen in the human disease, although without characteristic degenerative pathology.[47] Other mechanisms for the cardiac involvement have been hypothesized, including a potential relationship to a second gene adjacent to Mt-PK known to be responsible for progressive familial heart block, impaired glucose utilization possibly related to abnormal protein kinase function, and abnormal coronary reserve.[48] [49] [50]

CLINICAL PRESENTATION.

Myotonic dystrophy is the most common inherited neuromuscular disorder in patients presenting as adults. The global incidence has been estimated to be 1 in 8000, although it is higher in certain populations, such as French Canadians, and lower to nonexistent in other populations, such as African blacks.[32] The age at onset of symptoms and diagnosis averages 20 to 25 years. Common early manifestations are weakness in the muscles of the face, neck, and distal extremities. On examination, myotonia (delayed muscle relaxation) can be demonstrated

Figure 71-3 *A,* Schematic illustration showing the typical posterobasal myocardial involvement with lateral extension in classic Duchenne muscular dystrophy. The posterolateral papillary muscle is involved (arrow). LA=left atrium; LV=left ventricle; Ao=aorta. *B,* Necropsy section showing posterobasal involvement (arrows) of the left ventricle (LV) in a boy with classic Duchenne muscular dystrophy. The posterolateral papillary muscle was involved, resulting in mitral regurgitation and the jet lesion shown at upper right. (*A* and *B* courtesy of Joseph K. Perloff, M.D.)

Figure 71-4 Electrocardiogram from a 12-year-old boy with classic Duchenne muscular dystrophy. Sinus tachycardia is observed. The QRS complex is typical of Duchenne dystrophy, showing tall R waves in lead V_1 and deep, narrow Q waves in leads I, aVL, and V_4 to V_6 . (Courtesy of Charles Fisch, M.D., Indiana University School of Medicine, Indianapolis, IN.)

in the grip, thenar muscle group, and tongue (Fig. 71-7) (Figure Not Available) . Diagnosis when the individual is asymptomatic is possible using electromyography and genetic testing. Symptomatic myotonic dystrophy tends to present at an earlier age and with increasing severity in successive generations. This property is called anticipation and is related to the increasing amplification of CTG repeat length in successive generations.[38] [51] In general, cardiac symptoms occur after the onset of skeletal muscle weakness but can be the initial manifestation of the disease.

CARDIOVASCULAR MANIFESTATIONS.

Cardiac pathology is commonly seen in myotonic dystrophy and primarily involves degeneration (fibrosis and fatty infiltration) of the specialized conduction tissue, including the sinus node, AV node, and His-Purkinje system. Degenerative changes are observed in working atrial and ventricular tissue but only rarely progress to symptomatic cardiomyopathy (Fig. 71-8) .[52] [53] It is not surprising, based on this preferential degeneration of conduction tissue, that the primary cardiac manifestations of myotonic dystrophy are arrhythmias.

Electrocardiography and Arrhythmias.

The majority of adult patients with myotonic dystrophy have ECG abnormalities. In several large series, atrial fibrillation or atrial flutter was observed in 6 to 11 percent, first-degree AV block was found in 20 to 60 percent, right bundle branch block in 2 to 11 percent, and left bundle branch block in 5 to 13 percent. Q waves not associated with a known myocardial infarction are common. ECG abnormalities often progress over time (Fig. 71-9) .

Mitral valve prolapse is often observed on echocardiography and is believed to be related to papillary muscle dysfunction. The heart may be involved before myocardial degenerative changes in a manner similar to the myotonia in skeletal muscle. This has been hypothesized to be manifest by echocardiographic evidence of delayed early diastolic relaxation of the left ventricle.[54]

At electrophysiological study, the most common abnormality found is a prolonged His-ventricular (H-V) interval. This was observed in 56 to 90 percent of selected patients and in follow-up studies does appear to progress.[42] [55] Other findings at electrophysiological study include prolongation in the atrial-His (A-H) interval and inducible atrial arrhythmias, primarily atrial fibrillation. In patients without previously known ventricular tachycardia, the likelihood of inducing a sustained ventricular tachycardia is low.

Conduction system disease can progress to symptomatic AV block and necessitate pacemaker implantation. Current prevalence of permanent cardiac pacing in patients with myotonic dystrophy varies between 3 and 22 percent (or higher).[42] [56] Patient selection and indication for pacing is not clear or consistent in these series. Slowed conduction in the ventricles is present, as evidenced by a significant

Figure 71-5 Gross and microscopic cardiac pathological specimens and the electrocardiogram from a 45-year-old man with late-onset, slowly progressive Becker muscular dystrophy. *A,* Dilated, flabby left ventricle with focal endocardial thickening. *B,* Microscopic section from the left ventricle shows marked confluent scarring with variations in fiber size; there was no significant coronary artery disease. *C,* Electrocardiogram recorded at age 40 years. The 12-lead tracing shows left-axis deviation, a QRS of 0.14 second, small Q waves in leads I and aVL, and loss of R waves in leads V_2 and V_3 . The lower tracings, taken 4 years later (a year before death), show complete heart block with a variable QRS configuration. (From Perloff JK, et al: The cardiomyopathy of progressive muscular dystrophy. Circulation 33:625, 1966. Copyright 1966, The American Heart Association.)

incidence of late potentials on signal-averaged ECGs.[57] [57A] Atrial arrhythmias, primarily atrial fibrillation and atrial flutter, are common in myotonic dystrophy, being seen in approximately 10 percent of a general population, and are more common in those patients with more severe neuromuscular disease.[58] [59] [60] [61] Ventricular tachycardia can occur in patients with myotonic dystrophy.[62] [63] [64] [65] In at least two reports

Figure 71-6 Myotonic muscular dystrophy in three siblings. Note the unaffected mother (front). Demonstrated is premature balding (left) and characteristic thin facies (rear).

and a series of six patients, the ventricular tachycardia observed was related to reentry in the diseased distal conduction system, as characterized by bundle branch reentry and interfascicular reentry tachycardia (see Chap. 25) .[62] [65] Therapy with right bundle branch and/or fascicular radiofrequency ablation resulted in absence of further inducible ventricular tachycardia.[62] [65]

Sudden Death.

The incidence of sudden death in patients with myotonic dystrophy is substantial and believed to be primarily caused by arrhythmias. In a registry of 180 myotonic dystrophy patients from the Netherlands collected from 1950 to 1997, 29 percent of all deaths were classified as sudden, presumably secondary to arrhythmias.[66] This was secondary only to pneumonia (31 percent) as a cause of death. In a 10-year study of mortality in a cohort of 367 patients from Quebec, 75 (20 percent) patients died.[67] In these 75 deaths, 31 percent were characterized as secondary to cardiovascular causes, with 11 percent sudden. The mechanisms leading to sudden death in myotonic dystrophy are not clear. Both bradyarrhythmias and ventricular tachyarrhythmias may be responsible. Bradyarrhythmias can cause sudden death in that distal conduction disease producing AV block may result in a lack of an appropriate automatic escape rhythm and asystole or bradycardia-mediated ventricular fibrillation. Sudden death can occur in myotonic dystrophy despite previous permanent cardiac pacing, implicating the role of ventricular tachyarrhythmias.

TREATMENT.

Cardiac management in individuals with myotonic dystrophy is not well established. In patients in whom a dilated cardiomyopathy does develop, standard

---

Figure 71-7 (Figure Not Available) Grip myotonia in myotonic muscular dystrophy. Inability to release (bottom) after exerting grip (top). (Reproduced by permission from Harper PS, et al: Myotonic dystrophy. In Engel AG, Franzini-Armstrong C [eds]: Myology: Basic and Clinical. 2nd ed. vol. II. New York, McGraw-Hill, 1994, p 1195.)

therapy including angiotensin-converting enzyme (ACE) inhibitors and beta-blocking agents has improved symptoms.[68] Patients presenting with symptoms indicative of arrhythmic disease such as syncope and palpitations should undergo an extensive evaluation, including electrophysiological study, to determine an etiology. A low threshold for permanent pacing is warranted. In individuals who are asymptomatic from a cardiac standpoint the degree of appropriate screening is not well established. Most authors recommend ECGs yearly and consideration for 24-hour ambulatory monitoring. Whether significant or progressive ECG abnormalities require intervention (prophylactic pacing, invasive electrophysiological evaluation) is uncertain. In one series, in which 45 individuals with myotonic dystrophy were followed for a mean of 4.6 years, ECG evidence of conduction abnormalities increased from 38 to 62 percent.[60] In this study, baseline or progression of ECG abnormalities did not correlate with the need for pacemaker insertion (5 individuals) or sudden death (1 individual). More recently, a series of 53 patients observed for a mean time period of 6.3 years determined that a PR interval of 240 milliseconds or greater was useful in predicting cardiac events (atrial fibrillation, complete heart block, syncope, and sudden death).[69] The appropriate therapy for this higher risk group was not discussed. Trials encompassing more patients using a multicenter approach have been recommended.[56] Some groups have advocated invasive electrophysiological evaluation and prophylactic permanent pacing in a high proportion of myotonic dystrophy patients.[42] Certain families may be more prone to arrhythmic manifestations of myotonic dystrophy and should be considered for

Figure 71-8 Histopathology of the atrioventricular bundle in myotonic dystrophy. *A,* Fatty infiltration in a 57-year-old man (Masson trichrome stain, ×90). *B,* Focal replacement fibrosis and atrophy in a 48-year-old woman. Arrows demarcate expected size and shape of the branching atrioventricular bundle (Hematoxylin and eosin stain, ×90). LBB=left bundle branch, RBB=right bundle branch. (From Nguyen HH, et al: Pathology of the cardiac conduction system in myotonic dystrophy: A study of 12 cases. J Am Coll Cardiol 11:662, 1988. Copyright 1988, American College of Cardiology.)

more careful evaluation.[70] Anesthesia in individuals with myotonic dystrophy can increase the risk of AV conduction block and other arrhythmias, and therefore these individuals should be carefully monitored and prophylactic temporary pacing considered.

In patients presenting with wide complex tachycardia, invasive electrophysiological testing with careful evaluation for bundle branch reentry tachycardia should be done. The use of class I antiarrhythmic agents in suppressing ventricular tachycardia in myotonic dystrophy has had limited efficacy. Sotalol may be more effective.[63] Whether implantable cardioverter-defibrillators are appropriate or useful has not been described.

PROGNOSIS.

The course of neuromuscular abnormalities in myotonic dystrophy is highly variable. Death from progressive weakness and respiratory difficulty can occur in advanced muscular disease. Other individuals may be only minimally limited by weakness to ages of 60 to 70 years. [32] Sudden death may significantly reduce survival in patients with myotonic dystrophy, including those minimally symptomatic from a neuromuscular status. What evaluation and interventions are appropriate, and the degree of effectiveness to decrease the risk of sudden death, are unclear.

Emery-Dreifuss Muscular Dystrophy

GENETICS

Emery-Dreifuss muscular dystrophy is a rare familial disorder in which skeletal muscle symptoms are often mild but with cardiac involvement common and life threatening.[71] [72] The disease is primarily inherited in an X-linked recessive fashion, but there is heterogeneity in

Figure 71-9 Electrocardiograms obtained 1 year apart in a 36-year-old man with myotonic dystrophy (top older). Note the abnormal Q waves in the precordial leads. An increasing PR interval and QRS duration are observed consistent with increasing severity of conduction disease.

that families have been reported that fit an autosomal dominant and recessive inheritance pattern.

A gene responsible for the X-linked recessive Emery-Dreifuss muscular dystrophy was identified in 1994.[73] The candidate gene found on chromosome Xq28, *STA,* encodes a nuclear membrane protein called emerin.[74] [75] [76] The lack of emerin in skeletal and cardiac muscle is responsible for the disease phenotype. Recently, the autosomal dominant Emery-Dreifuss muscular dystrophy was linked to chromosome 1 with a candidate gene encoding proteins of the nuclear lamina.[77]

CLINICAL PRESENTATION.

Emery-Dreifuss muscular dystrophy is characterized by a triad of (1) early contractures of the elbow, Achilles tendon, and posterior cervical muscles; (2) slowly progressing muscle weakness and atrophy; and (3) cardiac involvement.[71] [72]

The disorder has been labeled "benign X-linked muscular dystrophy" to differentiate the slowly progressive muscular weakness from that of Duchenne muscular dystrophy. A definitive diagnosis can be made in Emery-Dreifuss muscular dystrophy and in carriers using antiemerin antibodies.[78] [79]

CARDIOVASCULAR MANIFESTATIONS.

Arrhythmias are the primary manifestation of cardiac disease in Emery-Dreifuss muscular dystrophy.[79A] Abnormalities in impulse generation and conduction are exceedingly frequent. ECGs are generally abnormal by age 20 to 30 years, commonly showing first-degree AV block. The atria appear to be involved earlier than the ventricles, with atrial fibrillation and atrial flutter or, more classically, permanent atrial standstill and junctional bradycardia, observed. Abnormalities in impulse generation or conduction are present in virtually all individuals by age 35 to 40 years, and permanent ventricular pacing is often required. Sudden death (presumed cardiac) before age 50 is exceedingly common and is reported to occur in as high as 40 percent of individuals.[80] This may be diminished with prophylactic permanent pacing.

Arrhythmia.

Ventricular tachyarrhythmias including sustained ventricular tachycardia and ventricular fibrillation have been reported. Invasive electrophysiological study data are limited in this rare condition. Mild prolongation of the H-V interval, atrial, AV nodal, and ventricular refractory periods has been observed.[81] Female carriers of Emery-Dreifuss muscular dystrophy do not develop skeletal muscle disease but do develop late cardiac disease, including conduction abnormalities; and sudden death can occur.[82] The characteristic arrhythmic involvement in Emery-Dreifuss muscular dystrophy may be related to the unique localization of emerin in desmosomes and fascia adherens of the intercalated discs.[83] If emerin functions in maintaining cell-to-cell adhesion, then its absence may impair conduction.

Localization of emerin in intercalated discs has not been observed by all investigators.[84] Although arrhythmic disease is the most common presentation of cardiac involvement in Emery-Dreifuss muscular dystrophy, a dilated cardiomyopathy can develop. This may be more common in patients in whom survival has been improved with permanent pacemaker implantation.[85] Both autopsy and endomyocardial biopsy have shown abnormal cardiac fibrosis.[85] [86]

TREATMENT AND PROGNOSIS.

Affected males should be carefully monitored for development of ECG abnormalities

of conduction. Ambulatory electrocardiography may reveal arrhythmic abnormalities during sleep that are not apparent during short-term ECG recording.[80] AV block can occur with anesthesia.[87] Permanent ventricular pacing is recommended once conduction disease is evident and can be life saving. After ventricular pacing, other cardiac manifestations can occur, including ventricular tachyarrhythmias and/or ventricular dysfunction. Female carriers do develop conduction disease, and ECG monitoring on a routine basis is appropriate. Whether prophylactic ventricular pacing is indicated in this group is not clear.

Cardiac disease including sudden death remains responsible for significant mortality in Emery-Dreifuss muscular dystrophy despite early pacing. Whether other therapy (implantable cardioverter-defibrillators) would diminish this mortality has not been tested.

Limb Girdle Muscular Dystrophy

GENETICS

Limb girdle muscular dystrophy constitutes a group of disorders with a limb/pelvic girdle distribution of weakness but with otherwise heterogeneous inheritance and clinical features.[88] Classically, the disorder is inherited in an autosomal recessive fashion, although autosomal dominant and sporadic genetic inheritance has been observed. Positional cloning has improved an understanding of the genetics of limb girdle muscular dystrophy. Abnormalities have been identified in a number of genes most commonly expressed as dystrophin-associated proteins.[89]

CLINICAL PRESENTATION.

The onset of muscle weakness is variable but usually occurs before age 30 years. Patients commonly present with complaints of difficulty with walking or running secondary to pelvic girdle involvement. As the disease progresses, involvement of the shoulder muscles and then more distal muscles occurs, with sparing of facial involvement. Slow progression to severe disability and/or death is common.

CARDIOVASCULAR MANIFESTATIONS.

Historically, cardiac involvement in limb girdle muscular dystrophy has been considered to be rare. However, as more has been understood about the genetic

constitution and heterogeneity of this group of disorders, a greater realization of the potential for cardiac involvement is emerging.

An autosomal recessive or sporadic limb girdle muscular dystrophy caused by a deficiency in the sarcoglycan complex associated with dystrophin may be associated with a dilated cardiomyopathy.[90] [91] [92] ECGs from several patients showed abnormalities such as increased R wave in V_1 , consistent with the pattern of dystrophin-related cardiomyopathy, as seen in Duchenne muscular dystrophy. Cardiac abnormalities seen with ECG or echocardiographic evaluation have been detected in up to 80 percent, but with a much smaller proportion of patients being symptomatic.[92] [93]

A recently recognized autosomal dominant limb girdle muscular dystrophy with a high incidence of cardiac arrhythmic involvement has been linked to chromosome 1q11-21.[94] In these families, affected members develop high-degree AV block by age 35 to 45 years. Sudden death believed to be cardiac was reported in eight individuals at a median age of 50 years, including those in whom permanent pacing was previously instituted. A dilated cardiomyopathy was diagnosed in two individuals. In one individual, postmortem examination revealed extensive cardiac fibrosis, including replacement of the specialized conduction tissue. Others have reported families with limb girdle muscular dystrophy in whom AV block, cardiomyopathy, and sudden death were the primary manifestations.[95] [96]

TREATMENT AND PROGNOSIS.

Because of the heterogeneous nature of limb girdle muscular dystrophy, specific recommendations for routine cardiac evaluation are difficult to make. In families in whom cardiac disease has been shown to be associated with their neuromuscular disorder, cardiac evaluation for arrhythmic disease and ventricular dysfunction should be considered. In individual families, prophylactic permanent pacing can be indicated.[95]

Facioscapulohumeral Muscular Dystrophy

GENETICS

Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder in which the genetic locus has been mapped to chromosome 4q35.[97] Genetic heterogeneity has been reported.[98] Neither the definitive gene nor the gene product responsible for facioscapulohumeral muscular dystrophy has been identified.[99]

CLINICAL PRESENTATION.

Muscle weakness tends to follow a slowly progressive but variable course presenting with facial muscle weakness and progressing to involve the shoulders, foot extensors, and pelvis (Fig. 71-10) .[100]

CARDIOVASCULAR MANIFESTATIONS.

Cardiac involvement in facioscapulohumeral muscular dystrophy has been reported but does not constitute a significant problem in prevalence or severity as it does in many of the other muscular dystrophies. In one series of 31 patients evaluated by physical examination, chest radiograph, ECG, and echocardiogram, no evidence of cardiac abnormalities was found.[101] Other series have reported a propensity toward

Figure 71-10 Facioscapulohumeral muscular dystrophy in a 32-year-old woman. *A,* The face is in repose (myopathic) with dimpling of the corners of the mouth. *B,* Typical winging of the scapulae. (*A* and *B* courtesy of Joseph K. Perloff, M.D.)

arrhythmias.[102] [103] In 30 patients (mean age, 35 years), ECGs were abnormal in 26, primarily with atrial abnormality or minor conduction disease. Ten patients underwent invasive electrophysiological study with findings of abnormal sinus node function in 3, prolonged H-V interval in 1, and inducible sustained or unsustained episodes of atrial fibrillation or atrial flutter with single atrial extrastimuli in 8. In 100 patients with facioscapulohumeral muscular dystrophy genetically linked to chromosome 4q35, 5 percent were found to have arrhythmic disease in the absence of cardiovascular risk factors.[103] Three patients were symptomatic, with one requiring pacemaker implantation for AV block. Clinical correlation and follow-up was not available in either of these studies. Early reports of permanent atrial paralysis in facioscapulohumeral muscular dystrophy are likely cases of Emery-Dreifuss muscular dystrophy.

TREATMENT AND PROGNOSIS.

Because significant clinical cardiac involvement is rare in facioscapulohumeral muscular dystrophy, specific monitoring or treatment recommendations are not well defined. One group has recommended yearly ECGs.[103]

FRIEDREICH ATAXIA

GENETICS

Friedreich ataxia is a progressive spinocerebellar degenerative disease characterized clinically by ataxia of the limbs and trunk, dysarthria, loss of deep tendon reflexes, sensory abnormalities, skeletal deformities, and cardiac involvement. It is inherited in an autosomal recessive fashion with linkage to chromosome 9.[104] The gene responsible has been identified and has been found to encode a 210-amino acid protein, frataxin.[105] Frataxin is a mitochondrial protein important in iron homeostasis and respiratory function.[106] [107] Abnormalities in frataxin leads to mitochondrial dysfunction, poor cellular response to oxidative stress, and apoptosis.[108] [109]

Messenger RNA for frataxin is highly expressed in the heart. The mutations identified have been primarily an amplified and unstable trinucleotide (guanine-adenine-adenine [GAA]) repeat found in the first intron. Increasing size of this expansion has been found to correlate with the age at onset and severity of neurological symptoms and the degree of left ventricular hypertrophy by echocardiography.[110] [111] [112]

CLINICAL PRESENTATION.

The estimated prevalence of Friedreich ataxia is 1 in 50,000. Neurological symptoms usually manifest around puberty and almost always before age 25. Progressive loss of neuromuscular function, with the individual wheelchair-bound 10 to 20 years after symptom onset, is the norm. Neurological symptoms precede cardiac symptoms in most but not all cases.

CARDIOVASCULAR MANIFESTATIONS.

Friedreich ataxia is frequently associated with a concentric hypertrophic cardiomyopathy (Fig. 71-11) .[112] Asymmetric septal hypertrophy is also observed. A left ventricular outflow gradient has been reported in some cases. Presentation with a dilated cardiomyopathy is more rare but can occur (Fig. 71-12) . Whether the dilated cardiomyopathy occurs as a progressive transition from the hypertrophic cardiomyopathy or is a distinct entity is not known. A recent study would support the former.[113] The prevalence of hypertrophy varies between studies but does increase in likelihood with younger age at diagnosis and with increasing GAA trinucleotide repeat length.[112] [114] As high as 95 percent of neurologically symptomatic patients have cardiac abnormalities on ECG and echocardiographic evaluation. Findings are consistent with ventricular hypertrophy. On ECGs, left ventricular hypertrophy is not always present despite echocardiographic evidence.[114A] Widespread T wave inversion is common (Fig. 71-13) .

Arrhythmias.

These can occur but are less common then what might be expected considering the high incidence of cardiac muscle involvement and hypertrophy. Atrial arrhythmias including atrial fibrillation and atrial flutter are associated with the dilated cardiomyopathy.[115] Clinically relevant disorders of impulse formation or conduction have not been reported despite histopathological evidence of conduction system involvement.[115] Ventricular tachycardia in the setting of dilated cardiomyopathy has been observed.[116] However, ventricular tachyarrhythmias are not associated with the hypertrophic cardiomyopathy. Sudden death can occur, but the mechanism of this

death has not been well characterized.

Endomyocardial Biopsy.

This procedure has demonstrated myocyte hypertrophy and interstitial fibrosis.[117] His

Ao=aorta; LA=left atrium. (From Perloff JK: Cardiac manifestations of neuromuscular disease. *In* Abelmann WH [ed]: Cardiomyopathies, Myocarditis, and Pericardial Disease. vol. 2. *In* Braunwald E [series ed]: Atlas of Heart Diseases. Philadelphia, Current Medicine, 1995, pp 6.1-6.19.)

Figure 71-12 *A,* Gross and histological specimens from a 17-year-old boy with Friedreich ataxia whose echocardiogram progressed from normal at age 13 years to a minimally dilated, hypocontractile left ventricle 3 to 4 years later. The gross specimen shows a mildly dilated left ventricle (LV) with normal wall thickness; the walls were flabby. The microscopic section from the left ventricular free wall shows marked connective tissue replacement. Although specifically sought, small-vessel coronary artery disease was not identified. *B,* Two-dimensional echocardiogram (apical window) showing the mildly dilated, thin-walled left ventricle (LV). LA=left atrium. (From Child JS, et al: Cardiac involvement in Friedreich ataxia. J Am Coll Cardiol 7:1370, 1986. Copyright 1986, American College of Cardiology.)

topathological examination, at the time of autopsy, revealed myocyte hypertrophy and degeneration, interstitial fibrosis, active muscle necrosis, bizarre pleomorphic nuclei, and periodic acid-Schiff-positive deposition in both large and small coronary arteries. Degeneration and fibrosis in cardiac nerves and ganglia and the conduction system have also been observed.[115] [117] Myocardial fiber disarray, as observed in genetic hypertrophic cardiomyopathy, is rare.[115] Deposition of calcium salts and iron have been reported. How these cardiac pathological findings relate to abnormalities in the protein frataxin is unknown.

TREATMENT AND PROGNOSIS.

No specific therapy for the neurological or cardiac disease is available. Progressive neurological dysfunction is common, with death from respiratory failure or infection occurring in the fourth or fifth decades. Cardiac death can occur, primarily in those developing a dilated cardiomyopathy. These patients tend to do poorly, with rapid progression to end-stage congestive heart failure.

Figure 71-13 Electrocardiogram from a 34-year-old man with Friedreich ataxia. Widespread ST and T changes are observed. (Courtesy of Charles Fisch, M.D., Indiana University School of Medicine, Indianapolis, IN.)

LESS COMMON NEUROMUSCULAR DISEASES ASSOCIATED WITH CARDIAC MANIFESTATIONS

The Periodic Paralyses

GENETICS

The primary periodic paralyses are rare, nondystrophic, autosomal dominant disorders that result from abnormalities in ion channel genes. They can be classified into hypokalemic and hyperkalemic (potassium-sensitive) periodic paralysis with several subclassifications in each. Hypokalemic periodic paralysis is characterized by episodic attacks of weakness in association with decreased serum potassium levels. Penetrance is complete in males and approximately 50 percent in females.[118] Hypokalemic periodic paralysis has been mapped to chromosome 1q31-32 with subsequent identification of mutations in the alpha$_1$ subunit of the dihydropyridine-sensitive calcium channel. [119] [120] The disease may be genetically heterogeneous, as observed with the identification of a family with hypokalemic periodic paralysis and a mutation in the skeletal muscle sodium channel (SCN4A).[118]

Hyperkalemic periodic paralysis also manifests as episodic weakness but with symptoms worsening with potassium supplementation. Complete penetrance is observed. Potassium levels are usually high but may be normal during an attack. Hyperkalemic periodic paralysis is due primarily to mutations in the alpha subunit of SCN4A found on chromosome 17.[121] Multiple different mutations in this gene have been reported and result in a potassium-sensitive failure of inactivation in the sodium channel.[122] Hyperkalemic periodic paralysis is genetically heterogeneous. Andersen syndrome, a potassium-sensitive periodic paralysis associated with characteristic dysmorphic features and ventricular arrhythmias, is not secondary to SCN4A mutations or known long QT syndrome genetic loci (Fig. 71-14) (Figure Not Available) .[123] The genetic abnormality in this disease remains unknown.

CLINICAL PRESENTATION.

Episodic weakness is usually the presenting symptom in both of the periodic paralyses. Attacks of weakness tend to be more severe and of longer duration with hypokalemic periodic paralysis than with hyperkalemic periodic paralysis. In both diseases, cold and rest after exercise can trigger an attack. Ingestion of carbohydrates can trigger an attack in hypokalemic periodic paralysis but may ameliorate an attack in hyperkalemic periodic paralysis.[124]

CARDIOVASCULAR MANIFESTATIONS.

Patients with the periodic paralyses are at an increased risk of ventricular tachycardias with occurrence more common with hyperkalemic periodic paralysis. In both, bidirectional ventricular tachycardia has been observed independent of digitalis intoxication.[123] [125] The bidirectional ventricular tachycardia occurs independent of attacks of muscle weakness, generally does not correlate with serum potassium levels, and can convert to sinus rhythm with exercise. Ventricular ectopy is common, often seen interspersed with bidirectional ventricular tachycardia (see Chap. 25) .

Prolonged QT interval can be observed. In some reports, this is episodic and associated with weakness, hypokalemia, or antiarrhythmic therapy. In other cases, a prolonged QT interval can be constant. Andersen syndrome is more commonly associated with a prolonged QT interval and ventricular tachycardia. Sudden death has been reported.

TREATMENT AND PROGNOSIS.

The episodes of weakness commonly respond to measures that work to normalize potassium levels.[124] Weakness in hyperkalemic periodic paralysis can respond to mexiletine. Treatment of electrolytes usually does not improve arrhythmias or, if it does, only transiently. Improvement in symptomatic nonsustained ventricular tachycardia associated with a prolonged QT interval has been reported with beta-blocker therapy. Class 1A antiarrhythmic agents can worsen muscle weakness and exacerbate arrhythmia associated with a prolonged QT interval.[125] Bidirectional ventricular tachycardia, not associated with a prolonged QT interval, may not respond to beta-blocker therapy. Imipramine has been observed to decrease the episodes of bidirectional ventricular tachycardia.[125] Whether other antiarrhythmic therapies have a role in the treatment of the periodic paralyses is unknown.

Copyright 1994, American Neurological Association.)

Mitochondrial Encephalomyopathies

GENETICS

The mitochondrial encephalomyopathies are a heterogeneous group of disorders resulting from mutations in mitochondrial DNA.[126] The number of distinct disorders is extensive. Mitochondrial DNA is inherited maternally, and the majority of these disorders are thus transmitted from mother to children of both sexes. Some of the disorders occur sporadically or are inherited in an autosomal fashion. It is not surprising, based on the important metabolic function of mitochondria, that these disorders manifest with systemic pathology involving metabolic, neurological, and cardiac function. Mitochondrial encephalomyopathies, which have cardiac manifestations, present as several clinical phenotypes, including chronic progressive external ophthalmoplegia, which includes the Kearns-Sayre syndrome; myoclonus epilepsy with red ragged fibers [MERRF]; mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes [MELAS]; and Leber hereditary optic neuropathy. Other, more rare mitochondrial disorders present primarily with cardiac manifestations, often a dilated cardiomyopathy.[127] Chronic progressive external ophthalmoplegia is primarily a sporadic disease, whereas the others listed are maternally inherited.

CLINICAL PRESENTATION.

Kearns-Sayre syndrome is characterized by the clinical triad of progressive external ophthalmoplegia, pigmentary retinopathy, and AV block (Fig. 71-15) . Diabetes, deafness, and ataxia can also be associated. Clinical features of MERRF include myoclonus,

Figure 71-15 An 18-year-old girl with Kearns-Sayre syndrome and bilateral asymmetrical ptosis. Within 24 months, her electrocardiogram changed from normal to bifascicular block (complete right bundle branch block and left anterior fascicular block). *A,* Asymmetrical ptosis when the patient looks straight ahead. *B,* Ptosis of the right lid persists when the patient looks up. She also had typical pigmentary retinopathy. (*A* and *B* courtesy of Joseph K. Perloff, M.D.)

seizures, ataxia, dementia, and skeletal muscle weakness. MELAS is the most common of the maternally inherited mitochondrial disorders and is characterized by encephalopathy, subacute strokelike events, migraine-like headaches, recurrent emesis, extremity weakness, and short stature. *Leber hereditary optic neuropathy* manifests as a severe, subacute, painless loss of central vision, predominantly affecting young men.

CARDIOVASCULAR MANIFESTATIONS.

In chronic progressive external ophthalmoplegia, primarily in the *Kearns-Sayre syndrome,* cardiac involvement manifests as conduction abnormalities.[128] [129] A dilated cardiomyopathy has also been reported.[130] In the Kearns-Sayre syndrome, AV block is exceedingly common, usually presenting after eye involvement becomes manifest. In one series reporting 5 cases and reviewing 30 additional cases, Stokes-Adams syncope occurred in 29 percent, 34 percent had permanent pacemakers implanted, and in 7 patients (20 percent) AV block was believed to contribute to death.[128] The H-V interval is prolonged, consistent with distal conduction disease.[131]

Leber hereditary optic neuropathy can be associated with a short PR interval and preexcitation syndromes in a significant proportion.[132] In a review of 55 patients from eight pedigrees, 16 were noted to have a PR interval less than 120 milliseconds, with 5 manifesting preexcitation. Supraventricular tachycardia has been reported.

In MERRF and MELAS, cardiac involvement manifesting as hypertrophic cardiomyopathy (symmetrical or asymmetrical) has been observed.[129] [133] These patients can develop chest pain with ECG abnormalities and myocardial perfusion defects.[134] Progression (or questionably a second entity) to dilated cardiomyopathy can occur with heart failure and death.

Preexcitation has been described with MELAS.[129]

Several mitochondrial DNA mutations can be associated with dilated cardiomyopathy in the absence of other clinical abnormalities.[126]

TREATMENT AND PROGNOSIS.

In *Kearns-Sayre syndrome,* the prophylactic implantation of a pacemaker has been advocated when distal conduction disease is evident. Pacing appears to improve survival.[128] [129] The degree of distal conduction disease that warrants prophylactic pacing is not clear. In *Leber hereditary optic neuropathy,* a baseline ECG may be prudent. In the other mitochondrial disorders, an understanding of the potential for cardiac involvement is necessary. Whether specific evaluation in these disorders without symptoms is necessary is uncertain.

Spinal Muscular Atrophy

GENETICS

Spinal muscular atrophies are a group of lower motor neuron disorders presenting as progressive, symmetrical muscle weakness. In most cases, an autosomal recessive pattern of inheritance is observed but there is genetic heterogeneity.[135] By means of linkage analysis, the spinal muscular atrophies were mapped to chromosome 5q11.2-q13.3.[136] Mutations in a particular gene, *SMN* (survival of motor neuron), are responsible for this disorder.[137] Severity of the disease is correlated with the degree of reduction of the protein product of this gene.[138]

CLINICAL PRESENTATION.

Spinal muscular atrophies are divided into three clinical groups characterized by the age at onset, degree of muscular weakness, and survival.[139] Type I (Werdnig-Hoffmann disease) and type II have early childhood onset with severe limitation of life span. Spinal muscular atrophy type III (Kugelberg-Welander disease) is characterized by childhood or adolescent onset of atrophy and weakness in proximal muscles with slow progression.

CARDIOVASCULAR MANIFESTATIONS.

Cardiac involvement in spinal muscular atrophies include coexisting complex congenital heart disease, cardiomyopathy, and arrhythmias. Congenital heart disease has been associated with type I and III spinal muscular atrophies.[140] The most common abnormality is atrial septal defect, with other abnormalities reported. In spinal muscular atrophy type III, a dilated cardiomyopathy may occur with endomyocardial biopsy specimens demonstrating fibrosis.[141] Progression leading to a fatal outcome has been reported. Arrhythmic abnormalities including atrial standstill, atrial fibrillation, atrial flutter, and AV block may be the most common cardiac manifestation in these diseases.[141] Permanent pacing for atrial standstill and AV block has been reported.

TREATMENT AND PROGNOSIS.

The skeletal muscle involvement in spinal muscular atrophy type I and II limit life span so significantly that treatment of associated cardiac abnormalities is often not indicated. In spinal muscular atrophy type III, awareness of the potential of associated cardiac abnormalities is necessary. Permanent pacing may be required.

Guillain-Barre Syndrome

CLINICAL PRESENTATION.

The Guillain-Barre syndrome is an acute inflammatory demyelinating neuropathy characterized by peripheral, cranial, and autonomic nerve dysfunction.[142] It is the most common acquired demyelinating neuropathy, with an annual incidence of 1.7 per 100,000 population. The syndrome usually occurs 5 days to 3 weeks after a viral respiratory illness, a gastrointestinal infection, an immunization, or surgery. This disorder usually presents as symmetrical limb weakness that can progress to involve

cranial and respiratory muscles. Approximately one third of individuals require assisted ventilation.

CARDIOVASCULAR MANIFESTATIONS.

Cardiac involvement in Guillain-Barre syndrome is related to accompanying autonomic nervous system

dysfunction that manifests as hypertension, orthostatic hypotension, resting sinus tachycardia, loss of heart rate variability, ST segment abnormalities, and both bradyarrhythmias and tachyarrhythmias.[143] [144] Significant autonomic nervous system dysfunction occurs primarily in severe cases of Guillain-Barre syndrome. Microneurographic recordings have shown increased sympathetic outflow during an acute phase of the disease that normalized with recovery.[145]

Life-threatening arrhythmias are common in severe cases of Guillain-Barre syndrome, primarily those requiring assisted ventilation. In a prospective study of 100 patients, serious arrhythmias occurred in 11 of 33 patients requiring ventilation.[143] This included asystole in 6, bradycardia of less than 30 beats/min in 1, rapid atrial fibrillation in 2, and ventricular tachycardia/fibrillation in 2. Thirteen deaths occurred, with four due to arrhythmias. All individuals with serious arrhythmias had signs of autonomic dysfunction. In this series and in other reports, asystole was commonly associated with tracheal suction.[143]

TREATMENT AND PROGNOSIS.

In addition to supportive care, early plasmapheresis and intravenous immunoglobulin can improve recovery.[142] In patients requiring ventilation, cardiac rhythm monitoring is mandatory. If serious bradycardia or asystole is observed, temporary or permanent pacing can improve survival. Atropine or isoproterenol during tracheal suction can be of benefit. The mortality rate in individuals hospitalized with Guillain-Barre syndrome is as high as 20 percent. In individuals who recover from Guillain-Barre syndrome, autonomic function also recovers, and no long-term arrhythmia risk has been observed.

Myasthenia Gravis

CLINICAL PRESENTATION.

Myasthenia gravis is a disorder of neuromuscular transmission resulting from production of antibody targeted against the nicotinic acetylcholine receptor.[146] The primary symptom, fluctuating weakness, usually begins with the eye and facial muscles and later can involve the large muscles of the limbs. Patients can present at any age, most commonly at a younger age in women and an older age in men. Myasthenia gravis is usually associated with hyperplasia or a benign or malignant tumor (thymoma) of the thymus gland. The prevalence in the United States is 1 per 33,000.

CARDIOVASCULAR MANIFESTATIONS.

A myocarditis can be associated with myasthenia gravis, especially that occurring with thymoma.[147] A cardiac muscle antibody may be responsible.[148] Whereas cardiac pathological changes at autopsy are believed to be common, signs and symptoms of cardiac disease have been historically considered to be more rarely observed and nonspecific. This lack of symptomatic involvement may not always be true. In one series of 108 myasthenia gravis patients, 17 (16 percent) had evidence of cardiac abnormalities not explained by another etiology.[147] In 11 (10 percent) of these patients, clinical cardiac manifestations primarily arrhythmic occurred. These included atrial fibrillation, AV block, asystole, and unexplained sudden death. Cardiac abnormalities were more common in thymoma patients (50 percent) than among non-thymoma patients (12 percent). Autopsy findings were consistent with myocarditis.

TREATMENT AND PROGNOSIS.

Myasthenia gravis is treated with anticholinesterase and immunosuppressive agents. Thymectomy is often indicated. Anticholinesterase agents may slow heart rate and lead to hypotension.[149] No specific therapy has been discussed for the cardiac involvement. Whether immunosuppressive agents or thymectomy improves cardiac disease is unknown. Use of quinidine and propranolol in patients with myasthenia gravis may precipitate an acute exacerbation of weakness.[147] [150]

ACUTE CEREBROVASCULAR DISEASE

CARDIOVASCULAR MANIFESTATIONS.

Acute cerebrovascular diseases, including subarachnoid hemorrhage, other stroke syndromes, and head injury, can be associated with severe cardiac manifestations.[151] The mechanism by which this occurs appears to be related to abnormal autonomic nervous system function, primarily a markedly increased sympathetic and parasympathetic output. Hypothalamic stimulation can reproduce the ECG changes observed in acute cerebrovascular disease. ECG changes associated with hypothalamic stimulation or blood in the subarachnoid space can be prevented or diminished with spinal cord transection, stellate ganglion blockade, vagolytics, and adrenergic blockers.

Electrocardiography.

Abnormalities on ECGs are observed in as high as 80 to 90 percent of individuals with subarachnoid hemorrhage.[151] [152] Abnormalities including ST segment elevation and depression, T wave inversion, and pathological Q waves are observed.[151] [153] Peaked inverted T waves and a prolonged QT interval may occur in 25 to 40 percent of patients (Fig. 71-16) . Hypokalemia is

Figure 71-16 Electrocardiogram from a patient with cerebral hemorrhage. Deep and symmetrical T wave inversions are observed. (Courtesy of Charles Fisch, M.D., Indiana University School of Medicine, Indianapolis, IN.)

Figure 71-17 A 49-year-old patient with cerebral hemorrhage. *A,* Electrocardiogram recorded within 3 hours of admission and 4 hours after onset of symptoms. QT interval prolongation is observed. *B,* Electrocardiographic monitoring at 6 hours after admission. Ventricular bigeminy precedes the onset of polymorphic ventricular tachycardia. Cardioversion was required. The patient was subsequently treated with a beta-adrenergic blocker without further ventricular tachycardia. *C,* Electrocardiogram done 2 weeks after admission. QT interval has normalized.

observed in up to 50 percent of patients with subarachnoid hemorrhage, and this increases the likelihood of QT interval prolongation.[154]

Other stroke syndromes are often associated with abnormal ECGs, but whether these are related to the stroke syndrome or to underlying intrinsic cardiac disease is often difficult to discern.[151] A prolonged QT interval is more common in subarachnoid hemorrhage than other stroke syndromes. Closed-head trauma can cause similar ECG abnormalities as subarachnoid hemorrhage, including a prolonged QT interval. Myocardial damage with liberation of myocardial enzymes and subendocardial hemorrhage or fibrosis at autopsy can occur in the setting of acute cerebrovascular disease. Like the ECG changes, these abnormalities are believed related to local myocardial catecholamine excess.

Neurogenic pulmonary edema may accompany the acute neurological insult.[155] [156] This edema can have both a cardiogenic component, related to systemic hypertension, and a noncardiogenic (pulmonary capillary leak) component.

Arrhythmia.

Life-threatening arrhythmias can occur in the setting of acute cerebrovascular disease. Ventricular tachycardia or fibrillation has been observed in patients with subarachnoid hemorrhage and head trauma.[154] [157] A torsades de pointes type of ventricular tachycardia can occur (Fig. 71-17) . Often this is observed in the setting of a prolonged QT interval and hypokalemia. Stroke syndromes, other than subarachnoid hemorrhage, appear to be only rarely associated with serious ventricular tachycardias.[151] Atrial tachyarrhythmias including atrial fibrillation and regular supraventricular tachycardia have been observed.[151] [152] [154] Atrial fibrillation is most common in individuals presenting with what is believed to be an acute thromboembolic stroke.[151] Separating an effect from a cause may be difficult. Bradyarrhythmias including sinoatrial block, sinus arrest, and AV block occur in up to 10 percent of individuals with subarachnoid hemorrhage.[154] Bradyarrhythmias are less common in other stroke syndromes.

TREATMENT AND PROGNOSIS.

Beta-adrenergic blockers appear effective in decreasing myocardial damage and in controlling both supraventricular and ventricular tachyarrhythmias associated with subarachnoid hemorrhage and head trauma.[158] Beta-adrenergic blockers can increase the likelihood of bradyarrhythmias.[154] Life-threatening arrhythmias appear to occur in the first day after the neurological event.[154] Continuous ECG monitoring during this period is indicated. Careful monitoring of potassium levels especially in patients with subarachnoid hemorrhage is warranted. Refractory ventricular tachyarrhythmias can be controlled effectively with stellate ganglion blockade.[159]

ECG abnormalities reflect adverse intracranial factors but do not appear to portend a poor cardiovascular outcome.[153] [160] [160A]

Head injury (blunt trauma or gunshot wound) and cerebrovascular accident are the leading causes of brain death in individuals being considered as heart donors. These donors may manifest ECG abnormalities, hemodynamic instability, and myocardial dysfunction related primarily to adrenergic storm and not to intrinsic cardiac disease. Experimental studies on whether contractile performance recovers with transplantation are still controversial.[161] [162] [163] Optimization of volume status and inotropic support with careful echocardiographic evaluation and possibly left-sided heart catheterization may allow the use of some donor hearts that would have otherwise been rejected.

Chapter 72 - Renal Disorders and Cardiovascular Disease

HARISIOS BOUDOULAS
CARL V. LEIER

The kidneys can be viewed as components of the circulatory system. Within this integrated system, the function, regulation, and adjustments of the heart and vasculature are closely linked to those of the kidneys. Renal dysfunction and failure adversely affect cardiovascular function, frequently leading to a cardiovascular disorder or failure and, consequently, further impairment of renal performance. Cardiovascular disease, dysfunction, and failure, in turn, can disturb renal function, occasionally to the point of evoking acute or chronic renal failure (CRF), which then causes further deterioration of the cardiovascular condition. Clinicians have for years appreciated the fact that failure of one component of the cardiorenal system (e.g., renal failure) greatly amplifies the difficulty in clinical management of the failure of another component (e.g., heart failure).

The effects of heart failure and cardiogenic shock on renal function are described in Chapters 16 and 35 , respectively. This chapter discusses other cardiovascular disorders that commonly affect renal performance and the primary renal conditions responsible for altering cardiovascular structure and function.

Cardiovascular Conditions That Affect Renal Function

INFECTIVE ENDOCARDITIS (See also Chap. 47)

In the preantibiotic era, 10 to 15 percent of deaths due to infective endocarditis were attributable to renal failure. Early recognition, precise identification of the infecting organism, and prompt, aggressive antibiotic therapy specifically directed at the offending organism have greatly reduced the renal complications of infective endocarditis, particularly renal failure. Nevertheless, more than 60 percent of patients with documented infective endocarditis have clinical, laboratory, or biopsy evidence of renal involvement.[1] [2] [3] [4] [107A] The manifestations of endocarditic renal disease range from none to hematuria, pyuria, proteinuria, and occasional renal failure. As many as one-third of patients with infective endocarditis present with serum creatinine values of 2.0 mg/dl or higher.[4]

The deposition of immune complex material in glomeruli represents the most common mechanistic link between infective endocarditis and its renal consequences. Circulating immune complexes and their subsequent deposition in kidneys (and elsewhere) account for the common laboratory finding of reduced serum levels of certain complements (e.g., C3, C4, C1q) in affected individuals. The resultant glomerular lesions are generally proliferative in histological type, with demonstrable immune deposits of IgG, IgM, and C3 along the basement membrane and in the mesangium. The distribution of the glomerular lesions ranges from focal/segmental to diffuse, and their clinical behavior from subclinical to rapidly progressive.

FOCAL/SEGMENTAL PROLIFERATIVE GLOMERULONEPHRITIS.

This is the most commonly encountered glomerulopathy in infective endocarditis and represents a wide spectrum of involvement, including focal inflammation of single tufts of glomerull, sporadic glomerular inflammation and fibrosis, and inflammation and fibrosis of most glomerull within a renal segment(s) in the midst of normal-appearing kidney.[1] [2] [3] [107A] The demonstration of immune complex components in the involved glomerull and the observation that similar glomerular lesions can occur in isolated right-sided heart endocarditis, nonendocarditic infections, and noninfectious inflammatory conditions implicate immunological mechanisms as the cause of the focal/segmental glomerulonephritis of infective endocarditis. The focal/segmental glomerulonephritis can be widespread, such that occasionally it is indistinguishable from diffuse proliferative glomerulonephritis. Although the urine of patients with focal/segmental glomerulonephritis may not be unusual. It customarily shows microscopic hematuria, sterile pyuria, or mild proteinuria.

DIFFUSE PROLIFERATIVE GLOMERULONEPHRITIS.

This lesion, viewed by many simply to represent a more severe and extensive form of focal/segmental glomerulonephritis, attacks most glomerull with a very proliferative cellular process, usually involving the entire glomerulus. The clinical consequences of systemic hypertension, nephritic proteinuria, and CRF are considerably more prevalent with the diffuse forms of proliferative glomerulonephritis. Hematuria, sterile pyuria, proteinuria, and heme or red blood cell casts are common features on urinalysis.

Renal biopsy reveals considerable proliferation and swelling of endothelial, epithelial, and mesanglal cells, giving the typically involved glomerulus a packed cellullar, even avascular, appearance. Rapidly progressive glomerulonephritis with widespread glomerular crescent formation can occasionally occur in infective endocarditis and is often the explanation for rapid loss of renal function.

MANAGEMENT.

Prompt identification and aggressive antibiotic treatment of the infecting organism are the principal means of preventing endocarditic renal disease. Antibiotic therapy has lowered the incidence of diffuse proliferative

glomerulonephritis during infective endocarditis from 55 to 80 percent to less than 15 percent.[1] [2] [3] [107A] [5] [6] Pharmacological control of systemic hypertension and dialysis for renal failure occasionally are necessary supportive measures.

RENAL EMBOLIZATION.

Although evidence of renal embolization is found at necropsy in 60 to 70 percent of patients who die of infective endocarditis, less than 25 percent have clinically recognizable renal emboli[1] [2] [3] [107A] [7] Hematuria is the most common sign of renal emboli. Back or flank pain and renal hemorrhage, rarely fatal, can occur with a large embolus and sizable renal infarction. Larger emboli most often originate from prosthetic valves or from valvular infections caused by*Staphylococcus aureus, Neisseria gonococcus, Streptococcus pneumoniae,* or fungi. On rare occasions, an infected embolus can evolve into a renal abscess. Currently available imaging methods (e.g.,

echocardiography) do not yet provide the information needed to reliably identify those at risk for systemic or renal embolization.[8] [9] [10]

THROMBOEMBOLIC DISEASE

CAUSES.

Table 72-1 presents the major cardiovascular conditions responsible for renal embolization. Because 14 to 20 percent of cardiac output passes through the kidneys and because of their direct proximity to the commonly diseased aorta, the kidneys represent favorite targets for arterial embolization.[11] [12] [13] [14] [15] [16] [17] [18] [19] The atherosclerotic aorta is a common source of fibrin, plaque, and cholesterol emboli (see Chap. 40) . Suprarenal aneurysms, aortic surgery, intraaortic balloon counterpulsation, cardiac or aortic catheterization, anticoagulation, and thrombolytic therapy increase the risk

TABLE 72-1 -- MAJOR CARDIOVASCULAR SOURCES, CAUSES, AND PREDISPOSING FACTORS FOR EMBOLIZATION TO KIDNEYS

AORTA
Atherosclerotic disease
Extensive atherosclerotic plaque formation; rupture, thrombus and cholesterol embolization
Suprarenal aortic aneurysm
Cardiac and aortic catheterization
Intraaortic balloon counterpulsation therapy
Anticoagulation
Thrombolytic therapy
Aortic surgery
ATRIA
Atrial fibrillation
Atrial enlargement
Cardiomyopathy
Atrial septal aneurysms
Paradoxical embolization
Myxoma (less commonly located in ventricles and on valves)
States of hypercoagulation (e.g., neoplastic diseases; protein C, protein S, or antithrombin III deficiency)
VENTRICLES
Mural thrombus
Myocardial infarction
Cardiomyopathy
Cardiac tumors
States of hypercoagulation (see Atria, above)
VALVES
Mitral stenosis (via atrial or valvular thrombus calcification)
Prosthetic valves
Endocarditis
Infective
Marantic (noninfective thrombotic)
Mitral annular calcification

of renal embolization from the atherosclerotic aorta. Massive embolization to skeletal muscle can exacerbate or cause renal dysfunction and failure via myoglobinemia-myoglobinuria. The more common cardiac conditions serving as embolic sources are atrial fibrillation, mural thrombi of the left ventricle, mitral stenosis, and prosthetic heart valves (see Table 72-1) .

Renal pathology ranges from isolated occlusion of an arteriole with minimal histological change, to segmental infarction ("white infarcts" and scarring), to complete occlusion of a renal artery with unilateral loss of renal function and mass. Cholesterol clefts and calcified debris are histological features of atherosclerotic emboli. Capsular rupture and retroperitoneal hemorrhage can complicate a large infarction.

Similar to embolization elsewhere, the majority are not likely to be detected clinically. Clinical manifestations include various degrees of hematuria, proteinuria, back or flank pain, systemic hypertension (secondary to elevated plasma renin), and renal dysfunction. Extensive embolization to both kidneys or a large embolus of a sole functioning kidney can result in anuria. Eosinophilia, depressed serum levels of C3 and C4, and rarely, lipid droplets floating in a urine sample can be noted with cholesterol emboli. The renal manifestations of atherosclerotic or cholesterol emboli are commonly part of an embolic multisystem "polyarteritis" presentation. Clinical suspicion of renal emboli is raised in patients with an obvious predisposition (e.g., prosthetic heart valve, atherosclerotic aorta, aortic surgery, recent cardiovascular catheterization). Perfusion defects secondary to large emboli are detectable with renal radionuclide scanning. Renal arteriography generally shows a cutoff sign at the point of occlusion, with few vascular markings distal to the occlusion. The rim sign (subcapsular contrast overlying regions of noncontrast) may be seen with extensive or large embolization.

MANAGEMENT.

This is generally directed at correcting the source of embolization with supportive therapy for accompanying systemic hypertension or renal failure. For large renal emboli, local thrombolytic therapy, angioplasty, retrieval via catheter, and surgical embolectomy are the principal interventional options.[18] [19] The approach to atherosclerotic-cholesterol emboli is somewhat limited; an obvious source (e.g., suprarenal atherosclerotic aortic disease or aneurysm) should be considered for resection, with the understanding that the aorta is usually diffusely involved with atherosclerosis and that further embolization may occur during and after surgery. Options to be considered in long-term medical management include lipid-lowering agents (particularly the statins), anticoagulation, and perhaps antiplatelet agents, although the effectiveness of these therapeutic modalities remains to be proved in this setting.[14] [17]

Other Cardiovascular Conditions

Aortic Aneurysm and Dissection (See also Chap. 40)

Atherosclerotic aneurysms can threaten renal function in a number of ways, including thromboembolism from a suprarenal location (see Thromboembolic disease, earlier), reduction of renal blood flow by local involvement or encroachment, rupture with hypovolemic shock, aortorenal vein fistula, ureteral obstruction, and the consequences of its surgical repair.[11] [20] [21] [22] Ten to 20 percent of atherosclerotic aortic aneurysms are complicated by renal artery stenosis. Clinical suspicion of renal involvement by an atherosclerotic aneurysm is prompted by recent onset or acceleration of systemic hypertension, location near the renal arteries, hematuria, proteinuria, occasional eosinophilla (in cases of atheroemboli), and renal dysfunction and failure. Aneurysmectomy with renal revascularization (when renal arteries are involved) is generally the treatment of choice.

Renal involvement by aortic dissection takes the form of renal artery occlusion or renal dysfunction secondary to compromised hemodynamics from

or acute myocardial infarction.[23] [24] Partial or total renal artery occlusion can occur via an ostial flap or displacement of the intima-media into the lumen as the dissecting hematoma moves into the renal artery. Renal manifestations can include proteinuria, hematuria, systemic hypertension (high plasma renin), renal infarction, azotemia, and renal failure. Anuria should bring bilateral renal artery occlusion (unilateral for a sole functioning kidney) into consideration. Operative correction of the dissection with renal revascularization remains the intervention of choice in most instances.[25] [26]

Congenital Heart Disease

CYANOTIC CONGENITAL DISEASE.

The clinical course of cyanotic congenital heart disease is often accompanied by the development of renal dysfunction.[27] [28] [29] Although the mechanism for the renal dysfunction is not known, its severity appears to be related to the level and duration of arterial desaturation, the degree of polycythemia, age, severity of right-sided heart failure, and elevation of systemic venous pressure. Histologically, the glomeruli enlarge ("glomerulomegaly") with mesangial hypercellularity, capillary congestion, focal glomerulosclerosis, and localized thickening of the basement membrane. Functionally, the disorder behaves as a glomerulopathy, with proteinuria occurring in 30 percent and microscopic hematuria in 15 to 20 percent of patients.[27] [29] Five to 10 percent develop considerable proteinuria and occasionally the nephrotic syndrome, usually after the age of 21 years.[27] [28] Tubular dysfunction can occur. Because of increased uric acid production during polycythemia and the tubular dysfunction, hyperuricemia is a common metabolic complication of cyanotic heart disease. A reduction in renal blood flow, glomerular filtration rate (GFR) and urea clearance also occurs over time. Most of the glomerular lesions, renal dysfunction, and urinary findings are reversible and usually return toward normal after successful surgical correction of the cardiac defect and subsequent improvement in hemodynamics, oxygen delivery, and hematocrit.

COARCTATION OF THE AORTA.

This malformation has a significant impact on renal physiology and function.[30] [31] [32] [33] The lower renal perfusion pressure (distal to the coarctation) evokes sustained release of renin, which contributes to the characteristic hypertension present in the vascular system located above the coarctation. Depending somewhat on the age of the patient and duration of the condition, surgical or angloplasty correction usually does not immediately lower systemic blood pressure (in fact, it may initially increase), and systemic hypertension can persist long term after correction in up to one-third of the patients.[30] [32] [33] Congestive heart failure (CHF), infective endocarditis, and aortic dissection are other complications of coarctation, which, in addition to postrepair systemic hypertension, can adversely affect renal function. Fibromuscular dysplasia and developmental hypoplasia of the renal arteries have been reported in association with coarctation or hypoplasia of the abdominal aorta.[34] [35]

Effects of Renal Failure on the Cardiovascular System

CARDIAC FAILURE CAUSED BY RENAL FAILURE

Left ventricular (LV) dysfunction and CHF are common complications of CRF.[1] [36] [37] [38] [39] [40] [40A] [40B] [41] [42] [43] [44] [44A] Factors that contribute to myocardial damage and dysfunction in patients with this condition are depicted in Figure 72-1 . Because it is usually difficult to attribute a predominant causative role to any one of these factors or events, the term*uremic cardiomyopathy* is often used to identify the cardiac disorder resulting from the integration of the various disruptive factors of CRF.

Factors Contributing to the Development of Congestive Heart Failure

The conditions contributing to the development of CHF in patients with CRF are presented in Figure 72-2 .

Figure 72-1 Factors contributing to myocardial damage in patients with chronic renal failure. ATPase = adenosine triphosphatase. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

VOLUME OVERLOAD.

Loss of renal function allows salt and fluid retention and the development of volume overload. Other factors that contribute to volume overload are chronic anemia and the arteriovenous (AV) access fistula. Normochromic, normocytic anemia is common in CRF, with nontreated hematocrit values ranging from 20 to 30 percent and hemoglobin from 7 to 9 gm/dl; the introduction of erythropoietin therapy in CRF has reduced the degree and consequences of anemia. In general, the overall hemodynamic effect of the typical upper-extremity AV access fistula is small; however, the fistula may contribute to the development of CHF in patients with LV dysfunction.

The contribution of volume overload to the development of CHF in CRF is related to the magnitude and time course of volume expansion and to the concomitant status of cardiac function. A sudden rise in plasma volume can increase LV end-diastolic pressure to levels that produce pulmonary edema, even in the presence of normal resting LV systolic function. In contrast, a gradual increase in plasma volume can allow compensatory ventricular dilatation and hypertrophy with less immediate elevations in LV diastolic pressure.

PRESSURE OVERLOAD.

Systemic hypertension, a common finding in patients with CRF, contributes considerably to the generation of acute and chronic CHF by placing an excessive afterload burden on the dysfunctional heart. Increased afterload in CRF is also a result of reduced compliance

Figure 72-2 Factors contributing to the development of congestive heart failure in patients with chronic renal failure. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

of the aorta and large arteries.[45] Renal artery stenosis with secondary or concomitant CRF can cause episodic, marked systemic hypertension and consequently evoke intermittent acute heart failure and pulmonary edema.[46]

NEGATIVE INOTROPIC EFFECTS.

Several factors in CRF may decrease myocardial contractility. These include hypoxemia (may occur during hemodialysis), subendocardial ischemia, certain buffers (e.g., acetate) added to the hemodialysis fluid, elevated parathormone levels, various metabolic and electrolyte abnormalities, and "uremic toxins."

EFFECTS OF DIALYSIS AND RENAL TRANSPLANTATION ON THE HEART

DIALYSIS.

During dialysis, changes in preload, afterload, arterialPO_2 , adrenergic activity, concentrations of electrolytes, ionized calcium, "uremic toxins," and other metabolites and the composition of the dialysis solution affect cardiac-ventricular performance (Fig. 72-3) .[1] [28] [29] [30] [31] [32] [33] [34] [35] [36] [37] [38] [39] [40] [40A] [40B] The baseline status of LV function before the initiation of dialysis therapy is a major determinant of LV performance during dialysis. In general, patients with normal LV function experience little change or a modest decrease in LV performance during dialysis, whereas LV performance in those with baseline systolic dysfunction often improves during the procedure. These observations are due in part to the fact that the preload reduction of dialysis has less effect on LV systolic performance in the dysfunctional (systolic) LV compared with the normal LV, whereas the opposite responses occur during shifts in afterload. Preload reduction during dialysis can adversely affect LV systolic performance and overall hemodynamics in patients with predominant LV diastolic dysfunction.

Changes in preload and afterload during peritoneal dialysis are more gradual and less in magnitude, and thus the effects of peritoneal dialysis on LV performance are not as marked as those of hemodialysis. However, large amounts of intraperitoneal fluid can impair LV systolic performance by reducing venous return and raising afterload.[1] [40]

RENAL TRANSPLANTATION.

LV systolic and diastolic volumes and ventricular mass decrease and ejection fraction generally increases over 3 to 4 months after renal transplantation. These changes are likely related to favorable alterations of LV preload and afterload, an increase in hematocrit value, and correction of the various metabolic/endocrinological abnormalities already discussed.[1] [43] Because commonly

Figure 72-3 Effects of multiple factors and events during dialysis on left ventricular (LV) performance. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura,

1992.)

used immunosuppressive agents (e.g., cyclosporine) can evoke systemic hypertension, blood pressure should be checked regularly and treated appropriately in posttransplant patients.

Management of Heart Failure in Patients with Renal Failure

The clinical presentation and evaluation of CHF in patients with CRF are similar to those of patients without this condition (see Chap. 17) . As in patients without CRF, the principles of CHF management in CRF include correcting remedially reversible lesions (e.g., operable occlusive coronary disease), improving contributory conditions (e.g., severe anemia), and optimizing preload, afterload, and cardiac rhythm. Restriction of dietary sodium to 2 gm/day or less is recommended. Angiotensin-converting enzyme inhibitors, digitalis, and vasodilators are often useful in this setting.[1] The duration of dialysis may be lengthened to increase fluid removal or to remove the usual amount of fluid volume more gradually and thus avoid hypotension. Peritoneal dialysis should be considered if problematic hypotension occurs during hemodialysis in patients with both CRF and CHF. Erythropoietin is an effective and safe means of increasing the hematocrit of CRF anemia, and an oversized AV access shunt may have to be modified. Long-term administration of 1alpha-hydrocholecalciferol may improve LV performance by reducing circulating parathormone and improving cellular calcium, phosphorus, and magnesium metabolism. Renal transplantation usually improves LV performance, hemodynamics, and CHF symptoms. In select patients with end-stage myocardial and kidney disease, combined cardiac and renal transplantation, preferably from the same donor, should be considered.[43] [47]

HYPERTROPHIC CARDIOMYOPATHY (See also Chap. 48)

For yet undetermined reasons, hypertrophic cardiomyopathy and asymmetrical septal hypertrophy are not uncommon complications of CRF.[1] Patients with CRF with hypertrophic cardiomyopathy also invariably have LV diastolic dysfunction, which, when combined with a LV outflow tract gradient, makes them particularly vulnerable to the occurrence of systemic hypotension during hemodialysis. Special care must be taken to avoid volume depletion during hemodialysis in these patients, with consideration for peritoneal dialysis in those who experience problematic hypotension. If symptoms or complications during dialysis appear to be exacerbated by high adrenergic tone, beta-adrenergic blockade is a reasonable option.

ACCELERATED CORONARY ATHEROSCLEROSIS (See also Chap. 31)

Atherogenic Factors in Chronic Renal Failure

CHRONIC RENAL FAILURE AND DIALYSIS.

Cardiovascular mortality remains high in these patients. This is in large part related to aging of the affected population and to the increased number of diabetic patients undergoing long-term dialysis. Thirty to 35 percent of patients on long-term dialysis management have overt diabetes mellitus. Women with CRF develop coronary artery disease (CAD) as frequently and severely as age-matched men with CRF, perhaps because of earlier menopause and alterations in the pituitary-gonadal axis in these women.[1] [36] [44] For yet unknown reasons,

patients with chronic pyelonephritis or interstitial renal disease develop CAD more frequently than patients with other forms of CRF.

The principal atherogenic factors of CRF are shown in Figure 72-4. Carbohydrate and lipid abnormalities, including lipoprotein (a), occur early in chronic renal insufficiency (serum creatine levels >3 mg/dl) and persist as the patient's condition advances into end-stage renal failure and necessitates long-term dialysis. Glucose intolerance and insulin resistance have been demonstrated in a large proportion of patients who have CRF and who are not overtly diabetic, and patients undergoing long-term dialysis develop carbohydrate and lipid disturbances similar to those of diabetes mellitus (insulin resistance, glucose intolerance, increased triglycerides). Although the total cholesterol concentration in serum of patients with CRF on maintenance dialysis can be normal, the level of the high-density lipoproteins is usually depressed. Caucasian men with CRF have lower levels of high-density lipoproteins than African American men so affected, which may account for the higher incidence of CAD in the former group.[1] [48] [49] [50] [51] [52] Other abnormalities that likely augment the atherosclerotic process include carnitine deficiency (adversely affects lipoprotein metabolism), secondary hyperparathyroidism, vascular calcification, increased homocystine, various states of hypercoagulation, and enhanced fibrin and platelet deposition.[53] [54] [55] Depressed nitric oxide and elevated local and circulating levels of endothelin in patients with CRF may also have a role.[56] [57]

NEPHROTIC SYNDROME.

Elevation of serum lipid values is a major feature of the nephrotic syndrome. Total cholesterol and low-density lipoprotein cholesterol concentrations are generally elevated, and high-density lipoprotein cholesterol level is normal or low.[1] [58] These lipid derangements can persist for some time after remission of the nephrotic syndrome, particularly in children. Chronic hypertension and corticosteroid therapy further accelerate atherosclerosis in this subgroup of patients.

RENAL TRANSPLANTATION.

Cardiovascular disease contributes heavily to mortality after kidney transplantation. Many patients with CRF have generalized arteriosclerosis-atherosclerosis at the time of transplantation, and thus their pretransplant and posttransplant cardiovascular disease represents a continuum, perpetuated by the persistence, worsening, and accumulation of atherogenic risk factors (e.g., age, hypertension, diabetes, hyperlipidemia, immunosuppressive drugs)[1] [59] [60] (see Fig. 72-4) . The number of acute rejection episodes is also linked as an independent risk factor to the development of cardiovascular disease.[1] Significant proteinuria occurs in 10 to 15 percent of transplant recipients and usually indicates various degrees of graft rejection or failure; urinary protein excretion exceeding 0.5 gm daily in posttransplant patients is associated with a significant rise in low-density and very low-density lipoprotein cholesterol and in total triglyceride values. Immunosuppressive therapy with corticosteroids evokes insulin resistance and hyperlipoproteinemia. Cyclosporine increases total cholesterol by elevating the level of low-density lipoprotein cholesterol.[59] [60] Therefore, the cumulative atherogenic risk factors--long-term dialysis, renal transplantation, and periodic graft rejection--account for the high prevalence of morbid cardiovascular disease in renal transplant recipients.

FACTORS AFFECTING MYOCARDIAL OXYGEN SUPPLY AND DEMAND IN CHRONIC RENAL FAILURE

Although the general determinants of myocardial oxygen supply and demand in these patients are similar to those of patients without renal failure, CRF adds several conditions that can evoke myocardial ischemia, even without occlusive CAD. CRF adversely affects coronary perfusion pressure, diastolic perfusion time, and oxygen-carrying capacity of blood (Fig. 72-5) . Volume and pressure overload increase ventricular diastolic pressure and thus can decrease coronary perfusion pressure (coronary perfusion pressure during diastole equals coronary artery pressure minus LV diastolic pressure). In the presence of occlusive CAD, coronary artery pressure distal to a high-grade obstruction is not only low but is also not significantly affected by the usual changes in aortic diastolic pressure. Therefore, distal to an obstruction, only changes in LV diastolic pressure can significantly alter coronary perfusion pressure in that region of the heart.[61] An increase in heart rate (as occurs with dialysis, AV shunt, or anemia) reduces myocardial blood flow simply by decreasing diastolic perfusion time.

Because, the majority of coronary blood flow occurs in diastole and the duration of diastole (diastolic perfusion time) has a nonlinear inverse relationship with heart rate, even small increases in heart rate can substantially reduce diastolic perfusion time.[62] Anemia, a common feature of CRF, reduces the oxygen-carrying capacity of blood. Hemodialysis with accompanying hypotension, tachycardia, and leftward shift in the arterial hemoglobin-oxygen dissociation curve can be especially threatening to myocardial oxygenation. Coronary blood flow has been shown to decrease in some patients during hemodialysis.[63]

Chronic Coronary Artery Disease

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION.

CRF modifies the clinical presentation of chronic CAD with a greater prevalence of painless ischemia, partially attributable to a large proportion of patients with CRF with diabetes mellitus, and with chest pain secondary to various nonischemic causes (e.g., uremic pericarditis, neuritis).[1]

Figure 72-4 Factors contributing to the development and acceleration of coronary atherosclerosis in patients with chronic renal failure. HDL = high-density lipoproteins. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

Figure 72-5 Factors affecting myocardial oxygen supply and oxygen requirements in patients with chronic renal failure. AV = arteriovenous; LV = left ventricle. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

Electrocardiographic findings similar to those of myocardial ischemia (e.g., ST segment depression, T wave inversion) are present in many patients with CRF without significant CAD (especially during and after dialysis), thereby limiting the specificity of this diagnostic method. The sensitivity of radionuclide exercise testing for detecting obstructive CAD in CRF is low, perhaps because of generally poor exercise capacity,[1] [64] and data defining the sensitivity and specificity of radionuclide-perfusion imaging after dipyridamole administration are insufficient. Dobutamine-stress echocardiography has been shown to be a promising means of detecting significant CAD in CRF.[36] [65] Coronary arteriography is often required in patients with suspected or problematic CAD to define their coronary artery anatomy and pathology and to develop the most appropriate management plan.

USE OF CONTRAST RADIOGRAPHY.

To minimize the renal complications of radiocontrast angiography in patients who have serum creatinine concentrations greater than 2 mg/dl and who are not yet undergoing long-term dialysis, preprocedural hydration and postprocedural volume replacement (saline solution for urine volume) are the most effective interventions.[66] [67] Routine administration of 20 percent mannitol solution is no longer advocated in this clinical setting. The smallest possible amount of radiocontrast agent should be used, because the degree of nephrotoxicity is closely related to the quantity injected. Acute renal failure requiring dialysis is extremely unusual in patients who receive less than 100 ml of contrast agent. Patients with renal artery stenosis are especially susceptible to contrast-induced nephropathy. The osmotic and volume load of radiocontrast material can also provoke acute pulmonary edema in patients with CRF and underlying volume overload or LV dysfunction. Nonionic contrast material evokes less intravascular volume expansion and should generally be used in CRF. To further reduce the amount and risk of administered radiocontrast agent, information about ventricular size and function should be obtained via two-dimensional echocardiography or radionuclide angiography. Avoidance of other nephrotoxic drugs, such as nonsteroidal antiinflammatory agents, is prudent. When renal failure requiring dialysis occurs in the days after the procedure, it is associated with a high in-hospital mortality and poor long-term survival.

MANAGEMENT.

The general management approach to CAD in CRF is similar to that for patients without this condition (see Chap. 37) , but certain aspects of management are unique to CRF.[1] [68] [69] [70] [71] [72] [73] [74] [75] [76] [77] [78] [79] A diet weighted with polyunsaturated fats and a carbohydrate content of approximately 20 percent of total caloric intake is generally recommended. Lipid-lowering agents are usually effective in this clinical setting, and HMG-CoA reductase inhibitors are generally better tolerated in CRF than most other agents. Because of an increased risk of developing skeletal myopathy and rhabdomyolysis, the HMG-CoA reductase inhibitors must be used with caution in patients receiving cyclosporine. Disturbed calcium-phosphorus metabolism and resultant peripheral and coronary vascular calcification are approached with long-term oral administration of phosphate-binding agents (e.g., calcium carbonate, calcium acetate). For problematic CAD, it is often necessary to administer erythropoietin to keep hemoglobin values at 10 gm/dl or greater. Inadequate hemodialysis is associated with a suboptimal response to erythropoietin therapy. Increasing the intensity of dialysis in patients who have anemia and who are receiving inadequate dialysis results in a significant increase in the hematocrit value.

Oxygen administration at a flow rate of 2 to 3 liters/min may be useful in reducing hypoxemia and ischemic events during hemodialysis. When possible, sodium bicarbonate instead of sodium acetate should be used as the dialysis buffer. This maneuver improves arterial oxygenation, evokes less hypotension, and reduces the tendency of this procedure to precipitate myocardial ischemia. Certain patients with severe CAD and ventricular dysfunction cannot tolerate hemodialysis because of problematic dialysis-induced reduction in cardiac output or blood pressure; some of these patients require cardioactive drug support (e.g., dopamine, dobutamine) during hemodialysis, and others are best treated with peritoneal dialysis.

Percutaneous coronary intervention can be performed in these patients; however, the restenosis rate is rather high. The high rate of angiographic restenosis in patients with end-stage renal disease seems to be related to the size of the vessel dilated and to an increased prothrombotic risk, as indicated by higher fibrinogen concentrations.[69] [72]

Coronary artery bypass graft surgery (CABG) can be performed with increased but acceptable morbidity and mortality in patients undergoing long-term dialysis. Further, mild renal insufficiency, even in the absence of dialysis, increases the risk of blood transfusion, low-output syndrome, and prolongs the length of intensive care unit and postoperative stay. CABG surgery results in considerable improvement in symptoms and functional status in this group of patients; long-term survival, however, is considerably less than in patients without CRF.[68] [71] [74]

PERIOPERATIVE MANAGEMENT

Table 72-2 lists the major recommendations for perioperative treatment of patients who have CRF and are undergoing cardiac surgery. Intravascular volume, serum potassium level, hematocrit value, and drug administration must be carefully monitored during the perioperative period.[1] [68] Preoperatively, daily dialysis (usually of shorter duration) against a low-potassium bath should be considered to control serum and whole-body potassium content. Hemoglobin and hematocrit values should be raised to 10 gm/dl or greater and 30 percent or greater, respectively, with erythropoietin administration or via red blood cell transfusion during dialysis in more urgent situations.[79] [82]

TABLE 72-2 -- PERIOPERATIVE MANAGEMENT OF CHRONIC RENAL FAILURE IN PATIENTS UNDERGOING CARDIAC SURGERY

PREOPERATIVE
Dental evaluation and correction (in valvular disease)
Decrease intake of sodium, potassium, and fluid volume
Short dialysis daily (low potassium bath)
Beta-blockade therapy throughout perioperative period
Antibiotic prophylaxis (start immediately before surgery and continue for 2 d after surgery)
Raise hemoglobin/hematocrit above 10 gm/dl/30 percent
INTRAOPERATIVE
Keep fluid administration to minimum
Do not administer potassium
Special effort to preserve arm vessels and arteriovenous access fistula
Hemodynamic monitoring (during and after surgery) as needed
POSTOPERATIVE
Determine serum potassium levels and arterial blood gases every 4 hr during first 24 hr
Perform dialysis as indicated
Use regional anticoagulation during dialysis over first 5 to 10 postoperative days

Patients should go to surgery at near "dry weight." Intravenously administered fluids are kept to a minimum, with little or no potassium administration. To prevent

excessive hemodilution during cardiopulmonary bypass, both blood and lactated Ringer's solution are used to prime the extracorporeal pump. Beta-adrenergic blockade should be continued throughout the perioperative period to avert the myocardial and dysrhythmic complications of the hyperadrenergic state of cardiac surgery. Intraoperative hemofiltration can be used to treat any excessive intravascular volume accumulated during cardiopulmonary bypass.

Postoperatively, dialysis is used to reverse hyperkalemia, significant azotemia, or volume overload. Regional heparinization or citration should be considered during the first 5 to 10 postoperative days as a means of controlling bleeding complications during hemodialysis. The perioperative management used for patients with CRF on regular dialysis also applies to nondialyzed patients with CRF undergoing cardiac surgery; renal function in the latter patients may have to be supported with dialysis over several postoperative days.[71] [73] [74] [77] [78] Patients with a functioning transplanted kidney can be managed in a near-routine (non-CRF) manner, with special attention directed at providing adequate corticosteroid support, avoiding nephrotoxic drugs, and maintaining adequate urine output.

Pericarditis is a common complication of CRF; total pericardiectomy should be considered as a reasonable elective addition to the cardiac surgical procedure in patients with CRF.

Acute Myocardial Ischemic Syndromes

The clinical presentation, diagnostic steps, and therapeutic measures for patients with CRF and acute ischemic syndromes are generally similar to those directed at patients without CRF. Renal artery stent implantation may improve symptoms in patients with significant renal artery stenosis presenting with acute ischemic syndromes, congestive heart failure, or both; these benefits most likely are related to neurohumoral and hemodynamic improvements. Unfortunately, patients with CRF also frequently exhibit abnormal electrocardiographic ST segment and T wave abnormalities and elevated serum cardiac enzyme values in the absence of myocardial ischemia-necrosis. Because of impaired renal clearance, total creatine phosphokinase (CK) and lactate dehydrogenase levels are often elevated. However, the total CK usually comprises brain band CK (CK-BB, increased in about 30 percent of patients with CRF) or skeletal muscle band (CK-MM). Therefore, when myocardial ischemia and infarction is suspected, careful monitoring of the myocardial band (CK-MB) over the ensuing 24 to 48 hours becomes important; new or transient elevation of the CK-MB fraction can usually be regarded as an indication of acute myocardial necrosis. Troponins are more likely to be elevated in dialyzed patients than in other patients with renal failure who are not on dialysis. The ability of cardiac troponin T and cardiac troponin I to predict risk for subsequent adverse outcomes in patients presenting with suspected acute coronary syndromes is reduced in the presence of renal disease.[36] [75] [79] [83]

Fluid overload is approached with dialysis in patients who have CRF with acute myocardial infarction and who are nonresponsive to intravenous administration of loop diuretics in moderate to high doses. Hemodynamic monitoring with a flow-directed indwelling pulmonary artery catheter is appropriate when a low perfusion state or heart failure develops. Electrolyte and metabolic abnormalities are controlled with dietary measures and dialysis as needed.

CARDIOVASCULAR CALCIFICATION

Dystrophic (metastatic) calcification commonly occurs in patients who have CRF and who are receiving maintenance dialysis; it can involve all tissues, including heart, vasculature, and kidneys. Hyperphosphatemia with elevation of the calcium-phosphorus product, shifts in plasma and tissue pH during and after dialysis, and secondary hyperparathyroidism are regarded as the most important factors responsible for tissue calcification in CRF (Table 72-3) .[37] [39] [40] [84] The calcification is exacerbated by excessive intake of milk, use of certain antacids, and calcium extraction from calcium polystyrene materials and surfaces (e.g., certain dialysis units).

The mitral annulus and valve and aortic valve are the cardiac sites predisposed to dystrophic calcification in CRF (see Table 72-3) . Consequently, hemodynamically significant valvular stenosis and/or regurgitation, usually manifested clinically as murmurs and occasionally as symptoms and signs of heart failure, are common complications of cardiac calcification in CRF. Myocardial calcification can cause conduction abnormalities (most commonly atrioventricular or bundle branch block), various arrhythmias, ventricular dysfunction, and CHF. Significant annular, valvular, and coronary artery calcification and regions of dense calcification elsewhere in the heart are usually detectable by image-amplified fluoroscopy, echocardiography, or magnetic resonance imaging. Technetium pyrophosphate scintigraphy may demonstrate uptake in areas of myocardial calcification. Pericardial calcification, usually microscopic in degree, contributes to the pathological process of uremic

TABLE 72-3 -- METASTATIC CALCIFICATION OF CHRONIC RENAL FAILURE: CONTRIBUTING FACTORS AND COMMON CARDIOVASCULAR SITES OF INVOLVEMENT

POSSIBLE CONTRIBUTING FACTORS	CARDIOVASCULAR SITES
Hyperphosphatemia	Mitral annulus and valve
Increased ionized calcium	Aortic valve
Increased calcium-phosphorus product	Atrioventricular nodeconduction system
Increased parathormone levels	Myocardium
Acute changes in blood pH	Interventricular septum
Increased calcium ingestion	Coronary arteries
Certain antacids	Pericardium
Extraction from calcium-containing polymers and materials	
Vitamin D preparations	

Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.

pericarditis. Dense pericardial calcification is not a feature of CRF and implicates another disease process.

Prevention of cardiovascular calcification is an important component of the management of CRF. Phosphate-binding agents and dietary measures (restriction of phosphate and avoidance of excessive calcium intake) are used for this purpose. Regression of calcification has been achieved by lowering serum phosphorus levels with oral phosphate-binding agents, parathyroidectomy, and renal transplantation; cardiovascular calcification, however, does not appear to be as readily reversible. Management of the CHF, AV block, and cardiac arrhythmias caused by cardiac calcification is directed at controlling symptoms.

HEART MURMURS AND VALVULAR HEART DISEASE

Heart murmurs and acquired valvular abnormalities are common in CRF. Dystrophic calcification (discussed earlier), infectious and noninfectious endocarditis, and certain renal diseases (e.g., polycystic kidney disease) are associated with structural abnormalities of heart valves.[1] [85] [86] However, heart murmurs are frequently noted in CRF without obvious underlying valvular abnormalities and are probably evoked by anemia, the AV access fistula, hyperadrenergic tone, and volume and pressure overload. Early diastolic murmurs of functional aortic or pulmonic regurgitation, generally related to pressure and volume overload, can appear during advanced stages of renal failure and often disappear after hemodialysis. An occasional murmur audible over the anterior aspect of the chest may be transmitted from an AV access fistula located in the upper limb. In patients with forearm shunt access, bruits can be heard in the ipsilateral axillary, clavicular, and cervical regions. Cervical venous hums are also common in these patients. Thus, murmurs in CRF can represent valvular disease, functional pulmonic or aortic valvular flow or regurgitation, transmission from an AV fistula, or a venous hum.

As in other conditions, each murmur requires clinical assessment to define the underlying cause and, if associated with valvular or congenital heart disease, evaluation of the severity of the lesion. A precordial systolic murmur secondary to high flow or transmission from the AV fistula can be easily distinguished from other murmurs by observing the response of the murmur to transient obstruction of the fistula. Functional murmurs secondary to pressure or volume overload decrease considerably with control of hypertension, reduction of fluid overload, correction of anemia, and so forth. Venous hums are usually audible throughout the cardiac cycle; are loudest at the base of the neck, in the upright position and during inspiration; and are abolished by compression of the neck veins or by the Valsalva maneuver.

Laboratory evaluation and overall management of valvular heart disease in patients with CRF is similar to that recommended for patients without CRF (see Chap. 46) . Cardiac valve replacement can be done with acceptable operative mortality and reasonably good cardiac rehabilitation in patients undergoing prolonged hemodialysis. Long-term survival for most of these patients is still limited by the clinical course and complications of CRF, but quality of life is generally improved after valve replacement.

Preoperative dental evaluation is mandatory, and dental treatment should be completed several weeks before cardiac surgery. Preparation otherwise is similar to that

described for CABG (see Table 72-2) . Patients who have CRF and who are undergoing open-heart surgery--especially placement of prosthetic heart valves--are at high risk for infective endocarditis. In the perioperative period,*S. aureus,* coagulase-negative staphylococci, and diphtheroids are the most common infecting organisms. No single antibiotic agent is effective against all of these organisms, and prolonged use of broad-spectrum antibiotics predisposes patients to superinfection with unusual or resistant organisms. Thus, antibiotic prophylaxis at the time of valvular surgery is primarily directed against staphylococci and should be started immediately before the operative procedure and continued postoperatively for approximately 2 days. The choice of mechanical versus bioprosthetic valve for replacement in CRF remains controversial.[1] [86] [87] When technically feasible, reconstructive valvular repair should be considered for problematic mitral regurgitation.[85] [86]

Figure 72-6 Factors contributing to the development of pericardial disease in patients with chronic renal failure. Ca = calcium; P = phosphorus. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

PERICARDIAL DISEASE

Pericardial disease remains a relatively common complication in these patients. The contributory factors are depicted in Figure 72-6 , and the evaluation and management of pericardial disorders are presented in Chapter 50 (see also Chap. 72) .

SYSTEMIC HYPERTENSION

HYPERTENSION-ASSOCIATED WITH CHRONIC RENAL FAILURE (see also Chap. 28) .

Systemic hypertension occurs in more than 80 percent of CRF patients before initiation of dialysis. Patients who have CRF and who remain normotensive most often have tubular and interstitial disease or obstructive uropathy as the underlying pathological process. In contrast, arterionephrosclerosis and glomerulopathies are usually associated with hypertension, often marked. The various factors that contribute to the development of systemic hypertension in CRF are presented in Figure 72-7 .[88] [89] [90] [91] [91A]

HYPERTENSION ASSOCIATED WITH RENAL TRANSPLANTATION.

The incidence of systemic hypertension after renal transplantation varies widely (25 to 80 percent) and is highest during the early months after transplantation. The incidence 5 years after transplantation is about 40 to 50 percent. Renal graft failure is increased considerably in the setting of poorly controlled systemic hypertension.[92] Renal artery stenosis (of the transplanted kidney or native kidneys), chronic rejection, native kidney disease, therapy with corticosteroids or cyclosporine, and essential hypertension before transplantation are the leading causes of systemic hypertension in posttransplant patient. Recipients of cadaveric kidneys from donors with a family history of essential hypertension are also more likely to experience posttransplant hypertension. On the other hand, essential hypertension can undergo remission for up to 8 to 10 years after successful transplantation of a kidney from a normotensive donor.

MANAGEMENT.

Diagnostic studies should be undertaken in patients with renal failure and hypertension to preclude a reversible renovascular cause (see Chap. 28) and determine the nature of the underlying renal disease. Distinguishing hypertension secondary to renal parenchymal disease from essential hypertension with resultant hypertensive renal disease is often difficult at this stage. The medical history may identify patients who have had longstanding essential hypertension and a familial tendency for

Figure 72-7 Pathophysiological mechanisms contributing to the development of systemic hypertension in patients with parenchymal renal disease and failure. ANP = atrial natriuretic peptide; SLE = systemic lupus erythematosus. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

such, diabetes mellitus, or an episode of glomerulonephritis before developing renal failure.

The treatment of systemic hypertension in patients with active glomerulonephritis and/or CRF is similar to that of essential hypertension (see Chap. 29) . However, in patients with CRF, the dosage schedule of drugs cleared by the kidneys has to be modified to match renal function to avoid the deleterious effects of accumulated drug or metabolite. Dialysis should be considered for patients with a substantial reduction of renal function and hypertension refractory to medical management (Fig. 72-8) [1] [93] Early initiation of dialysis decreases the consequences of uremia, allows easier control of hypertension, and reduces the complications of chronic hypertension.

Bilateral nephrectomy is reserved for severely hypertensive CRF patients whose hypertension is refractory to aggressive hemodialysis and optimal drug therapy. The results of nephrectomy are best in patients with markedly elevated plasma renin activity. The major but correctable disadvantages of nephrectomy are a further drop in the hemoglobin and hematocrit values (reduced erythropoietin) and exacerbation

Figure 72-8 General management of arterial hypertension caused by renal parenchymal disease. AV = arteriovenous. (Modified from Leier CV, Boudoulas H: Cardiorenal Disorders and Diseases. Armonk, NY, Futura, 1992.)

of renal osteodystrophy (depressed generation of certain forms of vitamin D). The availability of potent oral antihypertensive agents, such as central sympatholytic drugs (e.g., clonidine), high-dose anglotensin-converting enzyme inhibitors, and minoxidil, has now made bilateral nephrectomy an uncommon procedure in CRF.

The management of systemic hypertension is often complicated by drug therapy needed for the management of the renal disease. This is particularly relevant to posttransplant patients.[1] [94] Corticosteroids adversely affect hypertension control by increasing blood volume and insulin resistance and blunting responsiveness to antihypertensive drugs. Cyclosporine commonly provokes or exacerbates systemic hypertension, occasionally to extremely high levels of blood pressure; calcium channel blocking drugs are usually effective in controlling cyclosporine-induced hypertension. A marked and often refractory increase in systemic blood pressure and occasionally renal interstitial disease can follow administration of nonsteroidal antiinflammatory agents.

Because spontaneous improvement of systemic hypertension in posttransplant patients with obstructing renal artery lesions (usually at the site of vascular anastomosis) is not uncommon, conservative management is generally recommended for transplant recipients who have stable, adequate renal function and whose hypertension is amenable to medications. When stenosis-induced hypertension becomes difficult to control or renal function falls, percutaneous transluminal angioplasty of the arterial lesion becomes a therapeutic option. Surgical intervention may become necessary if angioplasty is not feasible or is unsuccessful. Effective treatment of posttransplant hypertension is very important for the long-term health and survival of both graft and patient.[88] [92]

CARDIAC ARRHYTHMIAS

Cardiac arrhythmias constitute a major clinical problem in CRF because of their increased prevalence and potentially serious complications; their episodic nature also makes identification and characterization difficult. A multicenter study of longstanding hemodialyzed patients showed that ventricular arrhythmias, as assessed by 48-hour ambulatory monitoring, were present in 76 percent of patients[95] ; 39 percent had two or more events of two or more sequential ventricular ectopic beats (i.e., couplets or nonsustained ventricular tachycardia) per hour. The frequency of ventricular arrhythmias rose significantly after the second hour of hemodialysis and lasted up to 5 hours following dialysis. The independent risk factors for the presence of ventricular arrhythmias were age over 55 years and LV dysfunction. The frequency of ventricular ectopic beats also appeared to vary directly with resting heart rate. Sixty-nine percent of the patients who had CRF and who were undergoing long-term dialysis had supraventricular arrhythmias, mostly nonsustained. Table 72-4 lists the major factors in CRF

TABLE 72-4 -- FACTORS CONTRIBUTING TO DEVELOPMENT OF CARDIAC ARRHYTHMIAS IN PATIENTS WITH CHRONIC RENAL FAILURE

Underlying Cardiac Disease
Myocardial disease (left ventricular hypertrophy, left ventricular dysfunction)
Coronary artery disease--myocardial ischemia
Pericardial disease--myocardial inflammation
Cardiac calcification
Hemodialysis
Rapid changes in serum electrolytes
Rapid changes in blood pH
Hypoxemia
Autonomic Dysfunction
High Calcium-Phosphorus Product
High Parathormone Levels(?)

From Leier CV, Boudoulas H: Cardiovascular Disorders and Diseases. Armonk, NY, Futura, 1992.

likely to contribute to the development of cardiac arrhythmias.[96] [97] [98]

MANAGEMENT.

As in other patients, the initial approach is directed at treating remediable cardiac disease and at reversing contributory factors (see Table 72-4) . Caffeine and other cardiac stimulants should be avoided by patients with CRF and tachyarrhythmias. If arrhythmias are related to hemodialysis, attention should be directed to the potassium concentration of the dialysis bath. A low potassium concentration of the dialysate can lead to hypokalemia and serious rhythm disturbances, particularly in patients who are receiving digitalis or are afflicted with CAD, LV hypertrophy, or LV dysfunction. A dialysate potassium concentration of 3.5 mEq/liter usually abolishes dialysis-related ventricular arrhythmias. If the dialysate potassium concentration exceeds 3.5 mEq/liter, dietary potassium restriction is usually necessary between hemodialysis runs to prevent life-threatening hyperkalemia. Arrhythmias secondary to pericarditis tend to respond to treatment of the inflammatory component, when present. Increased sympathetic activity contributes to cardiac arrhythmias in patients with chronic renal disease. Physical training in patients undergoing hemodialysis augments cardiac vagal activity and may decrease vulnerability to arrhythmia. Angiotensin-converting enzyme inhibition also decreases sympathetic hyperactivity.[96] [97] [98]

Processed, ng, 3/28/00

PREDISPOSITION FOR CARDIOVASCULAR INFECTIONS

Infections are common in patients with end-stage renal disease. Because these patients undergo dialysis 100 to 180 times a year, it is not surprising that infections often involve the AV access site or the abdominal catheter in patients receiving peritoneal dialysis. It is estimated that up to 6 percent of hemodialyzed patients will develop infective endocarditis sometime during the course of their disease; the most common culprit organism is*S. aureus,* followed by*Streptococcus viridans* and enterococci; the aortic valve is the usual target, followed by the mitral valve.[1]

Proper sterile technique during the entire dialysis procedure is mandatory to prevent infectious disease in this very susceptible patient population. Patients should maintain good oral health and personal hygiene to reduce other potential sources for bacteremia and infective endocarditis. Skin flora of dialyzed patients and the dialysis staff should be controlled with bactericidal soap. The staff (via nasal discharge, skin, and other sites) is not an uncommon source for culprit organisms.[99] [100] Patients who are undergoing long-term hemodialysis and who have prosthetic valves and those who have had renal transplantation should receive antibiotics prophylactically.

Recurrent or prolonged bacteremia and septicemia in patients who have CRF and are receiving dialysis implicates persistent infection of the access shunt or catheter or infective endocarditis. Appropriate antibiotic therapy, based on blood culture and antibiotic sensitivity data, should be initiated as soon as possible in these patients. Surgical consultation is indicated when access shunts show abscess or aneurysm formation, thrombosis, or bleeding. Clinical recognition of infective endocarditis in the setting of CRF is often difficult, because many features (e.g., recurrent bacteremia, anemia, and encephalopathy) can occur in patients with end-stage renal failure without infective endocarditis. It is prudent to suspect infective endocarditis in any such patient with fever, leukocytosis, or bacteremia, particularly if associated with an infected access site. The appearance of new murmurs or changes in murmurs increases the likelihood of infective endocarditis. Demonstration of valvular vegetations by echocardiography is most informative and can be diagnostic in the presence of other clinical manifestations of infective endocarditis.

AUTONOMIC DYSFUNCTION

Derangements of the autonomic nervous system in CRF most commonly manifested as postural or dialysis-induced hypotension, abnormal hemodynamic responses to Valsalva and other maneuvers, decreased heart rate variability,[96] [97] impairment of perspiration, and alterations in gastric motility, can evoke major symptoms and disability. The cause of autonomic dysfunction in these patients is multifactorial and attributable in some cases to the underlying cause of CRF (e.g., diabetes mellitus, amyloidosis), antihypertensive drugs (e.g., sympatholytic agents), aluminum intoxication from certain antacids, and the uremic syndrome itself.[101] [102] [103] Determination of the specific type of autonomic dysfunction can be difficult and may require additional diagnostic testing (e.g., nerve conduction, bladder and sphincter function, tilt studies). Informative yet simple and inexpensive clinical maneuvers include blood pressure and heart rate responses to upright posture or the Valsalva maneuver, heart rate response to normal and deep inspiration, and determination of heart rate variability.[96] [97] In general, specific therapy for the autonomic dysfunction of renal disease is rather limited, and symptomatic therapy is used in most instances.

CARDIOVASCULAR DRUG THERAPY IN PATIENTS WITH RENAL DISEASE

Patients with acute or chronic renal failure are often treated with drugs primarily cleared or metabolized by the kidneys. In comparison with patients with normal renal function, any dose or dosage schedule of such agents in patients with renal failure usually produces higher plasma concentrations for longer duration. In addition, patients with renal failure can react unpredictably and atypically to pharmacological agents; thus, the adverse effects of a drug in this clinical setting are often related to factors other than plasma drug concentration. For example, nausea and vomiting after ingestion of certain agents (e.g., analgesics, potassium elixirs) occur more frequently in patients with CRF because of preexisting chronic inflammation of the gastrointestinal mucosa, and the adverse effects of digitalis and antiarrhythmic agents are exacerbated by abnormalities in serum potassium, magnesium, and calcium levels; hypoxemia; and the hyperadrenergic state of renal disease and dialysis. Side effects of a drug must always be considered when a patient with CRF experiences unexpected or unusual symptoms.

Renal failure often modifies the pharmacokinetics and pharmacodynamics of a drug[1] [93] [104] [105] [106] [107] [107A] ; many of these variations, however, are not directly linked to the simple reduction in renal function and GFR. The pharmacokinetic pharmacodynamic modifications of CRF are also related to greater variability in drug absorption, protein binding, metabolism, and receptor affinity, sensitivity, and responsiveness. Lower protein binding for many agents is related to hypoproteinemia or hypoalbuminemia, an alteration of the protein molecule, or competition for protein-binding sites by endogenous substances and other types of CRF therapy. Nonesterified fatty acids, increased in CRF and with heparin administration, can displace certain drugs from their binding sites. Anemia with reduced red blood cell binding increases the plasma concentration of certain drugs. Patients with renal failure are commonly treated with several agents; drug-drug interactions can affect gastrointestinal absorption, protein binding, tissue distribution, drug metabolism and clearance, and pharmacodynamic properties.

For drugs cleared by the kidneys, dosing is adjusted for renal function. Three dosing modifications can be used: the dosing interval can be lengthened without altering the dose amount, the dose amount can be lowered without changing the dosing schedule, or a combination of both. The second approach is preferable in most patients because it averts wide swings in plasma drug concentration. Precise adjustment of dosing is usually not necessary for drugs with few

TABLE 72-5 -- CARDIOVASCULAR DRUG THERAPY IN RENAL FAILURE

DRUG	THERAPEUTIC RANGE/ml (PLASMA LEVELS)	ELIMINATION AND METABOLISM	HALF-LIFE--hr		PROTEIN BINDING %		ADJUSTMENT FOR RENAL FAILURE	REMOVAL BY DIALYSIS	COMMENTS
			Normal	Renal Failure	Normal	Renal Failure			
CARDIAC GLYCOSIDES									
Digoxin	0.8-2.0 ng	75% renal	45	72-96	25	18	Yes	No	Radioimmunoassay m overestimate serum levels in renal failure
Digitoxin	20-35 ng	95% hepatic	145	Unchanged	90-97	86-97	Decrease dose when creatinine clearance <10 ml/min	No	8% converted to digox protein binding decrea slightly by dialysis
Quabain		40-50% excreted unchanged	21	60-70	40	Unknown	dose	No

Isosorbide-2-mononitrate	--	Hepatic	1.5-2.4		--	--	Yes	--	--

Isosorbide-5-mononitrate	--	Hepatic	4.0-5.0		--	--	--	--	--
Nitroprusside	--	Nonrenal	<10 min	<10 min	--	--	No	Hemodialysis	Thiocyanate and cyan may accumulate
CONVERTING ENZYME INHIBITORS									
Captopril	--	Mostly renal, some hepatic	1.9	Prolonged	25-30	--	May be necessary when creatinine clearance <10 ml/min	Yes, hemodialysis	Deterioration of rena function in patients w bilateral renal artery stenosis
Enalapril	--	Mostly renal	11	--	--	--	When creatinine clearance <30 ml/min	--	Deterioration of rena function in patients w bilateral renal artery stenosis
Lisinopril	--	Renal	12	--	--	--	When creatinine clearance <30 ml/min	--	--
Enalaprilat	--	Renal	11	--	--	--	When creatinine clearance <30 ml/min	Yes	For IV injection
Benazopril	--	--	10--11	96.7	--	--	When plasma creatinine>3 mg/dl	--	--
Fosinopril sodium	--	50% Urine	12	(95	--	--	No	--	--
Ramipril	--	60% Urine	13--17	--	--	--	When plasma creatinine >2.5 mg/dl	--	--
Cilarapril		80--90% excreted unchanged	40--50	>50	No data	Unknown	(Dose	No	The active moiety is formed in liver
Pentopril		80--90%excreted unchanged	2--3	10--40	60	Unknown	(Dose if GFR <50 ml/min	Unknown	
Perintopril		<10% excreted unchanged	5	27	20	Unknown	(Dose if GFR <50 ml/min	Hemo-yes CAPD-unknown	
Quinapril		30% excreted unchanged	1--2	6--15	97	Unknown	(Dose if GRF <50 ml/min	Hemo-yes CAPD-unknown	
ANGIOTENSIN RECEPTOR BLOCKERS									
Losartan		10--15% excreted unchanged	3--10	4--6	30	Unknown	No	Unknown	
DIURETICS									
Thiazides	--	Renal1	1--2	4--6	70	--	Yes	--	May be ineffective wh creatinine clearance < ml/min
Metolazono	--	--	--	--	--	--	--	--	Can produce marke diuresis
Furosemide	--	Mostly renal	1	3	95	--	--	Yes, hemodialysis	Large doses necessar renal failure
Ethacrynic acid	--	Renal, hepatic	3	--	90	--	Yes	Yes, hemodialysis	Large doses necessar renal failure
Bumetanido	--	Renal,hepatic	1	--	90	--	No	--	Can be effective in patients with renal fail
Acetazolamide	--	Renal	8	Prolonged	80	--	Yes	--	Ineffective when GF <10 ml/min
Amiloride	--	Renal	7.5	Prolonged	Low	--	Yes	--	May cause hyperkale
Triamterene	--	Hepatic, renal	2--12	10	60	Decreased	Yes, avoid when creatinine clearance < 30 ml/min		Active metabolites ha long half--life; may cau hyperkalemia
Spironolactone	--	Hepatic	10--35	10--35	98	--	Yes, avoid when creatinine clearance < 30 ml/min	--	May cause hyperkale
Indapamide	--	Mostly renal, some hepatic	14	--	71--79	--	--	--	Oral antihypertensive--diur has little or no diuret effect in renal failur
Chlorthalidone		50% excreted unchanged	44--80	Unknown	76---94	Unknown	Avoid if GFR <10 ml/min	Not applicable	Ineffective with low G
Piretanide		30--40% excreted unchanged	1.4	1.6--3.4	94	Unknown	No	None	High doses effective ESRD, ototoxicity
Torasemide		25% excreted unchanged	2--4	4--5	97--99	Unknown	No	None	High doses effective ESRD, ototoxicity
ANTICOAGULANTS									
Heparin	--	Nonrenal	0.3-2.0	0.5-3.0	>90	--	No	Yes, hemodialysis and peritoneal dialysis	May potentiate uremic bleeding

Warfarin	--	Hepatic	40	40	99	Decreased	No	--	May decrease protein binding of other drugs; may potentiate uremic bleeding
THROMBOLYTICS									
Streptokinase	--	--	0.38	--	--	--	No	--	May potentiate uremic bleeding
Anistreplase	--	--	1-2	--	--	--	--	--	May potentiate uremic bleeding
Urokinase	--	Hepatic	0.33	--	--	--	--	--	May potentiate uremic bleeding
Tissue plasminogen activators (t-PA)	--	Hepatic	0.05	--	--	--	--	--	May potentiate uremic bleeding
Alteplase		Unknown	0.5	Unknown	Unknown	Unknown	No	Unknown	Tissue-type plasminogen activator
LIPID-LOWERING AGENTS									
Cholestyramine	--	Not absorbed	--	--	--	--	No	--	May cause hyperchloremic acidosis
Colestipol	--	Not absorbed	--	--	--	--	No	--	May cause hyperchloremic acidosis
Clofibrate	--	Renal (40-60%), hepatic	17	46-110	96	--	Yes	Hemodialysis	Restricted use because of high profile of adverse effects
Gemfibrozil	--	Renal, fecal	1.5	--	Low	--	Yes	--	
Nicotinic acid	--	Hepatic, renal	0.5-1.0	--	--	--	Yes	--	Frequent adverse effects in patients with renal failure; aspirin may reduce flushing
Lovastatin	--	Hepatic, renal	--	--	95	--	--	--	--

CAPD=continuous ambulatory peritoneal dialysis; ESRD=end-stage renal disease; GFR=glomerular filtration rate.
Modified from Leier CV, Boudoulas H: Cardiovascular Disorders and Diseases. Armonk, NY, Futura, 1992.

adverse effects and a large therapeutic index (safety margin). Pharmacokinetic and dose-adjustment information about the more commonly used cardiovascular drugs in renal disease is presented in Table 72-5 . [1] [93] In most instances, the application and monitoring of drug therapy in CRF are based on pharmacodynamic and clinical responses, occasionally supplemented by determination of the drug's plasma concentration (e.g., digitalis) or another laboratory endpoint (e.g., prothrombin time for warfarin).

The therapeutic objectives are fairly well defined for most cardiovascular drugs. For example, for drugs used to control systemic hypertension or edema, the therapeutic endpoints are clear (decrease arterial pressure, reduce edema) and are best followed by clinical observations (blood pressure, physical examination, body weight) for proper drug and dose selection. Angiotensin-converting enzyme inhibitors, most vasodilators, and calcium channel blockers have reasonably well-defined clinical endpoints (e.g., decrease arterial pressure, improve symptoms of heart failure, control angina pectoris). The therapeutic objectives of beta-adrenergic blocking drugs can be followed clinically in most patients (e.g., reduce arterial pressure, myocardial ischemia, and angina; control cardiac rhythms). For digitalis and antiarrhythmic drugs, the clinical endpoints are more elusive and are threatened by potentially serious adverse effects; determination of plasma drug concentrations for such agents often becomes an important component of optimally effective, safe dosing.

CARDIOVASCULAR COMPLICATIONS DURING DIALYSIS

SYSTEMIC HYPOTENSION.

Removal of fluid volume, redistribution of plasma volume, baroreceptor disturbances, dysfunction of the autonomic nervous system, depressed responsiveness to alpha-adrenergic receptor stimulation, concomitant drug therapy (e.g., antihypertensive agents), and LV diastolic dysfunction contribute to the propensity of patients with CRF to develop hypotension during hemodialysis. Interestingly, some patients who have renal disease with dialysis-induced hypotension have higher plasma concentrations of atrial natriuretic peptide and lower norepinephrine levels compared with patients with CRF without hypotension.[37] [39] [108]

Symptomatic depletion of fluid volume during dialysis can be averted by allowing a modest amount of weight gain between dialysis treatments. When feasible, antihypertensive therapy and other potential hypotension-inducing drugs (e.g., nitrates) can be withheld 4 to 6 hours before dialysis to minimize their contribution to the problem. Of the antihypertensive agents, minoxidil is least likely to cause unpredictable changes in blood pressure during hemodialysis; however, drug-induced hirsutism and occasional pericarditis make this drug unacceptable to some patients, particularly women. Small doses of noncardioselective beta-adrenergic blocking drugs can be effective in maintaining acceptable arterial pressure; the $beta_1$ - and $beta_2$ -receptor blockade allows circulating norepinephrine to evoke unopposed alpha-adrenergic receptor stimulation and vasoconstriction. Either peritoneal dialysis or renal transplantation is the best option for patients who have CRF and who poorly tolerate hemodialysis because of hypotension.

HYPOXEMIA.

The mechanisms for hemodialysis-induced hypoxemia have not been definitively established; leading explanations include nonbicarbonate buffers (e.g., acetate) used

in the dialysis bath, Cupraphane membranes, and pulmonic ventilation-perfusion mismatch elicited by systemic hypotension. Acetate buffer evokes a significant leftward shift in the hemoglobin-oxygen dissociation curve and can disturb ventilation-perfusion of the lungs through its vasodilatory properties. Activation of complement along Cupraphane exchange membranes can result in sequestration of leukocytes within pulmonary vessels, ventilation and perfusion abnormalities, and hypoxemia; this complication has been reduced considerably with the use of biocompatible dialyzers.[1]

ELECTROLYTE AND OTHER METABOLIC ABNORMALITIES.

Electrolyte disturbances, metabolic acidosis, and other metabolic abnormalities likely contribute to the development of various cardiovascular derangements in CRF (e.g., cardiac arrhythmias, depression of myocardial contractility). The rate of change in pH, electrolyte concentrations, and other metabolic factors during dialysis is probably as important as the actual degree of change with respect to the clinical consequences of these disturbances. The most common and crucial electrolyte disturbances in patients undergoing hemodialysis involve potassium. Hyperkalemia is a common problem in these patients, and plasma and whole-body potassium levels can be dramatically altered by hemodialysis. The dialysis buffer, acetate, transiently decreases serum bicarbonate level, and with repeated dialysis patients with CRF can become depleted of bicarbonate; bicarbonate has now largely replaced acetate as the dialysis buffer at most modern facilities.[1] [37] [39]

COMPLICATIONS OF THE ARTERIOVENOUS ACCESS FISTULA DURING HEMODIALYSIS.

The external access vascular shunt is used when a patient is expected to require only short-term dialysis (days to a few weeks). Because of fewer complications (e.g., lower infection rate and less thrombogenic) over time, the surgically constructed subcutaneous AV fistula is used for long-term dialysis management. In certain patients, particularly the elderly and those with peripheral vascular disease or diabetes mellitus, reduction of blood flow distal to the fistula can lead to local ischemia and infarction, occasionally requiring amputation of a digit or distal extremity.[1] [37] [39] An infrequent complication during hemodialysis involves a "steal syndrome," which may occur when the radial artery distal to a forearm fistula has not been ligated; this vascular arrangement can allow blood to flow from the ulnar artery through the palmar arch (as nonnutritive flow), retrograde into the radial artery and access fistula.

OTHER DIALYSIS-INDUCED COMPLICATIONS.

Air embolization and hemolysis, although rare, are serious complications. Hemolysis can occur from improper composition or chemical contamination of the dialysate. Severe illness and death have resulted from dialysate contaminated with excessive aluminum, calcium, or fluoride.[1] [37] [39] [109] Other substances, such as polyvinylchloride, have been leached from membranes, dialyzer shells, and tubing to cause systemic and cardiovascular toxicity.[110] With the use of high-flux polyacryionitrile AN 69 exchange membranes, patients who have CRF and are receiving angiotensin-converting enzyme inhibitors appear to be somewhat more susceptible to anaphylactoid reactions during hemodialysis.[1] [37] [39] [110]
